CHAPTER 10

Global Mental Health

Vikram Patel, Alex Cohen, Brandon Kohrt, Harvey Whiteford, and Crick Lund

Introduction

In 2015, all nations united around a shared mission of achieving the Sustainable Development Goals (SDGs). This set of goals represented an exponential advance from the Millennium Development Goals (MDGs), which the SDGs replaced, both in its aspiration to encompass a substantially broader agenda and through its explicit recognition that these were global concerns, affecting all nations, and requiring global actions. One notable example of this transformative vision was the recognition that health burdens went beyond the MDG focus on a selection of infectious diseases and maternal and child health. Noncommunicable diseases, mental health, and substance abuse received recognition, and several targets related to these concerns were specified (**TABLE 10-1**). At last, it seemed that the decades of science and advocacy had finally allowed mental health to take its rightful place on the global development agenda.

The discipline of global mental health has played a key role in the inclusion of mental health in the SDGs. The field of global mental health was the product of decades of interdisciplinary research and practice in diverse transnational contexts. Governmental and nongovernmental organizations in the United Kingdom such as the Department for International Development (DFID) and the Wellcome Trust funded much of the early work in mental health research and services in low- and middle-income countries (LMICs) in the later part of the 20th century. A series of publications drawing upon this large body of evidence generated by epidemiologists, clinicians, social scientists, and human rights advocates led to a "call to action" in 2007 to "scale up services for people affected by mental disorders built on the twin foundations of cost-effective interventions and respect for human rights" in all countries of the world, and in particular in LMICs, where the attainment of these rights was most seriously compromised (*The Lancet* Global Mental Health Group, 2007).

For the purposes of this chapter, we consider the definition of "mental health" to include all conditions that affect the nervous system that are leading causes of disease burden. Conditions with a vascular or infectious etiology, such as human immunodeficiency virus (HIV) infection of the brain or cerebrovascular diseases, are excluded here, as they are addressed in other chapters of this text. Mental disorders include intellectual disability, epilepsy, anxiety and mood disorders, psychoses (schizophrenia and bipolar disorders), substance use disorders (alcohol and drug use disorders), and dementia. Thus, this list of health conditions includes disorders that clinicians may categorize as psychiatric, neurological, or substance use disorders. This chapter uses the acronym MNS disorders (meaning "mental, neurological, and substance use disorders"), which is common nomenclature for the World Health Organization (WHO) and other health and development institutions.

TABLE 10-1 Mental Health in the Sustainable Development Goals

	United Nations' Sustainable Development Goals
SDG 3	Ensure healthy lives and well-being for all at all ages
SDG Target 3.4	Requests that countries: "By 2030, reduce by one third premature mortality from non-communicable diseases through prevention and treatment and promote mental health and well-being"
SDG Target 3.5	Requests that countries: "Strengthen the prevention and treatment of substance abuse, including narcotic drug abuse and harmful use of alcohol"
SDG Target 3.8	Requests that countries: "Achieve universal health coverage, including financial risk protection, access to quality essential health-care services and access to safe, effective, quality and affordable essential medicines and vaccines for all"

Modified from United Nations Sustainable Development goals: http://www.un.org/sustainabledevelopment/sustainable-development-goals/

This rich interdisciplinary treasure of knowledge laid the foundation for the landmark 2007 *The Lancet* series on global mental health. The authors of this series of articles arrived at the conclusion that the high burden and unmet needs for care constituted a global health crisis. They deliberated on what might be the most urgent, clear, and specific "call to action" for the global health community and, in the end, chose to focus on the needs of those individuals affected by a mental disorder, calling for actions to reduce the treatment gap by scaling up the coverage of services for mental disorders in all countries, but especially in LMICs (*The Lancet* Global Mental Health Group, 2007). The years following the publication of *The Lancet* series witnessed a tangible increase in the attention to the treatment gap in LMICs, as evidenced by the increase in development assistance for mental health, which more than doubled in absolute dollars in the years immediately after 2007 (Gilbert, Patel, Farmer, & Lu, 2015). In 2011, the Grand Challenges in Global Mental Health initiative, led by the U.S. National Institute for Mental Health (NIMH), emphasized implementation research questions as the priorities to reduce the treatment gap for mental disorders (Collins et al., 2011) (**TABLE 10-2**).

The publication of these priorities led to a slew of new research initiatives by the NIMH to support research and training in global mental health as well as a set of international "hubs" for research on task sharing and scaling up mental health interventions, while Grand Challenges Canada supported dozens of projects addressing some of these priorities in a number of LMICs. Simultaneously, a number of global institutions and coalitions began to advocate for mental health. WHO launched its flagship mental health Gap Action Programme (mhGAP) to scale up care for MNS disorders in 2008 and developed a series of seminal publications that provide guidance to health practitioners in nonspecialist settings regarding treatments for MNS disorders (WHO, 2010); track the status of mental health systems at the country level (WHO, 2015); and establish standards of care for mental health facilities (see www.who.int/mental_health for a comprehensive listing of WHO resources for mental health). This culminated in the Comprehensive Mental Health Action Plan 2013–2020, which was agreed by all nations of the world in 2013, and the establishment of a roadmap for achievement of a broad range of mental health–related targets (Saxena, Funk, & Chisholm, 2013). The Disease Control Priorities Network published its recommendations, targeting governments and development agencies, for which interventions should be scaled up through diverse platforms from the community to specialist care, ultimately forming the mental and neurological health component of the package of interventions for universal health care (Patel et al., 2016). Notably, both the Comprehensive Mental Health Action Plan and the Disease Control Priorities Network recommendations took a much broader view of mental health, emphasizing the continuum from promotion of mental health to prevention of mental disorders, to treatment, long-term care, and inclusion of persons with mental disorders.

Preceding these developments were a number of reform initiatives in specific countries—for example, in Brazil and Italy—that sought to influence and promote a public health approach to mental health care. These efforts aimed to provide community-oriented

TABLE 10-2 Grand Challenges in Global Mental Health, 2011

Rank	Five Leading Challenges for Global Mental Health
1	Integrate core packages of mental health services into routine primary health care
2	Reduce the cost and improve the supply of effective psychotropic drugs for mental, neurological, and substance use disorders
3	Train health professionals in LMICs to provide evidence-based care for children with mental, neurological, and substance use disorders
4	Provide adequate community-based care and rehabilitation for people with chronic mental illness
5	Strengthen the mental health component in the training of all healthcare personnel to create an equitable distribution of mental health providers

Data from Collins, P. Y., Patel, V., Joestl, S., March, D., Insel, T. R., Daar, A. S. (2011). Grand challenges in global mental health. *Nature, 475*, 27–30.

care along with both medical and psychosocial interventions, while strongly emphasizing the priorities of those affected by mental disorders. The ultimate goal was to demonstrate that such approaches could improve access to quality care.

Reforms in Italy began in the 1960s, and reforms in Brazil can be traced to the 1990s, with the psychosocial community center program known as *Centros de Atenção Psicossocial* (CAPS) beginning approximately four to five years prior to the mhGAP initiative. Civil society partnership with mental health professionals to promote a shared vision continued to grow during the twenty-first century. The most notable example was the Movement for Global Mental Health (www.globalmentalhealth.org), which was launched in 2008 as a virtual global alliance. By 2015, the Movement included 170 member institutions representing diverse stakeholders, from academics to civil society representatives. Since 2013, the Movement has been led by persons affected by mental disorders. In several countries, prominent individuals have "come out" with their personal accounts of mental disorders, indicating the growing acceptance of this form of human suffering. The field of global mental health has become a respected discipline in its own right, complete with academic programs and centers in universities around the world, specialist journals and books on the subject, and an annual calendar of scientific events. Not surprisingly, the discipline has been described as having "come of age" (Patel & Prince, 2010).

This chapter is organized in three parts. First, it presents a brief history of global mental health prior to the *The Lancet* series. Next, it discusses four foundations of the discipline: the influence of culture and social determinants on mental health; the burden and impact of mental disorders (including substance use disorders and neurological disorders); effective prevention and treatment strategies; and the ways that these strategies can be delivered in low-resource contexts. Finally, it considers the limitations of the field as it is currently conceptualized and the strategies for addressing global mental health issues in the future.

Historical Development of Global Mental Health

The earliest developments of public mental health care can be traced at least as far back as the early Islamic world of the Middle East, North Africa, and Spain. Although accounts differ, it seems that the first hospitals that cared for persons with mental disorder were established by Islamic physicians during the ninth century CE in Baghdad and Egypt (Dols, 1987). Within a few hundred years, institutional care had spread 3,000 miles to the west in Marrakech (twelfth century) and Fez (thirteenth century), Morocco (Moussaoui & Glick, 2015). Influenced by the practices in Morocco, in the fourteenth century a hospital in Granada, Spain, began to accept persons with mental disorders. In the fifteenth and sixteenth centuries, hospitals for persons with mental disorders were established in at least five cities in Spain. In Northern Europe, there is evidence of the establishment of institutional care that coincides with or predates the founding of the hospitals in Spain (Mora, 2008; Pierloot, 1975). The most famous examples from Northern Europe are Bethlem

Hospital in London, which traces its establishment to the thirteenth century, and the Colony of Geel in Belgium, whose origins date from approximately the same time (Mora, 2008).

The beginning of modern public mental health can be traced to the late eighteenth century, when there was a decided shift in beliefs about the nature of mental disorder. Before this time, "madness" was associated with a loss of rationality, which meant that persons with mental disorders were considered as less than human and, in an effort to restore them to reason, were treated as brutes (Scull, 1989). "Moral treatment," which was developed simultaneously and independently in France (Weiner, 1992), England (Digby, 1985), and elsewhere (Scull, 2015), rejected the notion that mentally ill people lacked reason and suggested, instead, that tolerance and confinement in a well-ordered and pleasant environment could restore a person to rationality and mental health (Grob, 1994). The example of the York Retreat in England, which was established in the late eighteenth century as one of the sites in which moral treatment was developed, gave rise to "a wave of enthusiasm and optimism" for the curability of madness (Scull, 2015). This new perspective on mental disorders and their treatment brought about a powerful movement to abolish the abuses and to establish public systems of institutions that would offer beneficent care and the prospect of recovery to persons with mental disorders. One of the best examples of this advocacy was the work of Jean-Étienne Esquirol, who, after visiting a number of psychiatric institutions in France, wrote a report in 1819 in which he advocated for a state-run system of asylums (Goldstein, 2001). In 1838, France followed Esquirol's advice; other countries established similar systems in first half of the nineteenth century (Scull, 2015). The importance of this form of care for persons with mental disorders can be seen readily in the thousands of articles about asylums that were published in the nineteenth century in the leading English-language medical journals (Cohen & Minas, 2016).

As soon as the public asylums opened, they were filled beyond capacity. Throughout the second half of the nineteenth century, the notion of small curative institutions was abandoned due to increasing demands for services and a reluctance on the part of governments to allocate more funds for the care of mentally ill indigent persons (Grob, 1994; Scull, 1989). In addition, as conditions in the asylums grew worse, the effectiveness of asylum care—an assumption that had underpinned the widespread establishment of asylums—began to be questioned. These developments can be seen in publications in *The Lancet* over a period of 50 years. In 1827, the journal published a letter decrying the conditions in private asylums and called for "the establishment of public hospitals for insane paupers," and called to task the British Colleges of Physicians and Surgeons for not devoting more attention to these issues (Humanitas, 1827). Thirty years later, *The Lancet* (1857) published an editorial, "The Crime of Lunacy and How We Punish It," that questioned the efficacy of asylums: "They are . . . mere houses of detention." In 1875, the journal established the Commission on Lunatic Asylums to investigate "the treatment, in public and special institutions, of patients laboring under the various forms of mental disease" (*The Lancet*, 1875). The conclusions of the Commission were not positive: "It has been found impossible 'to formulate the system of treatment' either for cure or relief. Practically, there is no general 'system' beyond that which may be described as control" (*The Lancet*, 1877). Thus, by the late nineteenth century, public mental health efforts were inextricably associated with the wretched, overcrowded conditions in asylums: "the positive images of hospitals that had prevailed in the mid-nineteenth century [had given] way to far more negative ones associated with hopelessness, abuse, and ultimately death" (Grob, 1994).

Despite these concerns, the colonial enterprise saw the global expansion of institutional care for persons with mental disorders starting in 1567 when Spain established a psychiatric institution in Mexico City. The first institution of its kind in the Western Hemisphere, it heralded what later became known as colonial psychiatry. Nearly 200 years later, and continuing throughout the nineteenth century and into the first decades of the 20th century, "lunatic" asylums were established by British authorities in India (Basu, 2016; Weiss, 1983). Asylums were also established in French (Edington, 2013; Keller, 2008), Italian (Scarfone, 2016), Dutch (Pols, 2006), Spanish (Meyer, 2010), and other British (Ng & Chee, 2006; Sadowsky, 1997; Swartz, 1999) colonies. These institutions have often been depicted as being a form of racism and a means of exerting social control over indigenous populations (Goddard, 1992; Jackson, 1999; Schmidt, 1967; Swartz, 1999). However, it is also true that asylums in the colonies merely reflected the values and treatments in the home-country asylums of the colonial powers (Weiss, 1983).

Despite deteriorating conditions in asylums (rebranded as mental hospitals and psychiatric hospitals in the United Kingdom and the United States, respectively [Cohen & Minas, 2016]), the number of psychiatric inpatients continued to increase in the wealthy nations of the West. Then, beginning in the 1950s, efforts in North America, Western Europe, and Australia were initiated to remove long-term patients

from psychiatric facilities and provide treatment and care in the community. The incentive for what came to be called *deinstitutionalization* evolved from a convergence of several forces. First, encouraged by successful treatment of soldiers traumatized by their experiences in World War II, psychiatrists became optimistic about their ability to effectively treat mental disorders outside of hospital settings (Grob, 1994). Second, there was a growing awareness that the abusive conditions found in public psychiatric hospitals, as well as the negative effects on patients of long-term institutionalization, were at least as harmful as the chronic mental disorders themselves. Third, caring for patients in large institutions that did not provide effective care was expensive. Finally, the discovery in 1954 of chlorpromazine, the first effective antipsychotic medication, offered people with chronic mental disorders the prospect of living in the community rather than as inpatients (Greenblatt, 1992).

Together, these forces brought about dramatic changes in institutionalized populations. In the United States, for example, 559,900 people were in psychiatric hospitals in 1955; 25 years later, that number had decreased to 138,000 (Goldman, 1983). In Britain, the number of psychiatric inpatients peaked at 148,100 in 1954 and then steadily decreased; by 1985, there were only 64,800 such inpatients (Thornicroft & Bebbington, 1989). In Italy, deinstitutionalization took place somewhat later, but had similar results: Early in the 1970s there were about 75,000 psychiatric inpatients, but that number had dwindled to only 38,000 in 1981 (Morosini, Repetto, De Salvia, & Cecere, 1985).

Deinstitutionalization has had mixed reviews. Although large numbers of patients were discharged from hospitals, many came to be accommodated, at least in the United States, in prisons, nursing homes, and adult homes for mentally disabled persons (Scull, 1985), where the worst aspects of the old asylums were often recreated (Human Rights Watch, 2015; Levy, 2002a, 2002b, 2002c, 2002d). In Europe, some evidence suggests that "reinstitutionalization" has taken place. For example, as the number of psychiatric beds in hospitals has decreased, the number of persons with mental disorders in prisons and forensic hospitals has increased (Fakhoury & Priebe, 2007; Human Rights Watch, 2016; Priebe et al., 2005).

Although deinstitutionalization is considered a global policy (WHO & Gulbenkian Global Mental Health Platform, 2014), it has occurred primarily in Western countries, with a few exceptions. For example, the number of psychiatric hospital beds has increased in South Korea (Kim, 2017). Not only does Japan have the highest rate of psychiatric beds in the world (28.4 beds per 10,000 people), but it also has the longest average length of psychiatric hospitalization (Imai et al., 2005). Deinstitutionalization has not taken place at all in the great majority of LMICs, such that hospital-based care remains at the center of what exists of those countries' national mental health systems (Saxena, Thornicroft, Knapp, & Whiteford, 2007). A noteworthy exception is Brazil, which, between 1995 and 2005, reduced its number of psychiatric beds by 41% while increasing community services by a factor of 9 (Andreoli, Almeida-Filho, Martin, Mateus, & Mari, 2007). Other research suggests that while psychiatric beds decreased in six South American countries, including Brazil, prison populations have increased substantially (Mundt et al., 2015). It has been noted, however, that the increase in the prison population cannot be definitively attributed to deinstitutionalization (Winkler et al., 2016). More recently, other large middle-income countries have begun reforming their mental healthcare systems: India launched its first national mental health policy in 2014 with similar principles while China has greatly expanded coverage of care for mental disorders through its 686 Project, which refers to the first 6.86 million Renminbi (USD$ 829,000 in 2004) invested by the Chinese government to free patients from seclusion and restraints throughout the country (Ma, 2012; Patel et al., 2017).

Perhaps the best way to consider the positive and negative effects of deinstitutionalization is to ask the consumers of mental health services whose lives have been most affected by this policy. When that has been done, the answer is clear. Despite the difficulties of life outside the hospital, the relative lack of supportive services, and the effects of stigma and discrimination, former long-term inpatients generally agree they prefer living in the community (Davidson, Hoge, Godleski, Rakfeldt, & Griffith, 1996).

The development of community mental health services was both an impetus for and a product of deinstitutionalization. Although the potential for treating people with mental disorders outside of hospital settings was recognized prior to the discovery of effective antipsychotic medications, the evolution of community-based services came about with the recognition that treatment and care required a range of social and rehabilitation services and involved more than just dispensing medication. Thus, while the definition of community care may have once simply meant care outside hospitals, it now encompasses, at least ideally, professional services in community settings, social reintegration, and support services, such as housing, employment, medical care, and welfare (Tansella & Thornicroft, 2001). The provision of community services to individuals with mental

disorders is now a central principle of global mental health (Alem, 2002; Alem, Jacobsson, & Hanlon, 2008; Hanlon, Wondimagegn, & Alem, 2010; Semrau, Barley, Law, & Thornicroft, 2011; Thara & Padmavati, 2013; Thornicroft, Alem, Dos Santos, et al., 2010; Thornicroft, Tansella, & Law, 2008), though this remains an unfulfilled goal for the vast majority of persons affected by mental disorders globally.

The scientific and policy foundations of global mental health can be traced, at least in part, to activities at WHO that were begun soon after the establishment, in 1949, of a mental health division and an Expert Committee on Mental Health (Lovell, 2014). Two reports by the Expert Committee were of particular importance to the field that would become known as global mental health. The first of these reports, *Epidemiology of Mental Disorders* (WHO, 1960), sought to lay the groundwork for an international system for the classification of the psychiatric disorders and, more generally, to advance the ultimate goal of creating a scientifically rigorous approach to psychiatric epidemiology. Direct outcomes of this work included WHO's international studies of schizophrenia (Jablensky et al., 1992; WHO, 1973), as well as studies of schizophrenia in Mauritius (Murphy & Raman, 1971) and Sri Lanka (Waxler, 1979). In fact, there was a burgeoning of psychiatric research in developing countries during the 1960s (e.g., Lambo, 1960; Leighton et al., 1963; Lin, Rin, Yeh, Hsu, & Chu, 1969), 1970s (e.g., Harding, 1973; Jilek & Jilek-Aall, 1970; Kulhara & Wig, 1978), and 1980s (e.g., Harding et al., 1980; Kleinman, 1980; Kulhara & Chandiramani, 1988). The second of the Expert Committee's reports, *Organization of Mental Health Services in Developing Countries* (WHO, 1975), followed a *British Journal of Psychiatry* series on psychiatric problems in the developing world (Carstairs, 1973; German, 1972; Leon, 1972; Neki, 1973) and recommended many actions to address the burden of mental disorders in developing countries. One of the most farsighted statements in the report was the following: "A number of innovations have been recommended, notably the sharing of mental tasks by a wide range of health workers and by other community agencies."

WHO followed up these recommendations with a series of projects that attempted to integrate mental health services into primary care settings in seven low-income countries (Sartorius & Harding, 1983). Now, more than 40 years later, this strategy remains central to the development of mental health services in low-resourced settings.

As important as all of these projects were, perhaps the "founding" event of global mental health was the publication of the results of the first Global Burden of Disease (GBD) study, which introduced the concept of disability-adjusted life-years, a single measure that represented the burden imposed by both mortality and morbidity (the most recent findings of this initiative are described in more detail later in this chapter) (World Bank, 1993). Prior to this report, infectious diseases were prioritized by international public health efforts. However, the GBD study revealed that noncommunicable diseases—neuropsychiatric disorders, specifically—accounted for a significant proportion of the GBD. These findings provided the most compelling evidence that mental disorders were priority public health disorders in low-, middle-, and high-income countries alike. Thus, the GBD study opened the way to the field that became known as global mental health.

Culture and Mental Disorders

It is crucial to understand the role of culture in the experience, diagnosis, and treatment of mental disorder (Kirmayer & Swartz, 2014). Common elements in the definition of culture are "values, beliefs, knowledge, norms, and practices and the notion that that these are shared among a specific set of people" (Hruschka & Hadley, 2008, p. 947). Beliefs refer to conscious psychological processes. Norms are behaviors maintained by social sanctioning and affective responses. Values are valences placed on beliefs, knowledge, and norms that lead to engagement in or avoidance of behaviors. These beliefs, norms, and values shape both lay and professional understandings of mental disorder. This section addresses the following topics: (1) the role of culture in biomedical classification systems; (2) alternative approaches to mental disorder categorization across diverse cultural contexts; and (3) cross-cultural methods and approaches to improve mental health research and services.

Cultural Considerations for Biomedical Psychiatric Classification

Understanding the origins and assumptions of different diagnostic systems is vital to implement best practices in research and clinical care for diverse global populations. The classification of diseases leads, in theory, to more accurate diagnoses and effective treatments. Valid and reliable systems of classification make it possible to determine accurate prevalence and incidence rates and, therefore, should guide decisions about the development of services. The classification of mental disorders, however, presents some unique

challenges. Psychiatric diagnoses do not "carve nature at the joint" and the boundaries between different conditions may not be distinct (Blacker & Tsuang, 1992; Kendler & Gardner, 1998; Tsuang, Stone, & Faraone, 2000). Unlike other diseases, there are no specific and replicable pathophysiological pathways to distinguish most mental disorders in a clinical setting. Moreover, clinical classification in psychiatry is based on the symptom profiles, rather than on the disorders' etiology (as in the case of infectious diseases) or their pathology (as in the case of vascular disease).

Two main biomedical systems of psychiatric classification are used today: the *International Classification of Diseases* [ICD] (WHO, 1990) and the *Diagnostic and Statistical Manual of Mental Disorders* [*DSM*] (American Psychiatric Association [APA], 2013). These approaches to psychiatric categorization took shape in the late 1800s with the work of Emile Kraepelin and others who developed diagnoses based on standardized factors related to symptom presentation, prognosis, and hereditary risks (Jilek, 1995). Kraepelin and his followers also influenced modern frameworks regarding the incorporation of culture into psychiatric classification. Kraepelin traveled to Java, Sri Lanka, India, Singapore, and the Americas to evaluate his diagnostic criteria with non-European populations. He and his followers developed a model with a biological core for mental disorders (i.e., pathogenic), with cultural influences shaping the presentation of that biological core (i.e., pathoplastic) (Jilek, 1995). For example, hallucinations were considered a universal biologically-determined feature of psychosis whereas culture shaped the content of those hallucinations. Most current classifications (e.g., DSM and ICD) continue this approach with cultural considerations for different conditions while assuming conditions are grounded in a core of presumed universal psychiatric pathology.

These classification systems—DSM and ICD—and their assumption of biological universality are often considered *etic* perspectives in cross-cultural psychiatry. "Etic" refers to a universal classification systems and is contrasted with "emic," which refers to classifications specific to a culture, which may or may not overlap with etic categorizations (Hahn, 1995). The use of the DSM and ICD psychiatric categorizations as overarching etic frameworks applicable across all cultures has been critiqued by some psychiatrists and social scientists (Kleinman, 1988; Kleinman & Good, 1985; Littlewood, 2002). The DSM and ICD do not incorporate all emic divisions from other cultures and medical nosologies, such as Chinese, Ayurvedic, or Q'uranic classifications of mental disorder. It is argued that classifications of psychiatric disorders largely reflect American and European emic concepts of psychopathology based on implicit cultural concepts of normality and deviance. In addition, the classification systems have not been comparably applied across racial/ethnic groups within the same clinical context. For example, in the United Kingdom and United States, African- and Caribbean-descent populations are more likely to be diagnosed with schizophrenia compared with white/Western European-descent populations with the same symptom profile; the latter are diagnosed with bipolar disorder more frequently than with schizophrenia (Bell, Williamson, & Chien, 2008; Louden, 1995). For a challenge to these claims, see the work of Selten and Hoek (2008) and Singh, Greenwood, White, and Churchill (2007).

Even when comparable symptoms are observed, the social and personal significance of the behavior or experience may not have the same meaning and their explanatory models may differ. Researchers have cautioned that there is a risk of confounding culturally distinctive behavior with psychopathology on the basis of superficial similarities of behavior patterns or phenomena, an assumption referred to as a "category fallacy" (Kleinman, 1987). Within European and North American cultural contexts, there also have been debates about the scope of depression and how it is—or is not—distinguished from normal grief (Wakefield & Demazeux, 2015).

Due to these shortcomings, cross-cultural studies in psychiatric epidemiology historically have suffered from several problems. For example, case identification techniques varied from site to site, and methods were not standardized (Gorenstein, 1992). These inconsistencies led to a movement to standardize the process of psychiatric measurement and diagnosis so that diagnoses would be more replicable among clinicians and across patient populations. In the United States, one expectation since the third edition of the DSM (APA, 1980) was that this kind of standardization would help to reduce bias and increase the reliability of diagnoses across populations and among clinicians. Similarly, the tenth revision of the ICD (ICD-10) was developed with the explicit purpose of being an international standard (WHO, 1990). Thus, efforts were made to ensure that the drafters of the ICD-10 were drawn from as many countries as was feasible, and the revised system of classification was field-tested by more than 700 clinicians in 39 countries from all continents. The vast majority of ICD-10 conditions have reasonable reliability (Sartorius et al., 1993).

In preparation for the ICD-11, which was due to be published in 2018, one approach to explore cultural bias has been to evaluate how clinicians across cultures categorize disorders based on their clinical experiences. In a study of 517 clinicians in eight countries ranging from Brazil to India to Japan, clinicians had strong inter-rater agreement regardless of their national or cultural origin (Reed et al., 2013). The same study found that the cross-cultural categorizations were generally consistent with DSM and ICD, but the clinician-generated categories were more consistent with the proposed changes for ICD-11 compared to the DSM-IV or ICD-10, in particular with regard to personality disorders.

Critiques of cultural biases in diagnoses are part of a broader movement in psychology that has detected biases when the vast majority of research is based on a single population demographic. This problem has been referred to as the bias of psychology research being dominated by WEIRD populations (Western, Educated, Industrialized, Rich, and Democratic), which account for 90% of psychology publications (Henrich, Heine, & Norenzayan, 2010b). When psychological studies have been conducted with non-WEIRD populations, researchers have discovered that presumed universal processes such as visual perception, spatial reasoning, and behavioral motivation related to fairness and cooperation have cultural variations. In addition, it is important to consider that diagnostic criteria of syndromes can and do change over time, as is well demonstrated by the regular revisions of international psychiatric classifications, and that these changes are considerably influenced by attitudinal, political, and historical factors. Anthropologists have investigated how diagnoses are developed out of specific social, economic, and political environments; for example, there are in-depth historical accounts with anthropological critiques of disorders including posttraumatic stress disorder (PTSD) (Young, 1995), bipolar disorder (Martin, 2007), and dissociative disorders (Hacking, 1998).

Fifty years of research suggests that concepts of psychosis are remarkably similar across diverse settings (Cohen et al., 2016). Cross-cultural reviews of depression, PTSD, and other conditions have found that some symptoms may vary across cultures, though they have also found many universals. In a systematic review covering 178 social groups (varied by location, ethnicity, culture, and/or geography), of which 115 were non-Western populations, DSM hallmark symptoms of depressed mood/sadness, fatigue/loss of energy, problems with sleep, appetite/weight problems, and suicidal thoughts were common across all groups (Haroz et al., 2017). At the same time, the review revealed that some symptoms with near universality are not captured in current biomedical classifications. For example, symptoms such as social isolation/loneliness, crying a lot, somatic complaints, and thinking too much were among the most common symptoms but are not included in DSM criteria. Even among Western populations, the symptoms of social isolation and crying a lot were among the top 10 most associated with depression. In contrast, DSM diagnostic symptoms such as psychomotor agitation/retardation, feelings of worthlessness/guilt, and poor concentration were not among the top 10 associated symptoms in Western and non-Western cultural groups.

A cross-cultural review of PTSD concluded that while this diagnosis is generally "valid"—that is, it reflects the reality of human experience across populations—there is considerable cultural variability (Hinton & Lewis-Fernandez, 2011). The PTSD review highlighted cultural differences in the meaning and interpretation of trauma symptoms, the prevalence of the diagnosis across groups, the prevalence of specific symptoms such as those related to avoidance and numbing, the likelihood that a person of one culture will develop PTSD compared to a person of another culture given the same trauma exposure, and the association with nontraumatic stressors.

These types of cross-cultural systematic reviews are helpful to identify potential cultural biases in psychiatric diagnoses and to point us toward approaches that may be more appropriate across populations.

Alternative Approaches to Categorize and Conceptualize Mental Disorders

Historically, classifications of mental disorders prior to the DSM and ICD have existed in different cultures. All cultures have some form of distinguishing normal from abnormal, or socially acceptable versus unacceptable behavior, and this is often the province of religious practitioners and traditional healers (Clifford, 1990; El-Islam, 1982; Kleinman, 1980; Kohrt, Hruschka, Kohrt, Panebianco, & Tsagaankhuu, 2004; Weiss et al., 1988).

As an example, the first Chinese Classification of Mental Disorders (CCMD) appeared in 1979; since then, the system has undergone several revisions. Its third and most recent version is heavily influenced by the ICD-10 and DSM-IV systems, but still retains local features. The main differences between the ICD-10 and the CCMD-3 are the CCMD-3's retention of the term "neurosis" and categories of neurotic disorders such as neurasthenia (Lee, 2001). Personality disorders are

less often diagnosed in Chinese populations; thus, two categories of personality disorders—borderline personality disorder and avoidant personality disorder—are excluded from the Chinese scheme. The CCMD also includes its own section of culture-related mental disorders such as *qigong*-induced mental disorder. *Qigong* is a trance-based form of a traditional Chinese healing system. The disorder is similar to a dissociative state, featuring identity disturbance, irritability, hallucinations, and aggressive and bizarre behaviors. These often acute, brief episodes are linked to excessive practice of *qigong* meditation by physically or psychologically ill subjects.

Emic conditions (i.e., locally relevant categorizations) that are not typically observed in Western culture have been referred to as culture-bound syndromes (Simons & Hughes, 1985). Examples include *latah* (a startle-based form of distress in Southeast Asia), *koro* (a fear of genital retraction also noted in Southeast Asia), and *ode ori* (a West African form of distress characterized by thinking too much and attributed to a worm crawling in the skull) (Makanjuola, 1987; Simons & Hughes, 1985). Over time, the "bounded" aspect of culture-bound syndromes has been challenged due to findings of similar patterns of distress in disparate cultural settings, a lack of cohesive symptom presentation characterizing a syndrome, and the diversity in etiological attributions and vulnerable groups (Hahn, 1995; Kirmayer & Minas, 2000). Dissatisfaction with the term "culture-bound syndrome" has led researchers to propose other labels, such as "idiom of distress," "popular category of distress," "cultural syndrome," and "explanatory model" (Nichter, 1981; Weiss, 1997). In DSM-5, the term "cultural concept of distress" (CCD) attempts to aggregate these concepts without implying cultural exclusivity: "*Cultural concept of distress* refers to ways that cultural groups experience, understand, and communicate suffering, behavioral problems, or troubling thoughts and emotions" (APA, 2013, p. 758).

There is now a large literature indicating commonalities in emic categories of psychological distress. A systematic review (Kaiser et al., 2015) identified 138 publications mentioning "thinking too much," with examples from every populated continent including terms such as *kufungisisa* (Zimbabwe), *reflechi twòp* (Haiti), *pensando mucho* (Nicaragua), and *kut careen* (Cambodia), and, in more recent studies, *ucingakakhulu* (South Africa) (Davies, Schneider, Nyatsanza, & Lund, 2016). Across cultures, "thinking too much" is characterized by ruminative, intrusive, and anxious thoughts that, if prolonged, result in a range of physical and psychological complaints. Common associated symptoms include low mood, anhedonia, poor concentration, social withdrawal, sleep disruptions, and somatic complaints across most populations. "Thinking too much" is associated with similar socioeconomic and traumatic stressors across populations. Moreover, coping mechanisms share commonalities across cultures, such as controlling or suppressing thoughts, distraction, and engaging in social activities—all of which overlap with evidence-based psychological treatments. This study is one of the few examples of how starting with a CCD rather than with a psychiatric category can help generate information on commonalities in psychological distress across populations.

A systematic review of CCDs and their overlap with DSM and ICD psychiatric categories demonstrates that the presence of a CCD increases the likelihood of persons meeting criteria for a psychiatric disorder (Kohrt et al., 2014). However, there is not a one-to-one match; that is, no CCD predicts a psychiatric diagnosis in 100% of individuals. On average, presence of a CCD does strongly predict PTSD, and to a lesser degree CCDs are predictive of depression and general psychological distress (**FIGURE 10-1**). Despite somatic complaints (i.e., physical symptoms such as headaches, digestive problems, and numbness and tingling) frequently being an aspect of CCDs, most CCDs are more strongly associated with common mental disorders than with somatoform disorders. Guidance for conducting rigorous epidemiologic studies of CCDs is now available with the tool known as Systematic Assessment of Quality in Observational Research for Cultural Psychiatry Epidemiology (SAQOR-CPE; Kohrt et al., 2014).

Cultural concepts of distress are increasingly recognized as an important component of culturally adapting mental health treatments, especially psychological treatments. Studies with the strongest effect sizes (i.e., those with the biggest improvements in mental health from pre- to post-treatment) do not utilize psychiatric categories when framing distress for patients and clients. For example, in India, depression and common mental disorders (CMDs) are often framed as "stress" or "tension" (Patel et al., 2010; Petersen et al., 2016), which are cultural idioms of distress that have many features of CMDs but are nonstigmatizing and facilitate treatment engagement (Weaver, 2017). In Zimbabwe, a lay health worker–delivered psychological treatment, "The Friendship Bench," uses the CCD *kufungisisa* (Shona for "thinking too much"; Patel, Simunyu, & Gwanzura, 1995) as a culturally acceptable way to discuss CMDs (Chibanda et al., 2016). Similarly, treatment of refugees and immigrants with culturally adapted cognitive-behavioral therapy has framed the interventions with CCDs (e.g., *nervios*-related conditions for

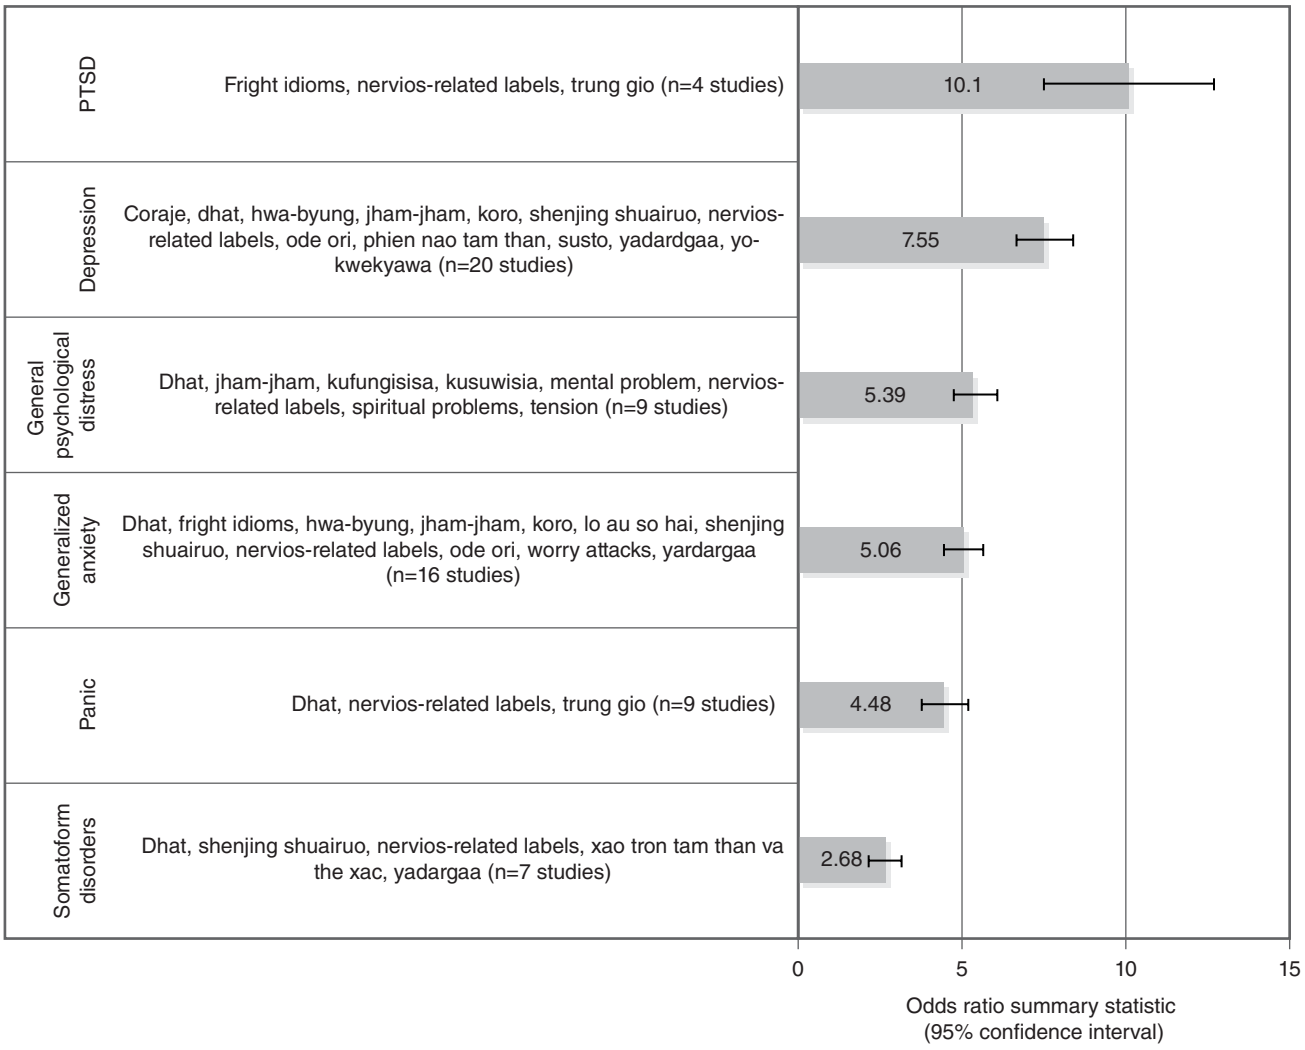

FIGURE 10-1 Psychiatric disorders and cultural concepts of distress.

Cultural concepts of distress and psychiatric disorders: literature review and research recommendations for global mental health epidemiology. *International Journal of Epidemiology 43*(2): 365–406.

Latinos and *khyaal attacks* for Cambodians), and studies have shown significant improvements in both the CCDs and in reduction of depression and PTSD (Hinton, Hofmann, Pollack, & Otto, 2009; Hinton, Rivera, Hofmann, Barlow, & Otto, 2012).

Within high-resource settings in European and North American cultures, there are also concerns about the generalizability and conceptual assumptions in psychiatric nosologies such as the DSM. In the United States, NIMH has proposed the Research Domain Criteria (RDoC) as a way to look at processes from genes to functional neuroscience to environment in an effort to understand etiology and presentation and ultimately guide treatment (Insel et al., 2010). This more dimensional system provides an alternative to the categorical divisions between "mentally ill" and "normal," which have been contested by cross-cultural researchers (Bilder, 2015). Moreover, this approach can incorporate social genomics and social neuroscience methods that are increasingly demonstrating that culture and biology interact (Cole, 2014; Rule, Freeman, & Ambady, 2013). Individual and collective experiences including acculturation, especially during child development, determine much of the biological and psychological processes observed in adulthood.

Ultimately, much of RDoC focuses on the individual level. Nevertheless, there are increasing calls for an analogous approach to societal-level causal mechanisms that would be useful from a public and global mental health perspective (Stein, Lund, & Nesse, 2013). Going forward, there is potential for social neuroscience and cross-cultural psychiatry to find areas of convergence to develop more accurate diagnostic approaches to apply across diverse populations (Kirmayer & Gold, 2012b).

Cross-Cultural Methods and Approaches for Mental Health Research and Services

Ultimately, diagnostic categories are a moving target, as they are continually being transformed by improved biocultural research that seeks to better understand mechanisms and improve the fit between types of interventions and persons with psychological distress. As diagnoses continue to change, it is crucial to have a set of rigorous methodologies that can integrate culture into global mental health research and interventions. Examples of these rigorous methods are transcultural translation and validation procedures for assessment and the Cultural Formation Interview for clinical care.

Cultural equivalence is needed for psychiatric assessment tools used for research, screening, and treatment monitoring. Lack of cultural equivalence risks category fallacies and under-, over-, and misdiagnosis. A tool is considered to have cultural equivalence (i.e., measurement invariance) if it measures the same construct across cultures. Content, semantic, technical, criterion, and conceptual equivalence are needed to achieve measurement invariance (Flaherty et al., 1988). These are defined as follows:

- *Content equivalence:* Does the phenomenon in question occur and is it locally recognized as distressing within the target culture?
- *Semantic equivalence:* Does the meaning of each item remain the same after translation?
- *Technical equivalence:* How does the method used in data collection affect results differentially between cultures? Technical methods could encompass response options on scales, item structure, and administration format (e.g., pen and paper, computerized assessment, interview administered). Challenges have been identified with the use of Likert scales, statements versus questions, positive versus negative wording, and pictorial response scales (Kohrt et al., 2011; Weobong et al., 2009).
- *Criterion equivalence:* What is an instrument's relationship with previously established and independent criteria for the same phenomenon? According to criterion equivalence, there should be comparable psychometrics (e.g., sensitivity, specificity, positive predictive value, negative predictive value) with a known marker, oftentimes a structured clinical interview.

There are now best practices for transcultural translation and validation that incorporate qualitative methods followed by a clinical validation study to establish psychometric properties, which have been used for both adult and child populations (Kohrt et al., 2011; Van Ommeren et al., 1999). This transcultural translation approach involves qualitative interviews including focus group discussions with target groups and cognitive interviewing, accompanied by a series of translations and back-translations, followed by a clinical validation study.

Regarding clinical services in global mental health, the cultural formulation interview (CFI; **EXHIBIT 10-1**) in DSM-5 is a new tool that can be applied to any patient or population and assures that cultural factors are integrated in diagnosis, treatment planning, and delivering care (APA, 2013). The CFI was developed to assess five components: (1) cultural identity of the individual, (2) cultural explanations for an illness, (3) cultural factors contributing to psychosocial environment and functioning, and (4) cultural factors influencing the clinician–patient/client relationship. Value must be placed on both folk beliefs about mental disorder and the biomedical system of psychiatry. It is important to investigate patients' "explanatory models"—that is, how patients understand their problems, including their nature, origins, consequences, and remedies, as these

EXHIBIT 10-1 Cultural Formulation Interview in DSM-5

This CFI is a tool for clinicians and treatment teams to improve mental health services by assuring that cultural factors are integrated into diagnoses, treatment planning, and delivery of care. The CFI includes four components:

- Cultural definition of the problem: Explanatory models including prominent idioms of distress, reasons for treatment seeking, and impact on functioning.
- Cultural perceptions of the cause, context, and support: Cultural models of causation, impact on and influence of one's social network, culturally relevant interpretations of social stressors, and cultural identity of the individual.
- Cultural factors affecting self-coping and past help-seeking: Self-coping, past help seeking, and prior barriers to care and recovery.
- Cultural factors affecting current help seeking: Patient preferences related to social networks and religion, and clinician–patient relationship factors. The provider must identify differences and similarities in cultural and social status that might influence diagnosis and treatment.

Modified from American Psychiatric Association. (2013). Diagnostic and statistical manual of mental disorders: DSM-5. Washington, DC: American Psychiatric Publishers, Incorporated.

aspects of understanding can radically alter patient–provider negotiations over appropriate treatment (Kleinman, 1988). The CFI can be used at individual, family, and community levels to inform clinical services and public health efforts in global mental health.

Ultimately, findings across diverse disciplinary approaches increasingly point toward commonalities for understanding mental disorder across cultural groups. As noted earlier, common manifestations and pathways for healing have been identified. Moreover, studies that have shown differences across groups have often shed light on the limitations of psychiatric practices that need to be changed to improve care in high-resource, Western cultural settings as well as in LMIC contexts. This point not only highlights the importance of cross-cultural work for global mental health in low-resource, non-Western settings, but also suggests how global mental health research can better inform mental health categorizations in high-resource, high-researched settings.

The Determinants of Mental Disorders

The etiology of mental disorders comprises a complex interplay among biological factors, most notably genetic predisposition, developmental factors, and psychosocial factors. Until the 1950s, the dominant notions about the etiology of mental disorders were hereditary and environmental in nature. For example, schizophrenia was attributed to abnormal parenting, and obsessive–compulsive disorder to "anal aggression." Beginning in the 1960s, however, a more balanced view emerged. Consensus was reached that both environmental and genetic influences contribute to the development of mental disorders. Psychotic conditions, which historically have been thought to arise predominantly from biological risk factors, have increasingly been shown to be strongly influenced by social determinants (Kirkbride et al., 2006; McGrath et al., 2004). The observation that many disorders have their onset in childhood and youth have placed focus on the developmental origins of these disorders (e.g., related to brain development during childhood and adolescence).

Although risk factors for the majority of mental disorders present themselves in childhood and adolescence, the major burden of mental disorders is found in early adulthood (Murray et al., 2012). Indeed, a range of childhood adversities, such as neglect and parental mental illness, are strongly associated with numerous mental disorders in later life, presumably due to the impact of "toxic stress" on the developing brain. These factors can be divided into risk factors and protective factors. Risk factors make it more likely that an individual will develop mental health difficulties, whereas protective factors mediate and reduce the effects of risk exposure. Risk and protective factors can exist in the biological, psychological, and social domains (**TABLE 10-3**). Many risk factors for mental disorder also predispose persons to a host of physical health and social problems. Adverse childhood experiences (ACEs), such as child abuse and domestic violence, loss of caregivers, nutritional deprivation, and severe childhood illness, are exposures that increase the risk of physical diseases (e.g., cardiovascular and metabolic disease), mental disorders (e.g., suicide, substance abuse, and common mental disorders), and early mortality (Anda et al., 2006; Van Niel, Pachter, Wade, Felitti, & Stein, 2014).

The question was therefore changed from *which* factors were relevant for a specific disorder, to *how much* each contributed to the condition. Ultimately, this question, too, proved to be based on an incorrect assumption—namely, that the environmental, developmental, and genetic factors exert their influences in an additive and independent manner. There is now recognition that they exert their influences in an interactive manner, which develops over the life course. Contemporary scientists are attempting to address the question of *how* they interact.

The Social Determinants of Mental Disorders

The social determinants of mental disorders may be organized into five broad domains (Lund, De Silva, & Stansfeld, 2014):

- The economic domain, which includes poverty, income, consumption, assets, income inequality, and employment
- The social domain, which includes social capital, social cohesion, and education
- The demographic domain, which includes age, gender, and ethnicity
- The neighborhood domain, which includes the area-level social and economic arrangement of people's lives such as housing, water and sanitation, and transport
- The environmental events domain, which includes natural disasters, such as floods, earthquakes, and climate change, as well as civil conflict and forced migration

Each of these domains exerts its influence on population mental health by means of both distal factors

TABLE 10-3 Selected Risk and Protective Factors for Mental Health

Domain	Risk Factors	Protective Factors
Biological	■ Exposure to toxins (e.g., tobacco and alcohol) during pregnancy ■ Genetic tendency to psychiatric disorder ■ Head trauma ■ HIV/AIDS and other physical illnesses	■ Age-appropriate physical development ■ Good physical health ■ Services provided at mother–baby clinics
Psychological	■ Maladaptive personality traits ■ Effects of emotional, physical and sexual abuse, and neglect	■ Ability to learn from experiences ■ Good self-esteem ■ High level of problem-solving ability ■ Social skills
Social		
Family	■ Divorce ■ Family conflict ■ Poor family discipline ■ Poor family management ■ No family	■ Family attachment ■ Opportunities for positive involvement in family ■ Rewards for involvement in family
School or workplace	■ Failure to perform at the expected level ■ Low degree of commitment to school or workplace ■ Inadequate/inappropriate educational provision or training opportunities ■ Experiences of bullying and victimization	■ Opportunities for involvement in school or occupational activities ■ Supportive, stimulating school environment that is tailored to children's developmental needs
Community	■ Community disorganization ■ Effects of discrimination ■ Exposure to violence ■ Social conflict and migration ■ Poverty ■ Transitions (e.g., urbanization)	■ Connectedness to community ■ Opportunities for constructive use of leisure ■ Positive cultural experiences ■ Positive role models ■ Rewards for community involvement

("upstream" social and structural factors, such as social policy, macro-economic trends, and environmental disasters) and proximal factors (the manner in which these distal factors are experienced by individuals and their families, such as employment, housing quality, and trauma).

Environmental Events Domain

According to the United Nations High Commissioner for Refugees (http://www.unhcr.org/4981c3dc2.html), as of 2007 an estimated 11.4 million refugees had fled their own countries, another 13.7 million were internally displaced, and 2.9 million were not considered citizens of any state. Many of these refugees have experienced enormous trauma in the form of violence, crime, or other humiliations; physical injury; economic dispossession; and disruption of family and community structures. Thus, the rates of mental disorders among these people would be expected to be at least as high as—and probably higher than—those for migrants in general. A study of more than 3,000 respondents

from postconflict communities in Algeria, Cambodia, Ethiopia, and Palestine found that PTSD was the most likely MNS disorder in individuals exposed to violence associated with armed conflict (de Jong, Komproe, & Ommeren, 2003). Other mental health consequences included mood and anxiety disorders.

In addition to exposure to trauma, a number of other factors may predispose refugees and immigrants to mental disorders, such as marginalization and minority status, socioeconomic disadvantage, poor physical health, the loss of social support systems, and cultural alienation in the new society. For illegal immigrants, there is also the constant fear of being found out and deported; as a consequence, access to possible sources of help is severely limited. In discussing these issues, it is relevant to note that the universal application of the concept of trauma-related mental disorders (in particular, PTSD) has been criticized because it is itself based on culturally influenced notions of how a person is supposed to react to trauma (see the earlier discussion on culture and mental disorders). While consensus exists that trauma does negatively affect a person's mental health, the question of whether this negative impact should be conceptualized in psychiatric terms (with the concomitant implications of diagnosis and treatment) or in social and cultural terms remains unresolved.

Economic Domain

There is now a substantial body of evidence demonstrating the relationship between poverty and socioeconomic inequalities with mental disorders. In the United Kingdom, for example, evidence has pointed to an association between a low standard of living and the prevalence of depression (Weich & Lewis, 1998). A systematic review located 115 studies in which the associations between poverty and anxiety and mood disorders in 36 LMICs were examined (Lund et al., 2010). Most of these studies reported positive associations between a range of poverty indicators and anxiety and mood disorders. Multivariate analyses showed that in community-based studies, 79%, 15%, and 6% reported positive, null, and negative associations, respectively. A robust association was found between anxiety and mood disorders and education, food insecurity, housing, social class, socioeconomic status, and financial stress. By comparison, the associations between anxiety and mood disorders and income, employment, and consumption were relatively inconsistent. People living in conditions of poverty are also at greater risk for physical health problems, and abundant evidence demonstrates the high degree of comorbidity between physical and mental disorders (Prince et al., 2007). Studies in developed countries have shown that mortality and morbidity rates are more affected by relative, rather than absolute, living standards. A survey in the United States, for example, showed an independent association between low income and living in income-unequal states with depression in women (Kahn, Wise, Kennedy, & Kawachi, 2000). This finding suggests that it is not just having low income, but having low income in relation to others, that increases risk for depression.

Social Domain

The association between poverty and poor mental health may be mediated both by individual psychological factors, such as low self-esteem and frustration, and by a breakdown in structural factors in the community, such as less social cohesion and poorer infrastructure. Reduced prevalence of common mental disorders has been found in populations with higher individual cognitive and ecological social capital (Ehsan & De Silva, 2015). The lack of social support and the breakdown of kinship structures may be important stressors for the millions of migrant laborers in the urban centers of Asia, Africa, and South America, as well as for the millions of dependents who are left behind in rural areas and whose primary source of income consists of the remittances that their relatives send from distant cities. In high-income countries, increased mobility of labor has reduced family ties and also led to the decline of the extended family.

The social consequences of low educational levels are obvious, especially in LMICs that are facing a growing lack of security for employees as those countries' economies are reformed. Lack of secondary education may produce a diminished opportunity for persons who are depressed—especially women—to access resources to improve their situation (Patel, Araya, de Lima, Ludermir, & Todd, 1999). Education also plays an important protective role: A consistent finding across countries is that higher educational levels are associated with reduced prevalence of common mental disorders (Lund et al., 2010), and in the long term education is protective in reducing subsequent late-life depression (Chang-Quan, Zheng-Rong, Yong-Hong, Yi-Zhou, & Qing-Xiu, 2010).

Demographic Domain

Gender is a major determinant of mental health. As described later, the excess prevalence of depression for women has been demonstrated in most community-based studies in all regions of the world.

Women are disproportionately affected by the burden of poverty, which in turn may influence their vulnerability to depression. Women are far more likely to be victims of violence in their homes; women who experience physical violence by an intimate partner are significantly more likely to suffer depression, abuse drugs, or attempt suicide. Women who are sexually abused as children are significantly more likely to suffer depression in adulthood, and experience of sexual and other forms of violence in youth is associated with depression in adolescence.

As an example of how gender influences the risk of depression, a study with women in low-income townships of Harare, Zimbabwe, revealed the high proportion of events involving humiliation and entrapment that were related to marital crises such as being deserted by husbands and left to care for children, premature death, illness of family members, and severe financial difficulties occurring in the absence of an adequate welfare safety net. As another example, studies in South Asia have shown that the culturally determined value placed on boys (as compared to girls) adversely influences maternal mental health. The risk for postnatal depression was elevated in mothers who had a girl child, especially if the desired sex was a boy or if the mother already had living girl children (Patel, Rodrigues, & DeSouza, 2002).

The excess prevalence of alcohol abuse for men has been demonstrated in every community-based study from every region of the world although the disparities are greatest in LMICs. The wide sex differences in alcohol abuse in Latin American countries and the Caribbean have been attributed to a number of gender factors (Pyne, Claeson, & Correia, 2002). Women, for example, face strict social scrutiny about many behaviors, drinking among them. Men's consumption of alcohol takes place in the public realm, whereas women's drinking more often occurs in private. Drinking among men has social meanings, such as maintaining friendships, whereas refusing a drink can imply lack of trust and denial of mutual respect. At the other extreme, intoxication of men is more socially acceptable than that of women; indeed, women often tolerate their male partners' intoxication as being a "natural" condition of manhood. Drinking and drunkenness are more often perceived to be consistent with gendered notions of masculinity; thus, men who conform closely to cultural norms are more likely to drink. Drinking may also be a coping strategy when men face serious life difficulties, such as unemployment, and are unable to live up to the traditional expectations.

The evidence that gender plays a role in eating disorders stems from two observations: (1) the enormous sex difference in prevalence (females with these disorders vastly outnumber men with the same conditions) and (2) the very low rates of these disorders in cultures that have been relatively immune to the media-driven creation of the ideal body image for women. A study from Fiji demonstrated that the introduction of television in a media-naïve non-Westernized population is associated with a rise in attitudes favoring thinner body image and self-induced vomiting in girls (Becker, Burwell, Gilman, Herzog, & Hamburg, 2002), lending credence to the theory that the emphasis on women's thinness by the media and fashion industries is now leading to a rise in disordered eating in societies that, through the forces of globalization, are being increasingly influenced by Western imagery and values.

Another demographic characteristic associated with greater risk of mental disorders is belonging to an ethnic minority population, which has been shown to be associated with an increased risk of a range of mental disorders, including psychosis, anxiety, and depression (Veling, 2013). This relationship is attributed to a range of mechanisms related to discrimination and the traumatic experiences associated with dislocation and migration. Indigenous communities represent a particularly disadvantaged group for a range of social, historical, and political reasons, and they bear a disproportionate share of the burden of mental disorders (**EXHIBIT 10-2**).

Neighborhood Domain

There is now robust evidence indicating that the characteristics of geographical areas have an important effect on population mental health, independent of individual-level characteristics such as poverty, educational level, and gender. In the current context of large-scale global urbanization, the conditions of urban slums therefore have an important influence on mental health. For example, low neighborhood socioeconomic status has been significantly associated with worse mental health, independently of individual-level socioeconomic status (Truong & Ma, 2006).

The Burden of Mental Disorders

This section describes how the burden of mental disorders (including neurological and substance use disorders) can be calculated using disability-adjusted life-years, discusses the limitations inherent in these measures, presents the burden estimates for 2015, and finally identifies important impacts of mental disorders that are not captured in burden of disease estimates.

EXHIBIT 10-2 The Mental Health of Indigenous Peoples

As many as 370 million indigenous persons may be living in approximately 5,000 distinct groups in more than 70 countries. They exhibit a wide diversity of lifestyles, cultures, social organization, histories, and political realities. Nevertheless, they share certain historical and political realities, including being subject to violence and genocide, depopulation from infectious diseases such as smallpox and measles, dislocation from their traditional lands, extreme poverty due to the destruction of their subsistence economies, and state-organized attempts to repress and eradicate their cultures. Given this history, it is not surprising that the indigenous peoples of the world are currently experiencing relatively high rates of depression, alcoholism, and suicide, as well as high rates of infectious diseases and relatively short life expectancies (Anderson et al., 2016).

The case of the indigenous communities of Australia serves to illustrate the confluence of these historical, political, social, and economic forces and contributes to our understanding of why the rates of mental disorders are higher among indigenous peoples. The indigenous peoples of Australia had a diversity of cultures dating back at least 40,000 years before the arrival of European settlers slightly more than 200 years ago. These societies had rich cultural belief systems that attributed spiritual importance to land. Social relationships were governed by codes of behavior, and local taxonomies of illness guided the treatment of health problems. The brutal history of colonization that ultimately led to the destruction and devastation of hundreds of indigenous groups, each with a distinct language and lineage, was marked by a number of severe social adversities. Notable among these were exposure to new diseases, removal from traditional lands, enslavement on white farms, imprisonment without trials, denial of basic political rights, brutal violation of human rights, sexual abuse of women, and, perhaps most tragic of all, the "stolen generations"—the children who were forcibly removed from their parents and fostered by white families in an effort to "breed" out the native population.

Among the indigenous peoples of Australia, the consequences of this history are reflected in socioeconomic, psychosocial, and health indicators of all kinds:

- High rates of unemployment, low levels of income, and poor educational status
- Age-specific mortality rates two to seven times higher, and life expectancies more than 15 years shorter, than those of the general population
- High levels of alcoholism and suicide

It is impossible to interpret the poor mental health experienced by these communities without considering the social and historical contexts of the systematic abuse of aboriginal communities. *Ways Forward*, the Australian national inquiry into indigenous mental health conducted in the early 1990s, prioritized holistic conceptions of emotional and social well-being among these groups. From these developments, greater emphasis has been given to providing access to culturally appropriate services within mainstream healthcare settings.

To understand the contributions that mental disorders make to the global burden of disease compared to other diseases and injuries, it is necessary to measure the impact of all disorders in the same way. A common metric is needed for measurement; otherwise, it is very difficult to quantify the burden imposed by cancer, for example, compared to that imposed by depression. A commonly used metric is the disability-adjusted life-year (DALY), a time-based metric that combines the years a person lives with disability (YLD) caused by a particular disorder with the years lost from life owing to a disorder (YLL). The DALY has been used by the World Bank, WHO, and in the Global Burden of Diseases, Injuries, and Risk Factors Studies to measure the gap between the health of the population at a point in time and living to a defined life expectancy in full health. Since DALYs, YLDs, and YLLs were first estimated for the year 1990, the data sources used have been greatly expanded and the methods applied to generate the estimates improved. The changes in methods have included dealing with inconsistent coding of deaths over time and between countries, introduction of disability weights from population-representative surveys, more precise severity distributions, introduction of comorbidity adjustments, and propagation of 95% uncertainty intervals around all burden estimates. As new methods are introduced, it is necessary to recalculate GBD estimates from previous years so as to make comparison with previously published data possible. A detailed description of how these burden of disease metrics are estimated for mental disorders can be found elsewhere (GBD 2015 DALYs and HALE Collaborators, 2016).

DALYs are derived by summing YLDs and YLLs for each disorder, location, age group, sex, and year, and are now provided for more than 300 diseases and injuries. In interpreting the burden of mental disorders, one must recognize that the mortality-associated (YLL) burden estimates for mental disorders in the GBD studies should not be interpreted as suggesting

that premature death in people with MNS disorders is relatively inconsequential. Premature mortality has been repeatedly shown to be significant in populations with mental disorders (Walker, McGee, & Druss, 2015), with suicide being a major contributor and large contributions coming from cardiovascular disease and cancer (Lawrence, Hancock, & Kisely, 2013). Even in high-income countries, people with mental disorders often do not receive preventive services, such as immunizations, cancer screenings, and tobacco counseling (Druss, Rosenheck, Desai, & Perlin, 2002), and they often receive a lower quality of care for their medical conditions (Björkenstam et al., 2012; Laursen, Nordentoft, & Mortensen, 2014). Excess mortality estimates can be generated based on the GBD data; while MNS disorders were directly responsible for only 840,000 deaths in 2010, individuals with these conditions were estimated to have more than 13 million excess deaths using natural history models (Charlson, Diminic, Lund, Degenhardt, & Whiteford, 2014).

Notwithstanding these caveats, the GBD estimates show mental disorders contribute substantially to the global burden of disease, with mental and substance use disorders being the leading cause of disability globally (Whiteford et al., 2013; Whiteford, Ferrari, Degenhardt, Feigin, & Vos, 2015). The burden peaks in early adulthood for mental and substance use disorders, but is more consistent across age for neurological disorders. Females accounted for more DALYs for all mental and neurological disorders, except for mental disorders occurring in childhood, schizophrenia, substance use disorders, Parkinson's disease, and epilepsy, where males accounted for more DALYs. Overall DALYs are highest in the Eastern Europe/Central Asia regions and lowest in the East Asia/Pacific regions. The relative proportion of DALYs from MNS disorders within the overall disease burden has been estimated to be 1.6 times higher in high-income regions than in lower-income regions, largely due to the relatively higher burden of other health disorders such as infectious and perinatal diseases in LMICs. Because of their larger population, however, most of the global burden from MNS disorders is found in LMICs.

The burden estimates for 2015 are provided in **TABLE 10-4** and **FIGURES 10-2** and **10-3**. Table 10-4

TABLE 10-4 Total DALYs (Numbers and Proportions) Attributable to Mental, Neurological, and Substance Use Disorders in 2015

Cause	DALYs per 100,000 Population	Proportion of All-Cause DALYs in GBD	Proportion of Mental, Neurological, and Substance Use Disorder DALYs
Neurological Disorders			
Alzheimer's disease and other dementias	238	1.0%	9.5%
Parkinson's disease	21	0.1%	0.8%
Epilepsy	124	0.5%	5.0%
Multiple sclerosis	12	0.1%	0.5%
Migraine	329	1.3%	13.2%
Tension-type headache	23	0.1%	0.9%
Medication overuse headache	92	0.4%	3.7%
Motor neuron disease	9	0.04%	0.4%
Other neurological disorders	24	0.1%	0.9%

(continues)

TABLE 10-4 Total DALYs (Numbers and Proportions) Attributable to Mental, Neurological, and Substance Use Disorders in 2015 *(continued)*

Cause	DALYs per 100,000 Population	Proportion of All-Cause DALYs in GBD	Proportion of Mental, Neurological, and Substance Use Disorder DALYs
Substance Use Disorders			
Alcohol use disorders	112	0.5%	4.5%
Opioid use disorders	121	0.5%	4.8%
Cocaine use disorders	10	0.0%	0.4%
Amphetamine use disorders	14	0.1%	0.6%
Cannabis use disorders	6	0.02%	0.2%
Other drug use disorders	19	0.1%	0.7%
Mental Disorders			
Schizophrenia	155	0.6%	6.2%
Major depressive disorder	442	1.8%	17.7%
Dysthymia	100	0.4%	4.0%
Bipolar disorder	90	0.4%	3.6%
Anxiety disorders	246	1.0%	9.9%
Anorexia nervosa	7	0.03%	0.3%
Bulimia nervosa	8	0.03%	0.3%
Autism	63	0.3%	2.5%
Asperger's syndrome and other autistic spectrum disorders	37	0.2%	1.5%
Attention-deficit/hyperactivity disorder	6	0.03%	0.2%
Conduct disorder	58	0.2%	2.3%
Idiopathic developmental intellectual disability	34	0.1%	1.4%
Other mental and substance use disorders	96	0.4%	3.9%

provides a global overview of the total burden from each MNS disorder included in the GBD study. The leading contributors to this burden are major depressive disorder, which accounts for almost 18% of the overall burden in the total group, with anxiety disorders and dementia both contributing close to 10%. Figure 10-2 shows that the proportionate burden from MNS disorders increased substantially in all countries, irrespective of their economic development status, between 1990 and 2015. For most disorders, the increased burden is being largely driven by population growth and aging. In areas of the world undergoing major demographic change, such as sub-Saharan Africa, where the population is expected to double by 2050, projections suggest there will be an increase of 130% in the burden of mental and substance use disorders (Charlson et al., 2014). Figure 10-3 shows that the burden is greatest in the adolescent to middle adulthood period of life, when productivity is the greatest.

To be included in the GBD data, disorders must meet the threshold for diagnosis using ICD or DSM criteria. While the application of these diagnostic criteria may bias estimates downward in regard to the burden of mental disorders in some cultures, the adoption of common case definitions is necessary to promote international comparison (Whiteford, Ferrari, & Degenhardt, 2016). Another challenge for generating estimates of mental disorder burden, and subsequently investigating trends over time and differences between countries, is the limited coverage of epidemiologic data. This is particularly problematic in LMICs and in subnational locations. As a result, estimates often have large uncertainty intervals that can mask true variations in burden between countries and over time. Furthermore, it is necessary to generate better data on the relationships between risk factors, such as economic deprivation, and the variations in burden that might be explained by these risk factors.

Depressive and Anxiety Disorders

In 2015, the global age-standardized prevalence was 3% for major depressive disorder and 1.4% for

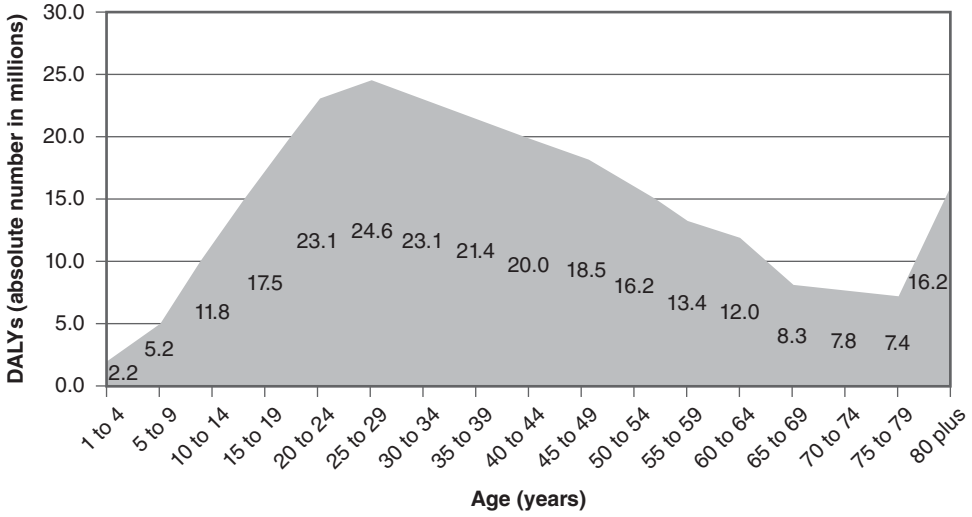

FIGURE 10-3 Global burden of mental, neurological, and substance use disorders.

Data from *Global burden of disease study 2015*. Retrieved from http://ghdx.healthdata.org/gbd-2015

dysthymia, making depressive disorders the largest contributor to the burden of disease, as measured by DALYs in the mental disorder group. The global prevalence is higher in females (5.1%) than in males (3.7%), and in countries where war and conflict are more prevalent. For example, Uganda had the highest rate of depressive disorder DALYs—although with the wide uncertainty estimates, this was not significantly different from the global mean. There is also a clear socioeconomic gradient in prevalence in many countries, with individuals having lower socioeconomic status also having increased risk for depression and anxiety disorders (Lund et al., 2010). Individual anxiety disorders are common and frequently co-occur with each other.

To prevent over-counting, GBD 2015 provides estimates for any anxiety disorder—a grouping that includes generalized anxiety disorder, panic disorder, and phobic disorders (agoraphobia, social phobia, and specific phobias) (Baxter, Vos, Scott, Ferrari, & Whiteford, 2014). It also includes obsessive–compulsive disorder, post-traumatic stress disorder, and acute stress disorders, although these are no longer classified as anxiety disorders in DSM-5. In 2015, the global age-standardized prevalence for all anxiety disorders combined was 3.6% (4.6% for females and 2.6% for males), making these disorders the second largest contributor to the burden of disease imposed by MNS disorders, as measured by DALYs. As is true for depression, there is considerable variability in the estimates, with anxiety disorder prevalence being impacted by factors such as sex, age, culture, conflict, urbanicity, and economic status (Baxter, Scott, Vos, & Whiteford, 2013). For example, a systematic review and meta-analysis of post-traumatic stress disorder alone in the general population in areas exposed to conflict found the prevalence to be 12.9%, after controlling for an extensive range of covariates (Charlson, Baxter, Cheng, Shidhaye, & Whiteford, 2016).

Schizophrenia

The age-standardized prevalence of schizophrenia was estimated in the GBD studies to be approximately 3% globally. This prevalence did not change from 1990 to 2015; however, the number of people with schizophrenia increased from 14.4 million to 23.4 million during this period, due primarily to population growth and aging. In 2015, schizophrenia contributed 15.5 million DALYs to the overall burden of disease globally, with roughly equal burdens noted in males and in females. Substantially higher prevalent cases and DALYs of schizophrenia were found lower-income regions of the world—a reflection of population size, but also coinciding with the highest treatment gaps. For example, China had the highest rate of schizophrenia DALYs, but this was closely followed by the U.S. rate, and neither country's rate was significantly higher than the global mean.

Bipolar Disorder

The global age-standardized prevalence of bipolar disorder was estimated at 0.5% across both sexes. As with the majority of mental disorders, the prevalence of bipolar disorder remained unchanged between 1990 and 2015, but due to population growth and changing age structures, the number of people with bipolar disorder increased from approximately 30 million in 1990 to 44 million in 2015. In terms of burden, bipolar disorder was responsible for 9 million DALYs, equating to 0.35% of all global DALYs in 2015. The DALY rates were consistent across the globe, with the difference between the lowest country estimate (China) and the highest country estimate (New Zealand) not differing significantly.

Substance Use Disorders

The burden of substance use disorders varies considerably across and within countries, between subgroups in a given population, and according to the substance being abused. Unlike other mental and neurological disorders, variations in substance use burden are influenced by additional factors, such as supply and availability of drugs, which can change prevalence and, in turn, burden. If dependence on tobacco (arguably the most common substance to be abused) is excluded, alcohol use disorders (AUD) are the most common substance abuse disorder in most countries. While AUD can refer to the entire range of health conditions associated with drinking alcohol above the recommended limit established by WHO, alcohol use disorders in the GBD studies refer only to alcohol dependence as defined by the ICD. Illicit drugs are those substances whose use outside medical settings has been prohibited under international and national control systems. In the GBD study, the drugs whose burden is estimated are opioids (including heroin), cannabis, amphetamines, and cocaine.

Globally, AUD were the most prevalent substance use disorders, with 63.5 million estimated cases in 2015. Cannabis dependence and opioid dependence were the most common illicit drug use disorders (19.8 million cases and 16.7 million cases, respectively). There were substantial geographic variations in the burden of disease and contrasting patterns for the association between total alcohol and illicit drug-attributable burden and per

capita income. Alcohol burden was highest in LMICs (with Russia being the highest), while the burden from illicit drugs was highest in Eastern European countries and the United States.

Childhood Disorders

The majority of mental disorders have their initial onset during childhood and adolescence, making this a crucial period for early intervention and identification. While substance use disorders tend to demonstrate a sharp increase in prevalence (and therefore burden) from late adolescence onward, certain mental and neurological disorders demonstrate significant burden between ages 5 to 14 years. Across both sexes, conduct disorder, depressive disorders, anxiety disorders, and autism spectrum disorders are responsible for almost 7.5% of all DALYs worldwide in this age group. For neurological disorders, migraine and epilepsy make up the majority of the burden of disease for children and adolescents (1.8% and 1.4%, respectively).

The implications of these estimates are significant, given that 85% of children and adolescents live in LMICs that generally have few or no child- and adolescent-specific mental health services. Furthermore, as infectious diseases continue to be successfully prevented and treated, more infants in these regions will survive into childhood and adolescence and, therefore, reach the ages where the incidence of mental disorders is higher. As such, it is important for these disorders to be recognized as significant contributors to the burden of disease in children and adolescents and for health resources to be allocated based on both current and future needs.

Dementia

The population of almost all countries is aging, and the size of the older population is growing fastest in low-income countries. Between 2015 and 2050, the number of older people living in higher-income countries is forecast to increase by 56%, compared with 138% in upper middle-income countries, 185% in lower middle-income countries, and 239% in low-income countries (https://www.alz.co.uk/research/WorldAlzheimerReport2015.pdf). Dementia is becoming a major contributor to global burden, with the total DALYs doubling for both men and women between 1990 and 2015.

Wider Health Impact of Mental Disorders

The limitations imposed by the GBD study methodology means the full impact of mental disorders is not captured in the DALY metric. Debate has arisen about where and how the burden of disease estimates related to mental disorders could be improved (Vigo, Thornicroft, & Atun, 2016; Whiteford, Ferrari, & Vos, 2016) in terms of measuring direct burden. One area where efforts to improve burden of disease estimates have been pursued is the relatively small number of deaths attributed to mental disorders. Suicide, for example, is recorded under "injuries" in the ICD cause-of-death coding guidelines. The inclusion of suicide deaths attributable to mental disorders into DALYs would have increased the burden of mental and substance use disorders in 2010 from 7.4% to 8.3% and increased the global ranking of these disorders from the fifth to the third leading cause of burden of disease (Ferrari et al., 2014).

The contribution that disorders make, as risk factors for other health outcomes, can also be dealt with through the comparative risk assessment (CRA) component of the burden of disease studies. The CRA quantifies the burden attributable to each risk factor exposure compared to an alternative (counterfactual) exposure distribution (GBD 2015 Risk Factors Collaborators, 2016). Mental disorders are considered risk factors if associated with elevated risk of mortality or disability from other diseases or injuries, though this area of the GBD studies is underdeveloped compared with the measurement of the direct burden of disease.

The burden of disease attributable to major depression as a risk factor for suicide and ischemic heart disease has been estimated (Charlson, Stapelberg, Baxter, & Whiteford, 2011; Li, Page, Martin, & Taylor, 2011). In 2010, major depression explained a further 16 million DALYs when it was considered as a risk factor for suicide. Overall, nearly half of DALYs originally allocated to suicide (included as intentional injuries in the GBD cause of death list) can be reattributed to major depression alone (Ferrari et al., 2013). Alcohol use and injecting-drug use as risk factors are now included in burden of disease estimates. In 2013, injecting-drug use was estimated to cause 39% of DALYs due to hepatitis C, 4% of DALYs due to HIV, and 1% of DALYs due to hepatitis B (Degenhardt et al., 2016). Injecting-drug use's contribution to the HIV burden of disease was highest in LMICs, and injecting-drug use's contribution to the hepatitis C burden of disease was highest in high-income countries. In 2015, DALYs attributed to alcohol use disorders were concentrated among transport injuries, cirrhosis, and cancers. Using DALYs per 100,000 population, Eastern Europe and southern sub-Saharan Africa have the highest estimated alcohol-attributable burden of disease, while Eastern Europe and North America have the highest illicit drug–attributable burden of disease.

This CRA area needs to be greatly expanded to capture the comorbidity between mental and other disorders. There is strong comorbidity between diet, diabetes, and mood disorders (Dipnall et al., 2015; Grigsby, Anderson, Freedland, Clouse, & Lustman, 2002), for example, and depression may increase the risk for diabetes (Rotella & Mannucci, 2013). Between 10% and 20% of people with schizophrenia have type 2 diabetes (Holt, Bushe, & Citrome, 2005). Depression is a risk factor for both ischemic heart disease (Charlson et al., 2013) and stroke (Pan, Sun, Okereke, Rexrode, & Hu, 2011). There is also strong evidence of the increased risk for depression *after* myocardial infarction (Strik, Lousberg, Cheriex, & Honig, 2004) and stroke (Aben et al., 2006). Infectious disease, cancer, diabetes, and cardiovascular disease are all more common with excess alcohol consumption (Rehm, 2011), with illicit drug use (Degenhardt & Hall, 2012), and in those persons with severe mental disorders (Hert et al., 2011).

In addition, anxiety and mood disorders and other common mental disorders (often called "somatoform disorders") can present in primary health care/general medical settings with physical symptoms (Escobar, Waitzkin, Silver, Gara, & Holman, 1998; Gureje, Simon, Ustun, & Goldberg, 1997). Such symptoms, which are sometimes termed "medically unexplained" because they cannot be attributed to physical disorders (Creed et al., 2012), are associated with considerable disability and high levels of help seeking and associated healthcare costs (Konnopka et al., 2012).

The coexistence of mental and physical disorders is also associated with worse outcomes of the physical disorder, through a variety of mechanisms. For example, depression after acute myocardial infarction has been associated with fatal and nonfatal cardiovascular events, adverse overall health status, and increased costs (Lichtman et al., 2014). Similarly, depression is associated with an increased risk of poor glycemic control and, therefore, increased mortality in people with diabetes (Lin et al., 2010). Similar findings have been reported for patients with HIV/AIDS, in whom depression is recognized as a predictor of worse clinical outcomes and poorer quality of life, often associated with a reduction in medication adherence (Nanni, Caruso, Mitchell, Meggiolaro, & Grassi, 2015). Clear recommendations have been made for improving the treatment of people with comorbid mental and physical disorders, especially those with severe mental disorders (Hert et al., 2011).

Another relationship that needs to be addressed is the strong association of mental disorders with a range of women's health concerns. Depression is strongly associated with dysmenorrhea, dyspareunia, and pelvic pain (Latthe, Mignini, Gray, Hills, & Khan, 2006). In some cultures in Asia, gynecologic complaints, such as abnormal vaginal discharge, are associated with depression (Patel et al., 2006). Maternal mental disorders are associated with a range of adverse outcomes in children, including low birth weight, premature birth, poor infant growth, and emotional, cognitive, and behavioral developmental delays that can persist into adolescence and beyond (Stein et al., 2014).

The Wider Social and Economic Impact of Mental Disorders

Just as one disease burden metric (such as the DALY) cannot capture the full health impact of mental disorders, it also cannot capture all of the social and economic impacts of these disorders on the individual, family, or society. Disease burden estimates do not account for the denial of basic human rights, ranging from limited opportunities for education and employment to torture and denial of freedom, sometimes within healthcare institutions. They also do not account for the time spent by family members in support and caring for the individual with mental disorder, the costs of treatment, or the productivity loss costs to the individual and his or her family.

A study undertaken for the World Economic Forum estimated that the cumulative global impact of mental disorders in terms of lost economic output may amount to $16 trillion over 20 years (Bloom et al., 2011). The Organisation for Economic Co-operation and Development (OECD, 2015) has conservatively estimated that the impact of mental disorders in high-income countries ranges from 2.3% to 4.4% of gross domestic product (GDP). Economic costs attributable to alcohol use and alcohol use disorders alone are estimated to amount to the equivalent of 1.3% to 3.3% of GDP in a range of high-income and middle-income countries, with more than two-thirds of this loss represented by productivity losses (Rehm et al., 2009). The global cost of dementia in 2015 has been estimated at $818 billion, equivalent to 1.09% of global GDP (Alzheimer's Disease International, 2015). Additionally, the social adversities associated with mental disorders, given the large and growing proportions of the global population affected by conflict or displacement due to environmental degradation and climate change, will likely increase the future burden of mental disorders.

In high- and middle-income countries, the productivity losses attributable to mental disorders have been shown to be very significant. As an example, the lost taxation revenue in Australia from people age 45 and older who retire early due to depression has been

estimated at AUD$ 278 million (USD$ 190 million), and income support for those individuals has been estimated at AUD$ 407 million (USD$ 278 million) in 2009 terms. The total impact on GDP of this group for this disorder alone was estimated at AUD$ 1.7 billion (USD$ 1.2 billion) (Schofield et al., 2011). The value of informal caring provided by family members was approximately AUD$13.2 billion (USD$10.3 billion) in 2015 (Diminic et al., 2016), much greater than the AUD$ 8 billion (USD$ 6.3 billion) that the national and state governments spent on mental health services in Australia.

Although the economic burden is large, increased spending within the health sector to increase treatment coverage for mental disorders appears to be more than offset by economic productivity gains and reduced outlays on social and income support (OECD, 2015; Wang et al., 2007). Evidence-based health and social interventions can avert the long-term cost burden and have a broad range of payoffs, both within the public sector and more widely, such as through better educational performance, improved employment/earnings, and reduced crime (Knapp, McDaid, & Parsonage, 2011). The view that treatment of mental disorders in LMICs is prohibitively expensive is a myth that needs to be dispelled. A fully scaled-up package of mental health care in sub-Saharan Africa and south Asia, based on a comparative cost-effectiveness analysis of 44 individual or combined interventions, has been estimated at USD$ 3 to USD$ 4 per person within a population (Chisholm, Naci, Hyder, Tran, & Peden, 2012). Of course, scaled-up treatment of common mental disorders globally can lead to large productivity gains. In a model consisting of 36 countries between 2016 and 2030, USD$ 230 billion was needed for scaled-up treatment of depression and USD$ 169 billion for scaled-up treatment of anxiety disorders (Chisholm, Sweeny, et al., 2016).

Interventions

This section briefly considers the role of mental health policies, human resources for mental health care, and the evidence for the prevention and treatment of mental disorders.

Mental Health Policies and Plans

A mental health policy presents the values, principles, and objectives for improving mental health and reducing the burden of mental disorders in a population. It should define a vision for the future and help to establish a model for action. A policy should be distinguished from a plan, which is a strategy for implementing actions to achieve the objectives of a policy.

In some countries, mental health policies are restricted to psychiatric services. However, a broader scope is preferable—one in which mental health services in general are addressed. These services may include primary care and specialized care, as well as all aspects of intervention—that is, promotion, prevention, treatment, and ongoing care (WHO, 2003c). Policies need to address the coordination between mental health services themselves, as well as between mental health services and other services such as housing, education, and employment. Other key issues that policies should address include financial arrangements for the private and public sectors, expenditure prioritization, and individual and organizational capacity development (WHO, 2003a). Finally, policies need to provide for continuous evaluation of mental health outcomes to ensure that those policies remain appropriate to contemporary circumstances and lead to effective services.

A country's capacity to deliver appropriate mental health services to its population is seriously hampered by the absence of a mental health policy. Thus, it is cause for concern that only 68% of countries (77% of those that responded to the WHO survey) have mental health policies (WHO, 2014). LMICs are less likely to have these kinds of policies: For example, only 71% of countries in Africa have established such policies. This is, however, a substantial improvement in recent years: In 2001, only 50% of African countries in Africa had established mental health policies (WHO, 2001).

Partly in response to this shortcoming, WHO developed the Mental Health Policy and Service Guidance Package during 2000–2005. This package consists of a series of interrelated, user-friendly modules designed to assist with policy development and service planning. One module provides a series of steps that can be taken to develop mental health policies: (1) assess the population's needs; (2) gather evidence for an effective policy; (3) consult and negotiate; (4) exchange ideas with other countries; (5) set out the vision, values, principles, and objectives of the policy; (6) determine areas for action; (7) identify the roles and responsibilities of different sectors; and (8) conduct pilot studies (WHO, 2005b).

Human Resources for Mental Health Care

The implementation of mental health policies and plans depends on both the quantity and the quality of the personnel available to implement interventions. There are vast differences among regions of the world

in terms of the availability of mental health professionals (**TABLE 10-5**). In almost all countries, there is a gap between the supply of personnel and the demand for their services. The deleterious consequences of the low numbers of mental health professionals are magnified when one considers that the distribution of mental health professionals is frequently uneven between countries in each region, and within countries. The number of mental health workers per 100,000 population is considerably higher in urban areas, for example. Also, the available personnel are often not used efficiently, and staff may be demoralized and demotivated.

Mental health programs require a cadre of well-trained mental health specialists, such as psychiatrists, psychologists, social workers, mental health occupational therapists, and psychiatric nurses. They are responsible for functions such as the management of patients with complex conditions, supervision and training of other specialists and generic health workers, research, planning, management, and consultation–liaison. It is vital that specialists stay abreast of modern international developments that are relevant for the functions they perform, including honing their skills of evaluation, capacity building, and supervision (Patel, Simon, Chowdhary, Kaaya, & Araya, 2009). At the same time, the application of such developments should be informed by local research and experience. Training efforts for mental health specialists should occur in parallel with training for generic health workers such as doctors, nurses, and community health workers, who provide the majority of care in LMICs. In keeping with the objectives of WHO's mhGAP program, a major initiative in recent years has been the training and supervision of nonspecialist health providers in the provision of basic mental health services—an approach known as "task sharing" or "task-shifting" (Kakuma et al., 2011). In keeping with the objectives of the Grand Challenges in Global Mental Health initiative (Collins et al., 2011), substantial research funding has been devoted to research in this area in LMICs, and the evidence in support of this approach is presented later in this chapter.

One sector that is particularly important in LMICs is the traditional health sector. In many LMICs, the majority of people seek care from traditional healers before seeing allopathic healers. There are several ways in which such providers can be engaged to provide mental health care. They can work side by side with allopathic mental health services, perhaps even operating from the same premises; they can be trained to recognize mental disorders and refer people suffering from them to allopathic services; and they can be recruited and trained to function as allopathic mental health workers. Whatever arrangements are made at an organizational level, individual mental health services providers should attempt to establish whether their patients are being subjected to any traditional

TABLE 10-5 Median Number of Mental Health Professionals per 100,000 Population in Each WHO Region and in the World

WHO Region	Psychiatrists	Psychiatric Nurses	Psychologists Working in Mental Health	Social Workers Working in Mental Health

interventions that are harmful. If they are, they should receive education and counseling that aim to reduce exposure to such negative interventions. Conversely, traditional practices that are helpful can be incorporated into allopathic care (Institute of Medicine, 2001).

Prevention and Treatment of Mental, Neurological, and Substance Use Disorders

Interventions for mental disorders have progressed enormously in the past few decades. The *Disease Control Priorities*, third edition (DCP-3), released by the World Bank, provides a synthesis of the evidence base and recommendations for the packages for prevention and treatment of MNS disorders (Patel et al., 2016). These recommendations identify the specific interventions for each group of disorders (**TABLE 10-6**) and the platforms through which they can be scaled up (**TABLE 10-7**).

Population-Level Recommendations

Evidence-based population-level recommendations include legislative measures to restrict access to means of self-harm and suicide (e.g., limiting access to guns and pesticides, such as through the use of lockboxes) and limiting availability of and demand for alcohol (e.g., through taxation and increased prices). Effective interventions, strategies, and policies to prevent and reduce substance use disorders can be categorized as regulatory, community based (including education), and health services based.

Prohibition has been attempted for alcohol products and is currently in place in some countries; this policy is also used with classes of substances including opioids, cannabinoids, and cocaine in most countries. Although prohibition can dramatically reduce substance use disorders in the short term, its costs in terms of civil disobedience and crime are enormous—so much so, that, in general, prohibition is not regarded as an acceptable policy option, with the exception of specific circumstances, such as drinking alcohol and driving (Wolf & Midanik, 2013).

Regulatory interventions include taxation, restrictions on availability, and total bans on all forms of direct and indirect advertising. Increases in alcohol taxes, for example, have been shown to reduce both the prevalence and the consumption of alcohol products. For young people, laws that raise the minimum legal drinking age reduce alcohol sales and problems among young drinkers. Reductions in the hours and days of sale, numbers of alcohol outlets, and restrictions on access to alcohol are all associated with reductions in both alcohol use and alcohol-related problems. A meta-analysis of studies in LMICs found a strong inverse effect between alcohol consumption and alcohol price and/or taxation (Sornpaisarn, Shield, Cohen, Schwartz, & Rehm, 2013), which is comparable to the impact of increasing price/taxes and decreasing consumption in high-income countries.

At the population level, there is also good practice evidence for interventions that seek to raise mental health literacy and reduce stigma and discrimination (Thornicroft et al., 2016). Social contact interventions, in which people engage with persons with mental disorders in recovery, changes attitudes and has the potential to instill behavior change (Corrigan, Morris, Michaels, Rafacz, & Rusch, 2012). Interventions within the criminal justice system are effective means to reduce alcohol and drug use, and to treat behavior disorders in adolescents and psychosis among adults. For example, mental health input in the criminal justice system can prevent the inappropriate imprisonment of people with mental disorders, make treatment for mental disorders available in prisons, and reduce the mental health sequelae of imprisonment for prisoners and their families. In high-income countries, mental health training of police through crisis intervention teams (CIT) reduces incarceration, increases mental health treatment, and reduces violence experienced both by police and by persons with mental disorders (Compton, Broussard, Munetz, Oliva, & Watson, 2011). There is increased attention to CIT and similar models in LMICs. For example, in Liberia, CIT training of police both improved mental health outcomes and reduced use of physical force against persons in acute psychological distress during the 2013–2016 Ebola outbreak (Kohrt, Blasingame, et al., 2015).

Community-Level Recommendations

Community-based mental health care is a major objective of the World Psychiatric Association and other mental health advocates and practitioners (Thornicroft et al., 2010). Life-skills training in schools to build social and emotional competencies is an example of a best practice to reduce the burden of MNS disorders. Systematic reviews of mental health promotion for children and adolescents have shown that school-based programs improve self-esteem, motivation, and self-efficacy (Barry, Clarke, Jenkins, & Patel, 2013; Fazel, Patel, Thomas, & Tol, 2014). Community mobilization and education have been used to prevent substance abuse in many countries. A crucial setting for prevention is in schools, where the goal of most alcohol education programs is to change adolescents' drinking beliefs, attitudes, and behaviors, or to modify factors such as general social skills and self-esteem

TABLE 10-6 Effective Interventions for the Prevention, Treatment, and Care of MNS Disorders

	Type of Disorder	Preventive Interventions	Drug and Physical Interventions	Psychosocial Interventions
Mental Disorders in Adulthood				
Schizophrenia (5.3% of total MNS DALYs)	■ Chronic or relapsing condition characterized by delusions, hallucinations, and disturbed behavior		■ Antipsychotic medication***	■ Family therapy/ support** Community-based rehabilitation* ■ Self-help and support groups*
Mood and anxiety disorders (41.9% of total MNS DALYs)	■ Group of conditions characterized by somatic, emotional, cognitive, and behavioral symptoms; bipolar disorder is associated with episodes of elated and depressed moods	■ Cognitive-behavioral therapy for persons with subthreshold symptoms**	■ Antidepressant, anxiolytic, mood stabilizer, and antipsychotic medications*** ■ Electroconvulsive therapy (ECT) for severe refractory depression**	■ Cognitive-behavioral therapy*** ■ Interpersonal therapy**
Mental and Developmental Disorders in Childhood and Adolescence				
Conduct disorder (2.2% of total MNS DALYs)	■ Pattern of antisocial behaviors that violate the basic rights of others or major age-appropriate societal norms	■ Life skills education to build social and emotional well-being and competencies** ■ Parenting skills training** ■ Maternal mental health interventions**		■ Parenting skills training** ■ Cognitive-behavioral therapy*
Anxiety disorders (2.3% of total MNS DALYs)	■ Excessive or inappropriate fear, with associated behavioral disturbances that impair functioning	■ Parenting skills training** ■ Maternal mental health interventions**		■ Cognitive-behavioral therapy**
Autism (1.6% of total MNS DALYs)	■ Severe impairment in reciprocal social interactions and communication skills, as well as the presence of restricted and stereotypical behaviors			■ Parental education and skills training* ■ Educational support*

Attention-deficit/ hyperactivity disorder (ADHD) (0.2% of total MNS DALYs)	■ Neurodevelopmental disorder characterized by inattention and disorganization, with or without hyperactivity–impulsivity, causing impairment of functioning	■ Psychosocial stimulation of infants and young children*	■ Methylphenidate**	■ Parenting skills training** ■ Cognitive-behavioral therapy**
Intellectual disability (idiopathic) (0.4% of total MNS DALYs)	■ Significantly impaired cognitive functioning and deficits in two or more adaptive behaviors	■ Psychosocial stimulation of infants and young children** ■ Perinatal interventions (e.g., screening for congenital hypothyroidism)** ■ Population-based interventions targeting intellectual disability risk factors (e.g., reducing maternal alcohol use)*		■ Parental education and skills training* ■ Educational support*
Neurological Disorders				
Migraine (8.7% of total MNS DALYs)	■ Episodic attacks where headache and nausea are the most characteristic attack features; the headache itself, lasting for hours to 2–3 days, is typically moderate or severe and likely to be unilateral, pulsating, and aggravated by routine physical activity	■ Prophylactic drug treatment with propranolol or amitriptyline***	■ Drug treatments: Aspirin or one of several other nonsteroidal anti-inflammatory drugs [NSAIDs]***	■ Behavioral and cognitive interventions*
Epilepsy (6.8% of total MNS DALYs)	■ A brain disorder traditionally defined as the occurrence of two unprovoked seizures occurring more than 24 hours apart with an enduring predisposition to generate further seizures	■ Population-based interventions targeting epilepsy risk factors (e.g., preventing head injuries; neurocysticercosis prevention)*	■ Standard antiepileptic medications (phenobarbital, phenytoin, carbamazepine, valproic acid)*** ■ Epilepsy surgery**	
Dementia (4.4% of total MNS DALYs)	■ A neuropsychiatric syndrome characterized by a combination of progressive cognitive impairment, behavioral, and psychological symptoms (BPSD) and functional difficulties	■ Cardiovascular risk factors management (healthy diet, physical activity, tobacco use cessation)*	■ Cholinesterase inhibitors and memantine for cognitive functions; medications for management of BPSD*	■ Caregiver education and support and behavioral training, and environmental modifications ** ■ Interventions to support carers of people with dementia**

(continues)

TABLE 10-6 Effective Interventions for the Prevention, Treatment, and Care of MNS Disorders *(continued)*

	Type of Disorder	Preventive Interventions	Drug and Physical Interventions	Psychosocial Interventions
Substance Use Disorders				
Alcohol use disorders (6.9% of total MNS DALYs)	■ Harmful use: "A pattern of alcohol use that causes damage to physical or mental health" ■ Alcohol dependence: A cluster of physiological, behavioral, and cognitive phenomena in which the use of a substance takes on a much higher priority for a given individual than other behaviors that once had greater value	■ Excise taxes*** ■ Restriction on sales** ■ Minimum legal age** ■ Measures to prevent drunk driving** ■ Advertising bans* ■ Restrictions on density* ■ Opening hours, closing hours, and days of sale** ■ Family interventions*	■ Naltrexone, acamprosate*	■ Family support* Motivational enhancement, brief advice, cognitive-behavioral therapy** ■ Screening and brief interventions*** ■ Self-help groups*
Illicit drug use disorders (7.8% total MNS DALYs)	■ A pattern of regular use of illicit drugs characterized by significantly impaired control over use and physiological adaptation to regular consumption as indicated by tolerance and withdrawal	■ Psychosocial interventions with primary school children (e.g., good behavior game or strengthening families program)*	■ Opioid substitution therapy (e.g., methadone, buprenorphine)***	■ Self-help groups, psychological interventions (e.g., cognitive-behavioral therapy)*
Suicide and Self-Harm				
Suicide and self-harm (1.47% of GBD; 22.5 million YLLs or 62.1% of suicide YLLs were attributed to mental and substance use disorders in 2010)	■ Suicide: The act of deliberately killing oneself ■ Suicide attempt: Any nonfatal suicidal behavior; includes intentional self-inflicted poisoning, injury, or self-harm that may or may not have a fatal intent or outcome	■ Policies and legislation to reduce access to the means of suicide (e.g., pesticides)** ■ Decriminalization of suicide* ■ Responsible media reporting of suicide*	■ Effective drug interventions for underlying MNS disorders** ■ Emergency management of poisoning**	■ Social support; psychological therapies for underlying MNS disorders*

Notes: Strength of evidence: *** evidence of cost-effectiveness (CE); ** Strong evidence of effectiveness (E) but not of CE; * modest evidence of E and either not CE or no evidence of CE.

TABLE 10-7 Intervention Priorities for MNS Disorders by Delivery Platform

Platform for Intervention Delivery						
			Healthcare Platforms			
Problem Area	**Population Platform**	**Community Platform**	**Self-Care and Management**	**Primary Health Care**	**First-Level Hospital**	**Specialized Care**
All MNS disorders	Awareness campaigns to increase mental health literacy and address stigma and discrimination Legislation on protection of human rights of persons affected by MNS disorders	Training of gatekeepers (e.g., community workers, police, teachers) in early identification of priority disorders, provision of low-intensity psychosocial support, and referral pathways Self-help and support groups (e.g., for alcohol use disorders, for epilepsy, parent support groups for children with developmental disorders, and for survivors of suicide)				
Adult mental disorders	Child protection laws		Physical activity Relaxation training Education about early symptoms and their management web- and smartphone-based psychological therapy for depression and anxiety disorders	Screening and proactive case finding for psychosis, depression, and anxiety disorders Diagnosis and management of depression and anxiety disorders* Continuing care of schizophrenia and bipolar disorder	***Diagnosis and management of acute psychoses*** Management of severe maternal depression* Management of depression and anxiety disorders in mothers, people with HIV, and people with other noncommunicable diseases*	*Electroconvulsive therapy for severe or refractory depression* Management of refractory psychosis with clozapine

TABLE 10-7 Intervention Priorities for MNS Disorders by Delivery Platform *(continued)*

Platform for Intervention Delivery						
			Healthcare Platforms			
Problem Area	**Population Platform**	**Community Platform**	**Self-Care and Management**	**Primary Health Care**	**First-Level Hospital**	**Specialized Care**
Child mental and developmental disorders	Child protection laws	**Parenting programs in infancy to promote early child development** **Life skills training in schools to build social and emotional competencies** Parenting programs in early and middle childhood (2–14 years) Improve the quality of antenatal and perinatal care to reduce risk factors associated with intellectual disability	Web- and smartphone-based psychological therapy for depression and anxiety disorders	Screening for developmental disorders in children and maternal mental health interventions Parent skills training for developmental disorders Psychological treatment for mood, anxiety, ADHD, and disruptive behavior disorders*	**Diagnosis of childhood mental disorders such as autism and ADHD** Stimulant medication for severe cases of ADHD Newborn screening for modifiable risk factors for intellectual disability	
Neurological disorders	Policy interventions to address the risk factors for cardiovascular diseases (e.g., tobacco control)		**Self-managed treatment of migraine** Self-identification/management of seizure triggers Self-management of risk factors for vascular disease (e.g., healthy diet, physical activity, tobacco use)	Diagnosis and management of epilepsy and headaches Community-based screening for detection of dementia Interventions to support caregivers of patients with dementia *Management of prolonged seizures or status epilepticus*	Diagnosis of dementia and secondary causes of headaches	Surgery for refractory epilepsy

Alcohol and illicit drug use disorders	**Regulate the availability and demand for alcohol (e.g., increases in excise taxes on alcohol products, advertising bans)** Penalize risky behaviors associated with alcohol (e.g., enforcement of BAC limits)	Awareness campaigns to reduce maternal alcohol use during pregnancy	Self-monitoring of substance use	**Screening and brief interventions for alcohol use disorders** Opioid substitution therapy (e.g., methadone and buprenorphine) for opioid dependence	*Management of severe dependence and withdrawal*	Psychological treatments (e.g., CBT) for refractory cases*
Suicide and self-harm	**Control the sale and distribution of means of suicide (e.g., pesticides)** Decriminalize suicide	Safer storage of pesticides in the community and farming households	Web- and smartphone-based treatment for depression and self-harm	Primary health-care packages for underlying MNS disorders (as described above)* Planned follow-up and monitoring of suicide attempters* *Emergency management of poisoning*	Treatment of comorbid mood and substance use disorder*	Specialist health-care packages for underlying MNS disorders (as described above)

Abbreviations: ADHD, attention-deficit/hyperactivity disorder; BAC, blood alcohol concentration; CBT, cognitive-behavioral therapy; MNS = mental, neurological, and substance use.
Italic type denotes urgent care; underlined type denotes continuing care; normal font denotes routine care.
Recommendations in **bold** = best practice; recommendations in normal font = good practice.
* There is no fixed time period for the management of these complex conditions. For example, in the management of depression, some individuals need relatively short periods of engagement (e.g., 6–12 months for a single episode) at the one end, while others may need maintenance care for several years (e.g., when there is a relapsing course).

EXHIBIT 10-3 Community Care for Severe Mental Disorders in Low-Resource Settings

A community mental health program for severe mental disorders in a rural setting in India was initiated in partnership with Ashagram ("village of hope"), a nongovernmental organization (NGO) working toward the rehabilitation for people affected by leprosy. The NGO was located in Barwani, one of the poorest districts in India. Mental health care was routinely provided through an outpatient clinic that required patients to travel to the hospital to be assessed and to receive treatment.

A community-based rehabilitation (CBR) model was devised for patients with chronic schizophrenia, based on a three-tiered service delivery system. CBR relies on the active participation of the disabled and their families in rehabilitation and takes specific notice of prevailing social, economic, and cultural issues. The highest tier was outpatient (OP) care. All patients were started on antipsychotic medication. The second tier consisted of mental health workers (MHWs) drawn from the local community. After a 60-day training program, the MHWs worked with patients, families, and the local community in providing services. Each MHW served five or six contiguous villages and carried a total caseload of 25 to 30 patients, including some of the study subjects. The third tier consisted of family members and other key persons in the community who formed the local village health groups (*samitis*). These groups served as a forum for the members to plan relevant rehabilitation measures and reduce social exclusion.

The evaluation of the CBR program showed that, among patients who actively participated, this model was more effective than standard outpatient treatment, as determined by a range of clinical and functional outcomes (Chatterjee, Patel, Chatterjee, & Weiss, 2003). A four-year follow-up of the cohort of persons in the CBR care arm showed that adherence with medication and participation in self-help groups predicted a favorable outcome (Chatterjee, Pillai, Jain, Cohen, & Patel, 2009). A subsequent randomized controlled trial of this intervention in three sites confirmed its beneficial effects in reducing levels of disability in people with chronic schizophrenia in India (Chatterjee et al., 2014). Because a lack of professional resources is a reality in LMICs, the CBR method takes advantage of active local community participation and low levels of technical expertise to deliver services.

that are assumed to underlie adolescent drinking. Structured universal interventions for children in settings of armed conflict have positive effects for behavior, self-esteem, and coping.

The most effective promotion initiatives take a multicomponent approach by integrating their activities with programs on topics such as microfinance or reproductive and sexual health education. Standalone mental health promotions, such as only doing cognitive-behavioral therapy, have produced fewer benefits. Other good practices include parenting programs with infants for early child development.

Community care using locally available resources is a key strategy for enabling people with severe mental disorders and disabilities to remain in the community. One such example is the Ashagram model in rural India (**EXHIBIT 10-3**).

Preventive efforts directed toward reducing the risk factors for epilepsy and developmental disabilities have focused on improving prenatal care and promoting safe delivery. Other preventive strategies include better fever control in children; strategies aimed at reduction of the causes of brain injury, such as children's use of safety seats and helmets; control of infectious and parasitic diseases that infect the brain; genetic counseling; screening programs for conditions that are known to be associated with mental handicaps, such as hypothyroidism; micronutrient supplementation, such as with iodine; and reductions in environmental levels of toxins such as lead.

Healthcare-Level Recommendations

Best practices at the healthcare level include self-management psychological interventions, such as web-based psychological therapy for depression and anxiety. Given the tremendous treatment gap, the lack of available mental health specialists in most of the world, and the desire to move treatment from institutions to communities, numerous efforts are being made to deliver mental health through primary care (Gwaikolo et al., 2017; Lund et al., 2012; Petersen et al., 2016; WHO, 2010). A key innovation to attain this goal is to address the supply-side barrier of inadequate mental health specialists through task sharing of front-line interventions with nonspecialist health workers. A growing evidence base testifies to the effectiveness of nonspecialist providers in facilitating management of a range of mental disorders, typically in primary care and community settings (van Ginneken et al., 2013).

Perhaps the strongest evidence base supports task sharing of psychological treatments among primary care workers, community health workers, and non-healthcare providers in the community (**EXHIBIT 10-4**). In Uganda, interpersonal therapy (IPT) was adapted so that it could be delivered by highly supervised lay

EXHIBIT 10-4 Do Talking Treatments Work in Low-Income Countries?

> Things were already going pretty badly for Florence Manyande. Then one day last spring, while walking down the street, she was hit by a car.
>
> "This woman saw, and she pulled me out of the road," recalls Manyande, 50. "She tried to talk to me, but I couldn't talk then. I had a lot on my mind."
>
> Her run of bad luck had begun in 2010, when Manyande's husband skipped out on her and her three kids. "I had no way to pay school fees for my children," she says, and no way to pay rent. "Even my relatives were shunning me. They couldn't take me in because they said, 'We have our own problems.'"
>
> By the time Manyande had her accident, she was thinking about killing herself.
>
> Then her fortune took a turn. The woman who found her, injured, on the road happened to be a health worker. She took Manyande to the clinic to get bandaged up. "While I was there," Manyande says, "she introduced me to the 'Friendship Bench.'" (Singh, 2017)

There has been skepticism about the applicability of psychological treatments—such as cognitive-behavioral therapy (CBT), interpersonal therapy (IPT), and dialectical behavioral therapy (DBT)—for mental health problems in low-resource, non-Western cultural settings. Lack of clinical psychologists and different cultural belief systems have been seen as barriers to applying these psychological treatments. However, a rapidly growing evidence base suggests that lay persons can be trained and closely supervised to effectively deliver psychotherapies (Singla et al., 2017).

In developing the "Friendship Bench," Dixon Chibanda, a psychiatrist from Zimbabwe, adapted problem-solving therapy by integrating local cultural psychological concepts such as *kuvhura pfungwa* ("opening of the mind"), *kusimudzira* ("uplifting"), and *kusimbisa* ("strengthening"). Moreover, rather than focusing on psychiatric labels that could be stigmatizing, such as "depression" or "general anxiety disorder," the treatment employed culturally acceptable idioms of distress, such as *kufungisisa* ("thinking too much"). The intervention was delivered in a nonstigmatizing setting—a bench outside of health clinics, leading to the "Friendship Bench" name for the program.

Six months after receiving the Friendship Bench psychological intervention, only 13% of patients had depression, compared with 50% of persons in a basic treatment comparison group (Chibanda et al., 2016). Numerous other psychological treatments delivered by nonspecialists in LMICs—such as the Thinking Health Program, Healthy Activity Program, and Problem Management Plus (PM+)—have shown similar benefits. These interventions demonstrate both the effectiveness and the feasibility of psychotherapy for mood and anxiety disorders in settings that vary by culture and resource availability around the world.

community members for treatment of depression among war-affected adults and youth (Bolton et al., 2007; Bolton et al., 2003). Cognitive-behavioral therapy (CBT) was adapted for treatment of perinatal depression by female community health volunteers through the Thinking Healthy Program in Pakistan, which is now being replicated in diverse settings in LMICs (Rahman, Malik, Sikander, Roberts, & Creed, 2008). Behavioral activation has been adapted as a lay health worker–directed Healthy Activity Program for treatment of depression in India (Patel et al., 2017); Counseling for Alcohol Problems is a similar lay psychological treatment adapted from motivation interviewing for treatment of harmful alcohol use (Nadkarni et al., 2016). A Common Elements Treatment Approach (CETA) has also been developed so that closely supervised nonspecialists can provide trans-diagnostic care that incorporates elements from multiple psychological treatments (Murray et al., 2014). All of these nonspecialist interventions have demonstrated superiority to the usual treatments. In fact, when all nonspecialist psychological interventions for common mental disorders were reviewed (24 studies as of 2016), there was a pooled effect size of 0.49 (Singla et al., 2017), which approaches the effect sizes observed in psychological treatments delivered by specialists in high-income countries (Huhn et al., 2014).

In task sharing, nonspecialists take on detection, diagnosis, and management of health conditions in conjunction with training, supervision, and referral support by specialists (WHO, 2008). Thus, a key component of task sharing is the recognition that integration is not a simple matter of training nonspecialist health workers. A collaborative care delivery model, in which primary and community care practitioners work together with specialists, is an essential element for integrating mental health in primary care (Patel et al., 2013). Furthermore, primary care mental health services, although essential, cannot meet all of the mental health needs of any given population. This is especially true for people who are suffering from psychotic disorders and who need access to community mental health and rehabilitation programs, as well as emergency inpatient facilities (Patel, Farooq, & Thara, 2007).

Studies have explored the role of lay community health workers in primary and secondary prevention (Mutamba, van Ginneken, Smith Paintain, Wandiembe, & Schellenberg, 2013). For example, prevention studies in LMICs have shown that such interventions can reduce the burden of depression and PTSD in adults. Antenatal programs to prevent postpartum depression have led to improvements in other health outcomes related to children and mothers, such as mother–infant engagement (Rahman et al., 2013). There is also a growing evidence base on "early interventions," such as supportive psychotherapy and low-dose antipsychotic agents, that may delay or prevent progression to a first mental disorder episode (McGorry, 2015). Reducing the duration of untreated psychosis at the onset of schizophrenia can dramatically impact the life course of the illness (Fusar-Poli et al., 2009). This consideration is especially important in LMICs, where the duration of untreated psychosis can average two years, and it is not uncommon to go more than five years without initiating treatment (Thirthalli et al., 2011).

According to DCP-3 guidelines, at the healthcare level, hospital care is recommended as a best practice for delivery of MNS specialty services for severe, refractory, and emergency presentations of MNS disorders. In addition, mental health care should be integrated into other specialty services ranging from obstetric and gynecologic care to infectious diseases services to oncologic treatment.

Humanitarian Emergencies

Mental health services are especially important to address the acute and chronic needs of populations affected by complex humanitarian emergencies, such as war, environmental disasters, earthquakes, and other causes of forced displacement. Refugees, internally displaced persons, and other survivors of collective trauma are at an increased risk of MNS disorders. Unfortunately, populations affected by humanitarian emergencies live in settings where the health, and especially the mental health, services sector may have been limited or nonexistent even before the disaster. There is a heightened need to identify and allocate resources for providing mental health care and psychosocial support in these settings, both for those with disorders induced by the emergency and for those with preexisting disorders.

Guidance on mental health and psychosocial response is available through the Inter-Agency Standing Committee (IASC, 2007). WHO (2015) has also released a Humanitarian Intervention Guide version of mhGAP, which provides treatment recommendations for acute emergency response and includes trauma and grief-related conditions not covered in the basic mhGAP. In a number of countries, such emergencies have actually provided opportunities for systemic change or services reform in public mental health (WHO, 2013c).

Delivering Effective Treatments and Scale-up

Despite the evidence presented earlier, the fact remains that only a small proportion of people suffering from mental disorders receive effective interventions. This failure to provide effective treatments to all people who need them, which has been termed the "treatment gap," is evident in all countries, but is more marked in LMICs. Globally, only one in five people with depression in high-income countries receives minimally adequate treatment; however, the situation is far worse in lower-middle income countries, where only one in 27 people with depression receives minimally adequate care (Thornicroft et al., 2017).

Factors contributing to the treatment gap may be categorized as supply-side barriers and demand-side barriers. The supply-side barriers include lack of trained mental health workers, availability of culturally competent providers to address diverse ethnic and social groups, lack of transportation, and lack of affordable services. As mentioned earlier, there is a severe shortage of specialists in LMICs, where the bulk of the resources available for mental health services are devoted to large psychiatric hospitals and services are concentrated in a few urban settings (WHO, 2014)—this represents a major supply-side barrier in these countries. The demand-side barriers include lack of recognition among the public about mental disorders, lack of awareness that mental disorders can be treated, and stigma that prevents individuals from seeking care.

A challenge to implementing recommended prevention and treatment programs, as described in the DCP-3, is lack of political will—evidenced by less than 1% of the total health budget being allocated to MNS care in most national health systems. Similarly, less than 1% of development assistance goes toward MNS services. Given that 30% of the countries in Africa and 26% of countries in the Americas rank NGOs as the second major funding source for mental health care (WHO, 2015), it is clear that these development funds are stretched incredibly thin. In one out of five countries around the world, households

are the main source of funding for mental health care, mainly through direct out-of-pocket expenses and private health insurance coverage. Governments in Africa and the Americas are more likely to put the financial burden for such care on households. Additionally, health insurance in many countries specifically excludes or greatly restricts reimbursements for mental health care.

Even when government, employer, or private insurance policies do fund mental health care, there may not be *parity* with physical health services—that is, only a limited number of outpatient visits or inpatient treatment days may be covered by insurance. Mental health leaders from the United Kingdom, Canada, Australia, and New Zealand have led efforts to achieve parity in mental health care around the world (Royal College of Psychiatrists, 2012, 2013). In contrast, the United States has traditionally lagged behind other high-income countries, with major disparities being noted in coverage of mental health services compared to physical health: For outpatient services, 77% to 90% of plans place limits on mental health care that are not imposed on physical health care and 66% to 74% limit inpatient MNS services (Thalmayer, Friedman, Azocar, Harwood, & Ettner, 2017). The U.S. Mental Health Parity and Addiction Equity Act of 2008 required parity in insurers' coverage of mental health and physical health. In LMICs, recent national mental health policies in South Africa, India, and Liberia exemplify initiatives to increase government engagement in and support of mental health services.

Lack of financial investment in mental health services is related to high levels of stigma and lack of mental health literacy that lead to low demand from constituents, as well as lack of technical leadership to design and implement MNS treatment programs. Strategies for health-system strengthening include efforts in the following areas:

- To enact WHO's Comprehensive Mental Health Action Plan (WHO, 2013b); to adopt a mainstream rights-based perspective
- To update health policies, plans, and laws to be consistent with international human rights and standards, such as the United Nations' Convention on the Rights of Persons with Disability (UNCPRD)
- To address stigma and enhance mental health literacy to increase demand for care
- To increase advocacy by mental health service users
- To improve MNS services financing through diversion of taxes (alcohol, tobacco, marijuana), promotion of low-cost generic drugs, and de-implementation of harmful or ineffective treatments (e.g., benzodiazepines and vitamins in primary care)
- To include MNS disorders in health management information systems as national indicators

There have been a number of recent initiatives in implementation science to address both the mental health treatment gap and the efficacy–effectiveness gap. The Program for Improving Mental Health Care (PRIME) is integrating mental health services into primary and community care, based on WHO's mhGAP program, in South Africa, Uganda, Ethiopia, India, and Nepal. PRIME's objectives include developing packages of care for integration of mental health services into primary care, based on mhGAP; training primary care workers to deliver mental services; and advancing policy to create sustainable mental health services that can be scaled up from proof-of-concept districts to country-wide services (Lund et al., 2012). Emerging Mental Health Systems in Low- and Middle-Income Settings (EMERALD) is a six-country program (PRIME countries plus Nigeria) that addresses the gap in health systems' ability to scale up packages because of inadequate policy, human resources, funding, and infrastructure. Building on the work of PRIME, EMERALD's objectives include evaluating health-system inputs (e.g., resourcing with WHO's OneHealth tool, fair and sustainable financing), evaluating health-system processes (e.g., policy, legislation, governance, consumer participation), and evaluating health-system outputs (e.g., development, implementation, and monitoring of mental health indicators and performance) (Semrau et al., 2015). Another resource to support best practices in global mental health and advance from research to implementation is the Mental Health Innovation Network (MHIN; www.mhinnovation.net). These initiatives hold promise for addressing the needs of women, men, and children with mental disorders around the world. **EXHIBIT 10-5** outlines examples of national scaling-up in three countries across the spectrum of economic development.

Involving a range of sectors is a key aspect of responding to this call to action in all settings, and arguably even more so in LMICs, where formal mental healthcare systems are typically inadequately developed. Intersectoral, community-based action has been used to prevent alcohol and drug abuse and for rehabilitation models for schizophrenia. Another sector that has made important contributions to mental health care and reforms in high-income countries

EXHIBIT 10-5 Scaling Up Mental Health Initiatives

The "686 Project": China (Ma, 2012)

The "Central Government Support for the Local Management and Treatment of Severe Mental Disorders Project" was initiated in China in 2004 with a first financial allocation of 6.86 million renminbi ($829,000 in 2004 dollars). The program was subsequently referred to as the "686 Project." Modeled on WHO's recommended method for integrating hospital-based and community-based mental health services, this program provides care for a range of severe mental disorders through the delivery of a community-based packages by multidisciplinary teams. The interventions are functionally oriented, and are provided as free outpatient treatment through insurance coverage (New Rural Cooperative Medical Care system) and as subsidized inpatient treatment for poor patients. The program covered 30% of China's population by the end of 2011.

Program evaluation showed improved outcomes for the more than 280,000 registered patients. The proportion of patients with severe mental disorders who did not suffer a relapse for five years or longer increased from a baseline of 67% to 90%, and there were large reductions in the rates of "creating disturbances" and "causing serious accidents." The program investment by the government amounted to 280 million renminbi in 2011, and its key innovations were the increased availability of human resources, including both the involvement of non-mental health professionals and intensive capacity building; the latter has added one-third of all psychiatrists now working in China.

The National Depression Detection and Treatment Program: Chile (Alvarado & Rojas, 2011)

Programa Nacional de Diagnóstico y Tratamiento de la Depresión (The National Depression Detection and Treatment Program) is Chile's national mental health program that integrates detection and treatment of depression in primary care. The program is based on the scaling-up of an evidence-based collaborative stepped care intervention in which most patients diagnosed with depression are provided with medications and psychotherapy at primary care clinics, while only severe cases are referred to specialists. Launched in 2001, the program operates through a network of 500 primary care centers, and presently covers 50% of Chile's population. The program has added a large number of psychologists in the primary care system, with a 344% increase in the number of these providers occurring between 2003 and 2008. Enrollment of the patients in the program is growing steadily, with approximately 100,000 to 125,000 patients starting treatment each year from 2004 to 2006 and close to 170,000 patients starting treatment in 2007. Universal implementation of the program has led to a greater utilization by women and less-educated individuals, contributing to reduced health inequalities. The program's success can be attributed to the use of an evidence-based design that was made available to policy makers, teamwork, and proactive leadership, strategic alliances across sectors, sustained investment and ring-fencing of new and essential financial resources, program institutionalization, and sustained development of human resources that can implement the program.

Building Back Better: Burundi (WHO, 2013a)

Civil war in the last decade of the 20th century and the first decade of the 21st century resulted in widespread massacres and forceful migrations and internal displacement of approximately 1 million individuals in Burundi. To address this humanitarian crisis, Healthnet TPO (Transcultural Psychosocial Organization) started providing mental health services in Burundi during 2000, when the then Ministry of Public Health had no mental health policy, plan, or mental health unit, and when virtually all the psychiatric services in Burundi were provided by one psychiatric hospital. Healthnet TPO conducted a needs assessment first and then built a network of psychosocial and mental health services in communities in the national capital, Bujumbura, and in 7 of the country's 17 provinces. A new health worker cadre, consisting of psychosocial workers, played a pivotal role in delivery of these services.

Considerable progress has been made in the last decade, with the government now supplying essential psychiatric medications through its national drug distribution center, and outpatient mental health clinics being established in several provincial hospitals. From 2000 to 2008, more than 27,000 people were helped by the newly established mental health and psychosocial services. In the three years from 2006 to 2008, the mental health clinics in the provincial hospitals registered almost 10,000 people, who received more than 60,000 consultations. The majority (65%) were people with epilepsy.

In 2011, funding from the Dutch government enabled HealthNet TPO and the Burundian government to initiate a five-year project aimed at strengthening the country's health systems. One of the project's components is the integration of mental health care into primary care using WHO's mhGAP guidelines. The government has now established a National Commission for Mental Health, and appropriate steps are being taken to support provision of mental health care in general hospitals and follow-up within the community.

and has only recently achieved recognition in LMICs are consumer- and family-led movements. The World Fellowship for Schizophrenia and Allied Disorders and Alzheimer's Disease International are examples of NGOs that have their origins in high-income countries, where strong consumer movements led by families of persons with schizophrenia and Alzheimer's disease led to their establishment. In the past decade, both NGOs have established a growing presence in LMICs. Similarly, Befriender International, a voluntary group that provides support to persons who are suicidal, has spread to a number of LMICs. Local NGOs led by families of persons affected by mental disorders are also multiplying rapidly in LMICs. There are fewer examples of community movements that are led by persons who are themselves suffering from mental disorders. Perhaps the best example is Alcoholics Anonymous, which is widely represented internationally, and which is one of the most well-described examples of an effective community-based intervention for a mental disorder.

Advocacy to policy makers, the media, and other sectors in the health system is a core activity of these civil society organizations. Prominent examples of the success of these advocacy efforts include the inclusion of mental disabilities in the disability legislation passed by some countries. Many groups also provide services, usually in the form of support groups or networking for affected families, but the larger groups also support research activities and medical care. The Movement for Global Mental Health (mentioned earlier), which was launched in October 2008, took its inspiration from the global HIV/AIDS movements that have transformed HIV/AIDS care through a massive scaling-up of resources and services to provide a comprehensive continuum of care for people living with HIV (PLHIV) across the globe; the Movement is perhaps the largest global coalition of such civil society groups centered on mental health issues in existence.

One of the challenges going forward as part of scale-up of mental health services is empowering front-line health practitioners, along with considering how managers and administrators in governmental and nongovernmental health systems can make the leap into being active players in addressing gaps in mental health services. Clinical guidance, ranging from *Where There Is No Psychiatrist* (Patel & Hanlon, 2018) to the mhGAP second edition (WHO, 2016), seeks to empower health workers at any level of expertise to engage in mental health services provision. However, approaches are needed to synthesize lessons learned at the health organization and administration level. The DCP-3 focuses on MNS disorders and can help health system administrators determine the type and content of interventions across levels of care. For example, DCP-3 can guide administrators in determining which MNS conditions should be screened and at which level, as well as which types of pharmacologic and psychological interventions should be available at different health systems levels. The QualityRights Toolkit developed by WHO (2012) is another essential tool that can be used to assess health facilities and other social services institutions to assure human rights are protected and promoted in the delivery of mental health care. Case studies have been successfully used to identify common features for success and common challenges in implementing community mental health services in low-resource settings (Cohen et al., 2011).

Quality improvement tools that assess the fidelity of replicated interventions, competency of health workers, and outcomes and satisfaction among patients can also be used by health system administrators to guide implementation of mental health care services (Glisson & Williams, 2015). In Ethiopia, the Mental Health Services Satisfaction Scale (MHSSS) was developed as a self-report instrument for services users to evaluate interpersonal factors such as interactions with health workers, efficacy of treatment, communication within the health system, technical competency of providers, and adequacy of facilities (Mayston et al., 2017). This tool can be combined with community forums, which are government-established meetings for community members to provide feedback to local health facility workers. In Nepal, the Enhancing Assessment of Common Therapeutic Factors (ENACT) tool was developed as a way to rate nonspecialist health workers on basic mental health skills (Kohrt, Jordans, et al., 2015); it can be used by health administrators to determine when health workers have achieved sufficient competency to provide care and to guide supervision geared toward ongoing quality improvement. In Liberia, a combination of qualitative interviews and health facility infrastructure surveys have been used to determine health system preparedness for integration of mental health services into primary care (Gwaikolo, Kohrt, & Cooper, 2017). Based on PRIME's reception in sub-Saharan Africa and South Asia, a set of eight principles (**EXHIBIT 10-6**) have been identified for successful implementation of mental health services in community and primary-care settings (Davies & Lund, 2017).

EXHIBIT 10-6 Lessons for Integrating Mental Health into Primary Care in Low-Resource Settings

1. *Engage actively and collaboratively with local stakeholders*. Participatory methods involving health workers, health system administrators, ministry officials, community representatives, and mental health service users and family members are crucial to identify facilitators and barriers to successful implementation. Theory of Change (ToC) workshops are a methodology that have been developed and successfully implemented in global mental health to determine assumptions, interventions, and indicators for programs (Breuer et al., 2014).
2. *Use primary care systems to access vulnerable populations.* Health programs that have been successful in engaging vulnerable populations, such as pregnant women, orphan children, and persons with HIV, malaria, or tuberculosis, can be ideal platforms for the introduction of mental health services. Given the syndemic nature of comorbid physical and mental health problems and high-risk social environments, primary care be the entry point for comprehensive care models (Mendenhall, Kohrt, Norris, Ndetei, & Prabhakaran, 2017).
3. *Use cultural concepts of distress and narrative-based vignettes to identify persons with potential mental health problems*. Because of both the stigma and the lack of familiarity associated with biomedical psychiatric terminology, availability of treatment may not translate into engagement with treatment. The framing of psychoeducation and psychological and pharmacologic treatments around culturally salient ways of describing mental health problems can overcome the barriers associated with psychiatric terminology. An even more effective way to facilitate treatment engagement may be the use of culturally salient vignettes describing individuals with mental health problems. In Nepal, the Community Informant Detection Tool (CIDT) was developed to facilitate referrals by community stakeholders. Studies showed that more than two-thirds of individuals referred using the CIDT sought treatment, and the accuracy of the CIDT was better than screening tools such as the PHQ-9 (Jordans, Kohrt, Luitel, Komproe, & Lund, 2015; Jordans, Kohrt, Luitel, Lund, & Komproe, 2017).
4. *Use manual-based approaches to deliver care through nonspecialist health workers.* Extensive work in the field of global mental health has focused on adapting psychological and psychiatric treatment manuals for nonspecialist, cross-cultural audiences (Balaji et al., 2012). Some manuals even cater to providers with only basic literacy (Verdeli et al., 2003). Thoroughly adapted and piloted manuals can be used to optimize fidelity to evidence-based treatments. Increasingly, e-versions of manuals and intervention materials are being produced to facilitate delivery by nonspecialists (Zafar et al., 2016).
5. *Set up systems of ongoing supervision and support*. Training is inadequate in the absence of ongoing supervision when initiating mental health services in a new context. Supervision can be provided in person, via phone, or online by specialists and peers. Competency assessment tools and fidelity checklists can be used to identify key areas for remediation in supervision (Kohrt et al., 2015).
6. *Adequately compensate nonspecialist workers for their services.* For sustainability of mental health services, compensation of providers needs to be addressed. The PRIME program has evaluated the cost of scaling up services (Chisholm et al., 2016). When creating projections of costs, it is important to consider whether governments will fund providers rather than relying upon volunteer mental health workers.
7. *Respond to crises by "building back better."* Crises ranging from Ebola outbreaks in West Africa to earthquakes in Nepal have drawn attention to the inadequacy of LMICs' existing health systems to meet their populations' mental health needs. When international attention is drawn to the humanitarian emergencies, it can be an opportunity to make sustainable changes. For example, the earthquake in Nepal contributed to a reexamination of that government's essential drugs list, which was still relying on half-century-old classes of psychiatry medications with high side-effect burdens. Through a combination of international NGO funding, local NGO advocacy, and expertise from local psychiatrists, the government revised the psychiatric medications list.
8. *Make use of policy windows*. In South Africa, pilot implementation of mental health services as part of primary care was conducted in a district that was also a national pilot site for the planned national health insurance reforms. In another district in South Africa, the department of health was launching an initiative titled the "First 1000 Days" to promote maternal and child health and education. Mental health researchers then selected this district to promote and initiate maternal mental health interventions in routine maternal health services.

Global Mental Health: Looking Ahead

Ten years on from the first *The Lancet* series that propelled mental health into the global health spotlight, it is time to consider where the field should head in the next decade. It is evident that, while the existing agenda to improve access to care is still very far from being attained (e.g., treatment gaps remain very large in all countries), this alone is unlikely to lead to a measurable impact not only in reducing the treatment gap but ultimately in reducing the global burden of mental disorders. In this section, we outline research priorities for global mental health to tackle these needs, and then we conclude with an agenda to address key challenges in the field.

Research Priorities in Global Mental Health

Research priorities in global mental health are continuously evolving and reflect national and global policies, funders and their priorities, public attention to health issues, advocacy from human rights and service users' groups, and other trends in national and global health. There have been recent inflection points in the development of global mental health research priorities. Notably, the group of scholars who produced the 2007 *The Lancet* Global Mental Health series conducted a priority-setting exercise to identify the top 10 mental health research questions (Tomlinson et al., 2009). The resulting priority questions were related to health policy and systems research, where and how to deliver existing cost-effective interventions in a low-resource context, and epidemiologic research on the broad categories of child and adolescent mental disorders or those pertaining to alcohol and drug abuse.

A priority-setting activity for the Global Forum identified priorities among researchers and stakeholders in LMICs (Sharan et al., 2009). Priorities included determining the burden of MNS disorders, identification of risk factors, and studying health systems. Prioritized disorders were depression and anxiety, substance use disorders, and psychoses. Prioritized populations were children and adolescents, women, and persons exposed to violence and trauma. Social sciences methods have also been recommended to complement epidemiologic and intervention studies (Kohrt, Mendenhall, & Brown, 2016).

As mentioned at the beginning of the chapter, the Grand Challenges in Global Mental Health (Collins et al., 2011) include a range of research priorities, with an emphasis on implementation science (**TABLE 10-8**). A priority-setting activity was conducted for mental health and psychosocial support research in humanitarian settings (Tol et al., 2011). This exercise yielded key questions to be addressed in global mental health, including identifying stressors faced by populations in humanitarian settings, determining methods to assess mental health in humanitarian settings, documenting how affected populations describe mental health, selecting indicators for monitoring and evaluation, adapting interventions to different sociocultural settings, and determining the effectiveness of family- and school-based preventive interventions.

Emerging research priorities in global mental health include enhancing our understanding of mental health problems through global representation of populations in basic science and neuroscience research (Stein et al., 2015). Because neuroscience models of mental health are dominated by research in WEIRD populations (Henrich, Heine, & Norenzayan, 2010a, 2010b), generalizability of these models to LMIC populations is limited and the progress in understanding the nature of mental health problems has been slow. This is especially problematic when these neuroscience mechanisms are selected as the prioritized targets for intervention before confirmation of similar processes in populations with different child developmental histories, different socioeconomic conditions, and different genetic admixtures (Kirmayer & Gold, 2012a). Nevertheless, potential synergies exist between global mental health and clinical neuroscience research priorities, such as development of reliable criteria for diagnosis of schizophrenia across populations and contexts, understanding responses to trauma and adversity including early-life adversity, understanding resilience across contexts, and development of interventions for nonspecialist providers and preventive measures for resilience promotion (Stein et al., 2015).

As in other areas of global health, there is increasing interest in the application of digital technology and mHealth to increase the delivery, accessibility, and effectiveness of mental health services. In global mental health, digital technologies have been predominantly used in the domains of supporting clinical care and educating health workers, facilitating diagnosis and detection of mental disorders, promoting treatment adherence, and supporting recovery, online self-help, and programs for substance misuse prevention and treatment (Naslund et al., 2017). To date, however, there has been limited research into the effectiveness of these approaches, and data are lacking for both clinical outcomes and cost–benefit analyses of digital technologies compared to traditional approaches. The

TABLE 10-8 Grand Challenges for MNS Disorders

	Top 25 Challenges	Illustrative Research Questions
Goal A: Identify root causes, risk, and protective factors	■ Identify modifiable social and biological risk factors across the life course ■ Understand the impact of poverty, violence, war, migration, and disaster ■ Identify biomarkers	■ What is the relationship between early fetal and child development and the onset of MNS disorders? ■ What are the phenotypes and endophenotypes of MNS disorders across cultural settings? ■ Which gene environment interactions are associated with increased risk for mental disorders? ■ Which factors promote resilience and prevent mental disorders in persons at extreme social disadvantage? ■ What role does social context play in the persistence of MNS disorders throughout life?
Goal B: Advance prevention and implementation of early interventions	■ Support community environments that promote physical and mental well-being throughout life ■ Reduce the duration of untreated illness by developing culturally sensitive early interventions across settings ■ Develop interventions to reduce the long-term negative impact of low childhood socioeconomic status on cognitive ability and mental health ■ Develop an evidence-based set of primary prevention interventions for a range of MNS disorders ■ Develop locally appropriate strategies to eliminate childhood abuse and enhance child protection	■ Which behavioral skills can enhance executive function, resilience, and cognitive flexibility throughout life? ■ Which neuroprotective agents and/or cognitive retraining paradigms can be used during the period of rapid brain development to reduce vulnerability to disorders in adolescence? ■ How effective are home- and school-based interventions for child abuse and neglect?
Goal C: Improve treatments and expand access to care	■ **Integrate screening and core packages of services into routine primary health care** ■ **Reduce the cost and improve the supply of effective medications** ■ Develop effective treatments for use by nonspecialists, including lay health workers with minimal training ■ Incorporate functional impairment and disability into assessment ■ **Provide effective and affordable community-based care and rehabilitation** ■ **Improve children's access to evidence-based care by trained health providers in LMICs** ■ Develop mobile and information technologies (such as telemedicine) to increase access to evidence-based care	■ How effective are brief screening tools for the detection of MNS disorders in routine care settings? ■ How effective are interventions for serious mental disorders delivered by lay health workers? ■ How will increased understanding of neural circuits lead to alternatives to current pharmacologic interventions? ■ How can mobile-phone technology be used to monitor seizure frequency? ■ How can video games and other electronic media be used for cognitive remediation across cultural settings? ■ Which psychosocial interventions produce the best outcomes for community-based care for MNS disorders across cultural settings?

Goal D: Raise awareness of the global burden of mental health disorders	■ Develop culturally informed methods to eliminate the stigma, discrimination, and social exclusion of patients and families across cultural settings ■ Establish cross-national evidence on the cultural, socioeconomic, and services factors underlying disparities in incidence, diagnosis, treatment, and outcomes ■ Develop valid and reliable definitions, models, and measurement tools for quantitative assessment at the individual and population levels for use across cultures and settings ■ Establish shared, standardized global data systems for collecting surveillance data on the prevalence, treatment patterns, and availability of human resources and services		■ What are the components of effective interventions to reduce stigma associated with MNS disorders? ■ Which interventions to reduce stigma and discrimination can be targeted to and implemented in health and social services settings in different health-system environments? ■ What is the impact of macroeconomic factors (such as unemployment rates, international trade, national income) on the prevalence of MNS disorders over time? ■ What is the impact of policy initiatives on the coverage of treatment for MNS disorders? ■ Which measurement factors contribute to differences in the prevalence of mental disorders across ethnic groups within and between countries?	
Goal E: Build human resources capacity	■ Increase capacity in LMICs by creating regional centers for mental health research, education, training, and practice that incorporate the views and needs of local people ■ Develop sustainable models to train and increase the number of culturally and ethnically diverse lay and specialist providers to deliver evidence-based services ■ **Strengthen the mental health component in the training of all healthcare personnel**		■ What is the most effective way to train primary healthcare workers to deliver evidence-based care with adequate fidelity to guidelines? ■ What is the comparative effectiveness of care for MNS disorders by different cadres of healthcare providers? ■ What are the views of low-income communities in high- and low-income countries on the priority research questions for MNS disorders?	
Goal F: Transform health-system and policy responses	■ Establish and implement minimum healthcare standards for MNS disorders around the world ■ Redesign health systems to integrate MNS disorders with other chronic-disease care, and create parity between mental and physical illnesses in regard to investments into research, training, treatment, and prevention ■ Incorporate a mental health component into international aid and development programs		■ What can we learn from different approaches (and associated costs) to integrated delivery of care across health systems? ■ What are the most effective health-system-wide strategies to reduce consumption of alcohol and illicit drugs? ■ What is the impact of legislation that ensures parity between mental and other illnesses on access to mental health services?	
Summary principles	■ Use a life-course approach to study	■ Use system-wide approaches to address suffering	■ Use evidence-based interventions	■ Understand environmental influences

Note: **Bold type** denotes the top five challenges ranked by disease-burden reduction, impact on equity, immediacy of impact, and feasibility.

abundance of studies focusing on digital technology that are currently in the research pipeline will likely transform the landscape of how mental health is studied, prevented, and treated in the coming decade.

With a focus on technological advances in methods and interventions through neuroscience and mobile innovations, it is important not to overlook important research priorities that have a major impact on the human rights and quality of life of persons with mental illness. Though the drive toward community mental health is certainly appropriate, there is a risk that the role and quality of inpatient and residential facilities might be overlooked in the haste to move services into outpatient settings. The focus on community services may falsely imply that such services can handle all possible cases and institutional services are not needed, or that there are appropriate facilities to which emergencies can be referred. Unfortunately, neither presumption is true. Physical restraint, such as chaining people in homes or to trees, is all too often the only option left to families and religious leaders when higher-level care services are not available in LMICs (Asher et al., 2017; Minas & Diatri, 2008). Research on the appropriate role of institutions in the protection and care of persons with mental illness is a major gap in global mental health initiatives.

Finally, a re-envisioning of mental health and economic development research priorities is needed. If we are to align global mental health with current international sustainable development policy (as formulated in the SDGs), then we need to demonstrate not only that providing mental health interventions (SDG3) can reduce the global burden of disease, but also that the SDGs have the potential to improve population mental health by addressing the social and economic determinants of mental health. Achieving this outcome requires a research agenda focused on the social determinants of mental health, such as elucidating the mechanisms by which social and economic conditions determine mental health across the life course, and generating evidence of interventions that might address the upstream risk factors for mental illness. This means linking mental health interventions to broader development agendas, particularly those focusing on poverty, violence, migration, and gender. In this context, mental health studies would need to demonstrate outcomes that go beyond mental health, such as reductions in violence and improvements in economic circumstances. Linking mental health care with other development interventions to demonstrate interaction effects could be very beneficial for showing the added value of including mental health services in broader development initiatives. This requires a focus on certain developmental phases, such as early childhood development and adolescence, that are critical periods for neurological development and neuroplasticity. Given the plasticity and associated vulnerability of these periods, interventions need to be tailored to adolescents according to their level of deprivation or trauma exposure. Studies that demonstrate awareness of this factor—for example, through flexible, tailored, multicomponent interventions—could capitalize on this developmental stage to optimize those interventions' clinical benefits and cost-effectiveness and to extend the longevity of positive benefits.

A Global Mental Health Agenda for the Next Decade

A number of barriers have prevented the transformation of the large body of science into actions, both at the global and local levels, and particularly in LMICs (Saraceno et al., 2007); these pose systemic and systematic threats that need to be acknowledged and addressed explicitly if we are to see radical change in the future.

First, compared to the experiences of other global health movements (e.g., HIV/AIDS and maternal and child health), advocacy for mental health has been hampered by the reliance on process indicators (e.g., increasing coverage of services) rather than outcome indicators (e.g., improved mental health). This orientation may cause reluctance among health authorities to support and prioritize mental health (WHO, 2003a; Howes, 2005).

Second, fragmentation of the advocacy by diverse constituencies and science from diverse disciplinary traditions poses a challenge. For example, approaches to mental health issues range from the happiness agenda promoted by economists, to the specialist care for mental disorders promoted by clinical professionals, to the quest to fight discrimination promoted by civil society activists, to the ventures related to mapping the human brain promoted by neuroscientists. This leads to contradictory messages being sent to governments by the diverse stakeholders concerned with mental health and may leave critical questions unanswered. For example, should we focus more on addressing social determinants or biomedical treatment? Do we need (and want) more or less hospital beds? Should we promote new-generation, more expensive drugs, or cheaper, older-generation agents?

Third, there has been an alienation of the mental health professional communities from the vision of global mental health. While reforms of mental health services from institutions led by psychiatrists and team-based approaches oriented to primary and community

care have been unanimously supported by many constituencies, they have been opposed, at times, by powerful national groups of psychiatrists and other mental health professionals. This opposition also risks derailing the process of reforming psychiatric institutions and, consequently, may prevent improvements in quality of care and greater respect for and enhancement of the human rights of people with mental disability. This resistance is problematic, because innovations in care delivery at all levels of the health system cannot happen without the full participation and support of psychiatrists and nurses (Berlin, 1969; Fisch, 1965; Johansson, Astrom, Kauffeldt, Helldin, & Carlstrom, 2014).

Fourth, there is the risk of global mental health becoming yet another silo, unlinked to other momentous initiatives in global health, such as Every Woman Every Child or Universal Health Care. This risk is exemplified by the lack of adequate engagement with mental health in the curricula of general health professionals and the continuing emphasis in psychiatric training on biomedical aspects of mental health, while often ignoring the important contributions coming from the social sciences and global health (Hilty et al., 2006; Lobo, de-la-Camara, Campos, & Saz, 2015; Wynaden, Orb, McGowan, & Downie, 2000).

The future requires a reimagining of the existing agenda of global mental health in a number of significant ways. First, the scope should be global, addressing concerns that are relevant in all countries. Indeed, as far as mental health is concerned, it would be fair to say that all countries are "developing" to one degree or another. Second, we must acknowledge that the biomedical approach to binary categories of diagnoses of mental disorders, while of utility to health workers, does not accurately reflect the multidimensional nature of mental health, and recommend a staged model in its stead (Patel, 2017). The theoretical framework underpinning this vision is that of the continuum of mental health spans from well-being to disability and health to ill health. Third, to emphasize a convergent model of mental health, we must recognize the complex interplay of environmental, biological, and developmental factors across the life course, from conception to the grave, across generations and genders. Finally, the global community must recognize mental health as a basic human right for all peoples, albeit with a specific focus on those who face the gravest danger of their rights being denied, such as populations living in institutions or facing severe social adversity.

Today, we have a historic opportunity to reimagine the global mental health agenda in light of the broader perception of mental health as an integral part of the SDGs, as envisioned in WHO's Comprehensive Mental Health Action Plan. There was a call for greater investment in mental health in the landmark summit hosted jointly by the World Bank and WHO in Washington, D.C., in April 2016. This call has been accompanied by explicit acknowledgment of mental health as a global development issue, the potential for a grand convergence of science across disciplines, and growing consensus between stakeholders. Improvements in mental health hold the potential to contribute to enhanced sustainable development and the improvement of people's lives. Indeed, the aging of populations across the world, and trauma and displacement consequent to conflict and climate change, are among the great social challenges of our time, and these translate into greater demand in society for higher-quality services as well as for greater social support for disability and elder care—areas where mental health care looms large. Over and above these concerns, the clearly evident effects of climate change, poverty, and inequality on mental health add urgency to the calls for broader social and economic transformation, and for a more equitable and sustainable world order.

In summary, there is an urgent need for a significant expansion of the agenda of global mental health, building on its achievements while also recognizing the limitations of its extant principles and strategies, by seeking to incorporate novel understandings of mental health and the alignment of mental health with the SDGs. At the heart of this reimagining of global mental health is a reframing of the goals of global mental health, from reducing the treatment gap for people affected by mental disorders to the more ambitious aim of enhancing the mental health of populations and reducing the actual global burden of mental disorders. Realizing this vision will require combined actions of promotion of population mental health, prevention of mental disorders, and effective medical and social care for people with mental disorders.

Discussion Questions

1. It is difficult to place mental health high on the public health agendas of LMICs that face an enormous burden from communicable diseases. Which evidence-based arguments might you make to challenge the notion that mental health is a luxury item on the health agendas of such countries?
2. The classification of mental disorders is mainly derived from the description of these disorders in high-income countries. Some argue that this fact limits the application of psychiatric knowledge and evidence to non-Western cultures.

How valid are these concerns? In which ways has the "Western" bias been addressed in classification of mental disorders in international public health?

3. Diseases that disproportionately affect the poor are typically prioritized by governments and donors. Some people believe that disorders such as depression are problems of the middle class and the affluent, or represent a "medicalization of misery," and, therefore, do not deserve a share of scarce resources. What is the evidence linking poverty with mental disorders? How might poverty interact with mental health?
4. While there is now a growing evidence base on effective treatments for most mental disorders, large treatment gaps can be found in all countries, especially in LMICs. What are the reasons for this treatment gap? How can they be addressed at the level of health policy and health service development?
5. Human rights are a major driver in global health. Even though people affected by mental disorders represent one of the most marginalized and discriminated groups in any context, their human rights are often ignored. Why is this the case, and what can be done to address this issue?

CHAPTER 11

Environmental and Occupational Health

Alex Macmillan, Tord Kjellstrom, Kirk R. Smith, Ajay Pillarisetti, and Alistair Woodward

Introduction

This chapter describes the important current issues in environmental and occupational health, including the scope of those issues and the methods used to assess them. It first explores the definition of "environment" and its ways of affecting human health. In doing so, it takes note of (1) several key disciplinary perspectives, (2) the international spectrum and burden of environmental health issues, and (3) the ongoing emergence of larger-scale environmental problems. The significant conceptual development in approaches to environmental health is made apparent—namely, the shift from considering the environment as a source of hazard to considering the Earth as habitat, a perspective that requires more integrative approaches to ecological sustainability and health. The main conceptual and methodological issues that relate to environmental health research and public health action are described. Five of the most pressing current issues linking environment and health are examined in illustrative case studies. We finish by considering future prospects, issues, and priorities for environmental health research and practice.

The word "environment" is broad and elastic in scope. In this chapter, "environment" refers to those external physical, chemical, and biological exposures and processes that shape the health and well-being of both individuals and populations. Environmental health research and practice have evolved significantly over the past three decades, from a primary focus on viewing the environment as a unidirectional source of risk or hazard, to a greater reconnection with understanding humans as part of natural ecological systems that support human health, and with which we have bidirectional relationships. Such systems include hydrological, atmospheric, climate, and biological systems. Human-created built environment systems can also support flourishing, yet be a source of hazards for health.

These definitions of "environmental health" exclude social, cultural, and economic environments that are also important for health, and which are dealt with elsewhere in this text (see the *Culture, Behavior, and Health*; *Understanding and Acting on Social Determinants of Health and Health Equity*; and *Health and 'The Economy'* chapters). However, these different environments are closely intertwined, and they often mediate relationships between physical, microbiological, and chemical exposures and health. Although injury (e.g., road traffic injury, workplace injury, and injury in the home) is a significant outcome of human interactions with the physical environment, it has developed its own public health specialization and is addressed separately in this text (see the *Unintentional Injuries and Violence* chapter). Occupational health, which is most often focused on environmental health

in the workplace setting, remains closely linked with environmental health and is considered together with environmental health in this chapter.

Because of their philosophical, geographic, and topical breadth, environmental health research and practice are undertaken by a wide range of professional experts. These range from epidemiologists to qualitative researchers, from biochemists to ecologists, and from water quality officers to urban planners.

Environmental Hazards, Exposures, and Risks

When considering environmental hazards, the environment can be categorized in several ways for easier consideration, including in relation to environmental media (air, water, soil, and food), the economic sector (transport, land use, and energy generation), physical scale (local, regional, and global), setting (household, workplace, and urban environment), and disease outcomes (cancers, congenital anomalies, and others). A useful classification that comprises five categories is used here, defined jointly by physical scale and by setting:

1. Household
2. Workplace
3. Community
4. Regional
5. Global

This categorization is not strictly bounded; many relationships between environment and health occur across these scales, so an additional "cross-scale" category should be kept in mind. This final category recognizes that the scale at which an environmental health impact eventually occurs may not be the scale at which the hazard was initiated.

To demonstrate this categorization, consider the hierarchy of environmental health consequences of energy use. The impacts of energy production and use contribute significantly to the total human impact on the environment at each of the six previously mentioned levels. That is, the extraction, harvesting, processing, distribution, and use of fuels and other energy sources have major environmental impacts at all scales, from individual households to the globe itself. Combustion occurs locally, causing local air pollution, both indoors and outdoors, but it also contributes to regional acid rain and, on a global scale, to the accumulation of carbon dioxide as a heat-trapping greenhouse gas in the lower atmosphere.

Of note, the workplace has some characteristics that make it a special setting for environmental exposure (the combination of hazard and people being present), which has led to occupational health and safety developing as its own specialization. These characteristics include higher than ambient levels of chemical and mechanical hazards in confined environments; exposure to hazards that are not present outside the workplace (such as chemicals that are used only in manufacturing); and workers who are overall healthier and arguably less vulnerable to negative impacts of exposures than other sectors of the population (such as older adults and young children). Nevertheless, the links between occupational health and environmental health remain vital: Occupational studies have commonly led to a greater understanding of the health impacts of non-workplace environmental exposures, while the impacts of workplace environmental hazards almost universally have repercussions at the community level (either via hazardous wastes or through the wider impacts of workplace injury and death). We therefore consider occupational and environmental health and hazards together in this chapter.

In defining these hazards, it is worth noting that exposures to some hazards arise because of natural conditions, whereas others are due to human interventions. Natural exposures arise from seasonal, latitudinal, or altitudinal gradients in solar irradiation, extremes of hot and cold weather, the occurrence of physical disasters, and local micronutrient deficiencies in soil. While many of these natural hazards can be mitigated by specific intervention and design, some—such as the 2011 earthquakes in New Zealand and Japan, and the devastating tsunami in Japan—cannot be "kept under control" even in the highest-income countries.

TABLE 11-1 provides examples of the types of environmental health hazard exposures that can occur at the different scales discussed in this chapter. Note that exposures may come via air, water, food, or other media, depending on the specific situation. Studies of environmental health impacts will, therefore, require an understanding of a number of specialized scientific disciplines.

The Burden and Distribution of Disease from Environmental and Occupational Hazards

Conceptualizing the Public Health Impact of Environmental Exposures

There are many ways of attempting to capture and express the idea of public health impact. Suppose the results of a study show that the mortality rate within a

TABLE 11-1 Examples of Sources of Unhealthy Environmental Exposures

Scale	Household	Workplace	Community	Regional	Global
Types of Environmental Exposure					
Microbiological	Contaminated drinking water; poor sanitation and food safety	Spread of infectious diseases via air or needlesticks in health services	Contamination of local rivers and lakes from animal and human feces	Spread of contamination to major rivers	Large-scale spread of infectious diseases (e.g., malaria) due to climate change
Chemical	Exposure of children to lead from household paint	Solvents exposure from glues or paints in manufacturing industries	Urban air pollution from motor vehicles or industry	Confluence of urban air pollution into larger areas (e.g., Asian brown cloud)	Global spread of persistent organic pollutants; greenhouse gas emissions
Physical	Too-cold or too-hot indoor temperatures in households	Noisy machinery and processes; excessive workplace heat exposure	Traffic noise	Ionizing radiation from nuclear accidents (e.g., Chernobyl, 1986)	Increased ultraviolet (UV) radiation due to ozone layer depletion
Ergonomic	Injury risks in badly designed dwellings	Heavy lifting and injury risks caused by machinery	Traffic safety risks due to poor urban design		

community for a particular disease has increased by a factor of 1.3, with a 95% confidence interval of 1.1 to 1.6. What does this mean? If the disease in question is rare, the 1.3-fold increase may represent no more than a few extra cases per million exposed people per year. If the disease is common, however, the same relative risk carries a much greater population-level health impact. Approaches to quantify this impact include estimation of (1) the number of cases per year that are due to the exposure (also known as attributable cases), or (2) the number of cases that would be prevented if present exposures ceased, or (3) the number of cases that would occur over a longer time period (e.g., a lifetime) under different scenarios relating to population susceptibility and exposures. These types of measures are sometimes referred to as health impact estimates (Talbot et al., 2009).

In the last two decades, a considerable amount of work has been done to estimate the global and national burden of disease attributable to environmental exposures (Gakidou et al., 2017; Landrigan et al., 2017; Prüss-Üstün & Corvalán, 2006; Prüss-Üstün, Wolf, Corvalán, Bos, & Neira, 2016). Such estimates are difficult to construct, both because knowledge about disease etiology is incomplete and because of the latency between environmental exposures and chronic health outcomes. The complex relationships among environmental conditions, socioeconomic circumstances, demographic change, human movement, and health present further difficulties in estimating the environmental contribution to disease burden (Prüss-Üstün et al., 2016).

For example, the combination of population pressure and poverty among rural populations in low- and middle-income countries (LMICs) often leads to land degradation, deforestation, flooding, further impoverishment, and increased risks to health from infectious disease, food shortages, and nutritional deficiencies.

The situation of sub-Saharan Africa—with its persistent poverty, environmental stresses, and marginalization in the global economy—illustrates these complex relationships. Although significant improvements have occurred in sub-Saharan Africa's health, education, and living standards in the past quarter-century, the region remains far behind the rest of the world in advancing economic, environmental, and health goals. The final report on the United Nations' Millennium Development Goals noted that 41% of people in this region live in extreme poverty, 42% lack safe drinking water, and 69% lack proper sanitation (United Nations, 2015a). Child mortality rates in sub-Saharan African countries are more than 50% higher than those in the next highest region, and average life expectancy is about a decade less (World Health Organization [WHO], Global Health Observatory, 2016).

The Environmental Risk Transition

As discussed in the *Measures of Health and Disease in Populations* chapter, certain changes in disease patterns accompany economic development (the epidemiologic transition). In general, there is also a tendency for environmental health risks to shift during the economic development process in terms of geographical scale, types and severity of hazards, and disease outcomes. First, as described in the "environmental risk transition" (Mock et al., 2017; Smith & Ezzati, 2005), environmental hazards shift from the household to the community and then to regional and global scales. Environmental risks in low- and middle-income societies are dominated by poor food, water, and air quality at the household level from inadequate sanitation, contaminated water, and combustion of low-quality fuels (WHO, 1997). Some of the activities that help solve these problems act to transfer problems to the community level in the form of urban air pollution, hazardous waste, and chemical pollution. In high-income countries (HICs), where many community and household problems have been subjected to considerable control, problems have to some extent shifted to the global scale—for example, through greenhouse gas emissions and regional scale air pollution; at the same time, low-income communities within these countries are often still at risk from local environmental hazards (Mock et al., 2017; WHO, 2008).

A shift in disease patterns also occurs during the epidemiologic transition, from mainly infectious diseases to cancer and other non-infectious diseases. This disease shift is accompanied by a temporal shift. Many important infectious diseases—diarrhea, malaria, and measles, for example—have relatively short latency periods (hours to weeks) between exposure and development of disease. Cancer and other chronic non-infectious diseases, by comparison, often entail delays of several decades before they become manifest. Global processes such as anthropogenic climate change may involve even longer time periods. This temporal shift has important implications for research and social policy (McMichael, 2009), especially since political cycles result in short policy horizons.

Current Estimates of the Environmental Burden of Disease

Over time, estimates of the global burden of disease due to environmental factors have become more consistent, with these factors estimated to account for one-fourth to one-third of the total burden of disease in disability-adjusted life years (DALYs) (Landrigan et al., 2017; Prüss-Üstün & Corvalán, 2006; Prüss-Üstün et al., 2016; WHO, 1997). This standardized metric combines mortality and morbidity data in a manner suitable for international comparisons (see the *Measures of Health and Disease in Populations* chapter). In this section, three such estimates are discussed.

One of the most recent integrated comparative risk assessments of the global and regional burden of disease due to environmental risk factors was published by WHO in 2016 (Prüss-Üstün et al., 2016), based on data from 2012. Compared to previous estimates, the authors of this report included a broader range of environmental factors in their assessment—for instance, the built environment and climate change. They also employed a combination of methods, including comparative risk assessment where possible, limited epidemiological data, and transmission pathways. Where none of these were available, they utilized expert surveys. Their estimates of the total burden of disease attributable to environmental risk factors were consistent with the previous comprehensive assessments: 23% of deaths and 22% of DALYs. Like previous estimates, the WHO analysis almost certainly underestimates the environmental burden of disease, since only a small proportion of all risks possible are covered in the literature. For example, estimates of the health impacts of climate change have been limited in their scope thus far (WHO, 2014). **TABLE 11-2** summarizes the population-attributable fractions of disease from environmental factors from the WHO assessment, by stage of development (LMICs and HICs) and by disease group. Note the significant contribution of occupational risk factors across diseases.

In 2016, the Global Burden of Disease Risk Factor Collaborators reported their most recent analysis of the "behavioural, environmental, occupational, and metabolic" risk factors for disease—a global and national comparative risk assessment of 83 such

TABLE 11-2 Health Burden Due to Environmental Risk Factors in 2012 by Development Status (population-attributable fraction [PAF] of total disability-adjusted lost life years due to the environment, with diseases ranked by combined total global burden of disease in DALYs and environmental contribution)

Disease or Disease Cluster	PAF (%): LMICs	PAF (%): HICs	Main Environmental Risk Factors
Cardiovascular Diseases Ischemic heart disease Stroke	 39 46	 23 22	Household and ambient air pollution, secondhand tobacco smoke, chemicals, and environments encouraging physical inactivity (e.g., urban design)
Diarrheal diseases	58	13	Water, sanitation, hygiene, agricultural practices
Lower respiratory tract infections	37	1	Household and ambient air pollution, secondhand tobacco smoke
Cancers	16–48	13–21	Air pollution, chemical exposures, radiation, and occupational safety
Chronic obstructive pulmonary disease	38	12	Household air pollution, secondhand tobacco smoke, occupational safety
Road traffic injuries	42	17–42	Traffic system environments and land-use planning
Neonatal conditions	11	6	Air pollution, secondhand tobacco smoke, water and sanitation in birth settings
Malaria*	40–64	40–64	Environmental management of vector habitats, contact between humans and vector habitats
Non-Road Traffic Injuries Falls Fires, heat Drownings Other	 31 78 74 45	 26 42 54 30	Home, community, and occupational safety, climate change
Musculoskeletal disorders*	15–27	15–27	Occupational stressors and ergonomics, prolonged sitting, carrying water and solid fuels for household needs
Asthma*	44	44	Household and ambient air pollution, secondhand tobacco smoke, indoor damp and mold, occupational allergens
Depression*	12	12	Occupational stress, work–life imbalance, environmental degradation

*no comparative data available by income

Modified from Prüss-Üstün, Wolf et al. 2016. PAF Population Attributable Fraction, LMICs low-middle income countries, HICs high-income countries.

risk factors (Gakidou et al., 2017). The distinction between behavioral and environmental risk factors is a difficult one to make, especially since it is increasingly understood that individual behaviors are heavily influenced by physical environments. Within the top 30 risk factors contributing most heavily to the global burden of disease in terms of DALYs, the authors identified 9 environmental and occupational risk factors: ambient air pollution (7); household air pollution (10); unsafe water (16); unsafe sanitation (21); occupational injury (22); no access to handwashing facility (23); occupational carcinogens (24); lead exposure (28); and secondhand tobacco smoke (30). We would argue from the evidence, though, that other top risk factors also have major environmental components—for example, high body mass index (6) and low physical activity (25), which are increasingly understood as being underpinned by physical environments that build in unhealthy eating patterns and exclude activity from people's daily lives; and unsafe sex (17), an occupational risk for sex workers.

Another study conducted to estimate the size of the health problem due to environmental factors was the 2017 *The Lancet* Commission on Pollution

(**EXHIBIT 11-1**). In this case, environmental pollutants were defined as "unwanted, often dangerous, material that is introduced into the Earth's environment as the result of human activity, that threatens human health, and that harms ecosystems." Based on the work of the Global Burden of Disease project, *The Lancet* Commission estimated that approximately 9 million premature deaths per year occurred worldwide in 2015 that were attributable to pollution (Landrigan et al., 2017).

Across all recent burden of disease estimates, certain outcomes and diseases are either entirely or significantly associated with modifiable environmental conditions. Some diseases, such as those caused by intestinal nematodes (hookworm, roundworm, whipworm) and trachoma (*Chlamydia trachomatis*, the main infectious cause of blindness), are considered to be 100% attributable to modifiable environmental factors. In both of these examples, the diseases are related to sanitation, the availability of clean freshwater, hygiene, and housing conditions. Other outcomes that are significantly attributable to modifiable environmental factors include road traffic accidents, drowning, venomous animal bites, falls, and fires/heat as well as malaria, dengue, and asthma. In addition, the prognosis for nearly every disease will be better when people live in cleaner and well-organized home and community environments; thus, environmental quality is a factor to some extent in many, if not all, risk factors. Exhibit 11-1 provides information on more recent estimates of environmental factors and their contributions to the burden of disease, which includes some discussion of issues surrounding how such estimates are done.

Finally, an important caveat should be noted: The burden of disease due to factors in the environment is not directly related to statistical significance. That is, a small *p* value does not guarantee an important result (in terms of how strong the effect, or the impact on a population). Moreover, a large burden of disease does not always translate into a high priority in policy and prevention: Other relevant considerations are whether interventions are available to reduce exposures, and what the costs and concomitant benefits of putting these interventions into action would be.

EXHIBIT 11-1 *The Lancet* Commission on Pollution and Health

The Lancet Commission on Pollution and Health is one of several dozen such commissions over the past decade, though it was greeted by more media attention than were the reports of any of the previous commissions (Cohen, 2017; Nesbit, 2017; Scutti, 2017). This effort focused on the health impacts of just the most well-understood types of pollution exposures in LMICs and found that, in total, pollution exposures are responsible for a large part of the global burden of disease today, essentially similar in size to the burden associated with high blood pressure, smoking, and poor diets worldwide, for example. Its report also included a section on economics, indicating a large impact on the world's per capita income from the ill health that is created by pollution.

As indicated in the following table, *The Lancet* Commission found that close to 9 million premature deaths can be attributed to pollution exposures in recent years, nearly all in LMICs. This is approximately 17% of all annual deaths.

Estimated Global Deaths by Pollution Risk Factor and Age at Death, 2015

	GBD Study Best Estimate (95% CI)	WHO Best Estimate (95% CI)
Air (total)	6.5 (5.7–7.3)	6.5 (5.4–7.4)
Household air	2.9 (2.2–3.6)	4.3 (3.7–4.8)
Ambient particulate	4.2 (3.7–4.8)	3.0 (3.7–4.8)
Ambient ozone	0.3 (0.1–0.4)	-
Water (total)	1.8 (1.4–2.2)	0.8 (0.7–1.0)
Unsafe sanitation	0.8 (0.7–0.9)	0.3 (0.1–0.4)
Unsafe source	1.3 (1.0–1.4)	0.5 (0.2–0.7)
Occupational	0.8 (0.8–0.9)	0.4 (0.3–0.4)
Carcinogens	0.5 (0.5–0.5)	0.1 (0.1–0.1)

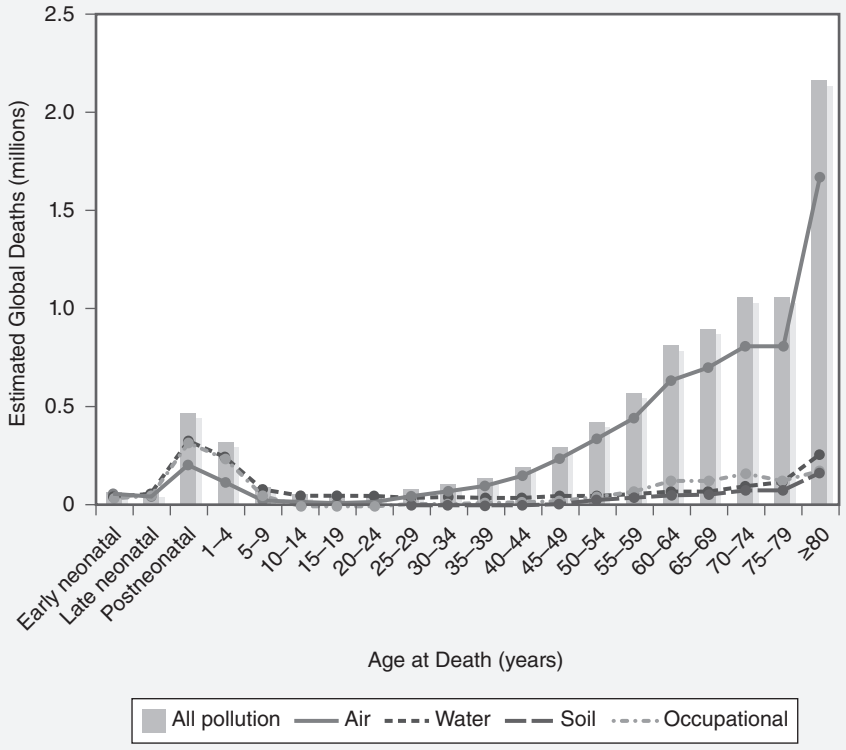
Particulates	0.4 (0.3–0.4)	0.2 (0.2–0.3)
Soil, heavy metals, and chemicals	0.5 (0.2–0.8)	0.7 (0.2–0.8)
Lead	0.5 (0.2–0.8)	0.7 (0.2–0.8)
Total	9	8.4

Note that the totals for air pollution, water pollution, and all pollution are less than the arithmetic sum of the individual risk factors within each of these categories because these have overlapping contributions—e.g., household air pollution also contributes to ambient air pollution and vice versa.

Also shown in the table, are the somewhat different estimates provided by the two main organizations doing global burden estimates, the WHO and the Institute for Health Metrics and Evaluation (IHME). The stated uncertainty bounds do not always overlap for an individual risk factor, although as it turns out the totals are similar. Of course, it is impossible to know exactly what these numbers are, so a better approach is probably to take the overall spread as the real range of estimates and not to pick precise values. The two organizations use some of the same methods and databases, but also differ in others. Thus, it woud be extremely difficult to decide which organization is more accurate for any one estimate.

Note that the totals in each major category are less than the total of the parts within that category. For example, the totals for air pollution from each organization are less than the sum of the individual components of air pollution. This difference arises because there is some overlap in estimated effects, due to both physical and epidemiologic reasons. The degree of overlap is not well known. Therefore, the totals are probably more uncertain than indicated.

Finally, although the press and the public are thought to best understand the number of deaths as an indicator of ill health, it is actually quite a poor indicator, particularly when combining effects across the age spectrum. Put simply, no child should die, but all adults must die, albeit sometimes at ages less than desirable. This is why the international health community tends to use a measure of lost time as the best indicator, which weights child deaths much more heavily. The difference can be substantial, as indicated in the accompanying figures from the report.



The distribution of lost lives from pollution exposures globally.

Data from Landrigan, P. J., Fuller, R., Acosta, N. J. R., Adeyi, O., Arnold, R., Basu, N., et al. (2017). The Lancet Commission on pollution and health. *The Lancet*.

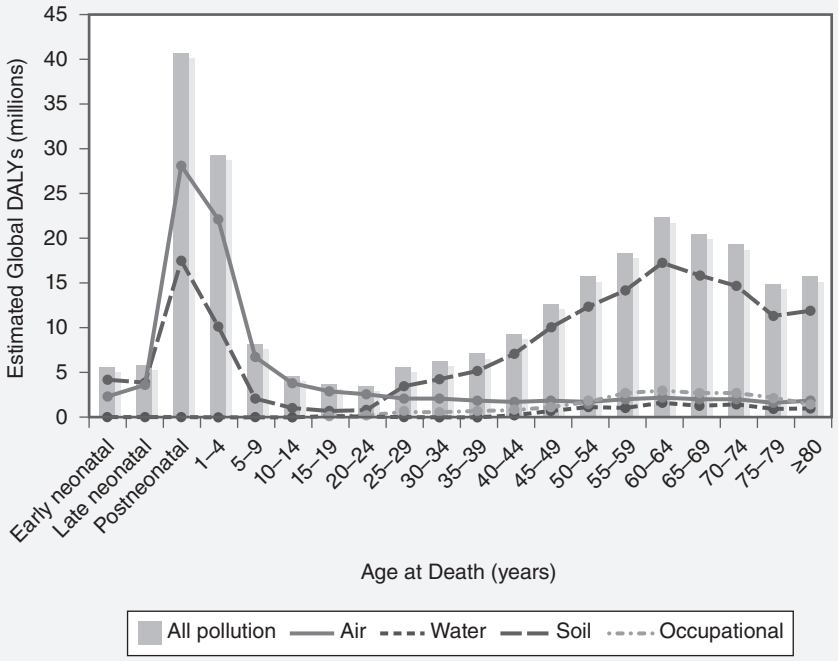
EXHIBIT 11-1 *The Lancet* Commission on Pollution and Health *(continued)*



The distribution of lost DALYS from pollution exposures globally.

Data from Landrigan, P. J., Fuller, R., Acosta, N. J. R., Adeyi, O., Arnold, R., Basu, N., et al. (2017). The Lancet Commission on pollution and health. *The Lancet*.

While the impacts look most important at older ages, when deaths alone are considered, they are distributed more widely across the age spectrum when considered as lost healthy life years (DALYs), as the impact on children dominates when this perspective is adopted. Arguably, the graph depicting the impact in this way is a better representation of the problem from a global health perspective.

Distribution of and Factors Influencing the Environmental Burden of Disease

As shown in Table 11-2, the largest environmental health burdens occur in LMICs with significant household-level risks and tend to affect young children in particular. Indeed, as a percentage of total burden as well as in absolute terms (e.g., DALYs per capita), environmental risks are most important in the poorest populations. Both the Millennium Development Goals (agreed to in 2000 by all UN member states) and now a second WHO environmental burden of disease assessment allow for longitudinal analysis of environmental hazards. These demonstrate well the environmental risk transition, with globally declining burdens of infectious, neonatal, and nutritional disease deaths attributable to environmental factors, and increasing deaths from noncommunicable diseases and injuries. In addition to between-country differences by income, low- and middle-income populations within all types of countries are the most vulnerable to the health impacts of environmental degradation and change. They are typically more exposed, in terms of residential and occupational location, and have fewer resources for taking protective or adaptive action.

Inequities between and within countries by income and ethnicity, relative to both environmental hazards that cause harm and positive aspects of environments that support good health, have led to the development of civic movements for environmental justice. What started as a 1980s civil rights movement in the (United States protesting the local-scale siting of toxic waste facilities in ethnic minority communities has since grown into global-scale research and activism. For example, notions of "climate justice" were central in the negotiations that led to the Paris Agreement on climate change (Agyeman, Schlosberg, Craven, & Matthews, 2016), and the term is recognized on the first page of that agreement (United Nations Framework Convention on Climate Change, 2015).

Changes in the age structure of populations also affect vulnerability. For instance, as average life expectancies increase, populations become more vulnerable to many environmental stressors because of the increasing proportion of elderly persons, although there is also somewhat less population vulnerability due to the

lower proportion of the very young. Many physiological and biochemical functions of the human body—such as kidney function, liver function, eyesight, and hearing—decline with age, even after early adulthood.

At an individual level, constitutional characteristics frequently influence susceptibility to environmental exposures. Readily seen examples include skin pigmentation modulating the risk of solar-induced skin cancer, and age modulating the efficiency of intestinal absorption of lead. Individual variations in metabolic phenotype, which are substantially determined by genotype, are also important. Many enzyme pathways are known to be involved in the activation or deactivation of potentially carcinogenic or other toxic chemicals, such as the various oxidizing enzymes of the mitochondrial P450 system, the acetylation pathway (which yields phenotypically "fast" and "slow" acetylators), the glutathione transferase pathway, and the alpha-1 antitrypsin pathway. A steadily accumulating body of epidemiologic evidence indicates that these polymorphisms modify the disease-inducing effects of an external environmental exposure, such that a gene–environment interaction is observable at the individual level. Discovery of such linkages opens up important opportunities for higher-resolution research. When study subjects are stratified on a metabolic polymorphic characteristic relevant to the external exposure, then the effect within the susceptible subgroup will become more evident than when the effect is diluted (averaged) across the susceptible and nonsusceptible subgroups.

Emerging Issues in Environmental Health: Moving from Hazard to Habitat

Most analyses of environmental health effects have focused on specific single, direct-acting hazards within a localized setting. As described in the introduction to this chapter, hazards can be investigated (1) based on which of these categories they fall into, (2) through their route of exposure (ingestion, inhalation, dermal), or (3) through the locations in which they occur (home, school, outdoors). Occupational or workplace hazards are often considered separately from the previously mentioned categories, partly because workplace settings are higher-risk environments, with both increased intensity and longer duration of exposure, and partly because working populations are usually different from the overall population, having fewer vulnerable groups such as the very young, old, or ill, and because they personally gain, at least conceptually, in the processes that lead to risk.[1]

As part of an environmental health assessment, exposures are assessed at either the individual level or the group level, as are health outcomes. From the resulting exposure and outcome data, exposure–response[2] relationships can be estimated, usually by fitting the data to statistical models. Where data are sparse, model fitting may be guided by theoretical considerations. Once exposure–response relationships have been satisfactorily estimated, and if the causal interpretation is convincing, the results can be used to guide environmental policy. There are some caveats, however: Exposures have often been higher in workplaces than in the ambient environment, and many of the published dose–response relationships are based on occupational epidemiologic studies. As such, they sometimes do not reflect the exposures experienced by the broader population.

During recent decades, this mode of environmental and occupational health research, which culminates in formal risk assessment (National Academy of Sciences, 2009; Samet, Schnatter, & Gibb, 1998), has prevailed in high-income countries. Using this system, ambient and workplace environmental exposure standards have been set for several hundred specific environmental exposure agents. There are currently more than 140,000 human-made chemical substances in commercial use worldwide, and 5,000 of these are in widespread use (Landrigan et al., 2017). Further, thousands of naturally occurring chemicals are in general use, including many in LMICs. Insufficient epidemiologic and toxicologic data are available to evaluate the potential health effects of most of these chemicals (Moochhala, Shahi, & Cote, 1997; National Academy of Sciences, 2009), and the risks tend to be evaluated for individual agents only, if at all. As such, the regulatory and monitoring paradigms for dealing with these chemicals may be insufficient to deal with the complex mixtures to which individuals are exposed, through multiple routes, on a regular basis (National Research Council, 2012).

Meanwhile, larger-scale environmental hazards to human health began to emerge in the final decades of the 20th century. All around the globe, a spectacular shift of human populations into the world's cities has been occurring. The urbanized proportion of the world's population has skyrocketed from approximately 5% to more than 50% in the past two centuries and is still rising (United Nations Habitat, 2016). This

[1] For instance, consider a factory worker using dangerous, job-specific machinery involving repetitive motion for many hours each day, 5 days a week for 30 or 40 years. Similarly, agricultural workers may perform repetitive tasks and be exposed to heat, lack of water, and pesticides for many hours each day for many years.

[2] These are sometimes called "dose–response" relationships, a term from toxicological studies in which a known dose of toxin is administered to animals under study. For most environmental hazards, however, exposure is the best metric that can be determined.

urban migration reflects, to varying degrees in particular geographic areas, the advent of industrialization, the contraction of rural employment, the flight from insecurity, and the search for jobs, amenities, or a stimulating environment. With such vast movement to urban areas comes new challenges, including overcrowding; exposures to both traditional and modern environmental health risks, which are amplified in urban slums; occupational and economic risks, as many jobs in cities are unregulated and sometimes exploitative; and environmental degradation, as many urban centers expand without adequate planning.

A major consequence of the increasing scale of the human enterprise is the potentially important health impact of global environmental changes. Humankind is now disrupting some of the biosphere's life-support systems—the natural processes of stabilization, production, cleansing, and recycling that our predecessors were able to take for granted in a less human-dominated world (McMichael, Woodruff, & Hales, 2006; Millennium Ecosystem Assessment, 2005). We no longer live in such a world. The scale and intensity of these human-initiated global environmental changes has led to the assertion that we are shifting out of the Holocene and now live in a new, human-dominated geological epoch, the Anthropocene (Lewis & Maslin, 2015).

In 2009, Johan Rockstrom and his colleagues introduced the concept of planetary boundaries, a framework at a global level for considering ecological levels of risk to human health, well-being, and society. They identified nine such boundaries and have been quantifying the current status of determining variables (Steffen et al., 2015), summarized in **FIGURE 11-1** and discussed in more detail in this section.

With increased emissions of greenhouse gases and various ozone-destroying gases, the basic composition of the world's lower and middle atmospheres is being altered by human actions. The world's great geochemical cycles of sulfur and nitrogen are also being significantly perturbed by human actions. Human-induced environmental changes are causing worldwide depletion of soil fertility, aquifers, ocean fisheries, and biologic diversity. The ongoing mass extinction might cause approximately one-third of all species alive in the 1800s to disappear before the end of the 21st century (Ceballos, Ehrlich, & Dirzo, 2017).

The loss of key species would weaken whole ecosystems, creating adverse consequences to humans, such as disturbing the ecology of vector-borne infections and food-producing systems that depend on pollinators and the predation of pests, and impairing the cleansing of water and the circulation of nutrients that normally pass through ecosystems. A rich repertoire of genetic and phenotypic material would also be lost. To maintain the hybrid vigor and environmental resilience of food species, a diversity of wild species needs to be preserved as a source of genetic diversity (Chivian & Bernstein, 2008). Similarly, many modern medicinal drugs in Western medicine have natural origins, and many defy synthesis in the laboratory. Indeed, scientists continue to test thousands of novel natural chemicals each year, seeking new drugs to treat human immunodeficiency virus (HIV), malaria, drug-resistant tuberculosis, and cancers. And, more fundamentally, the species with which we share our planet have profound connections with human well-being via complex relationships that extend back through evolution.

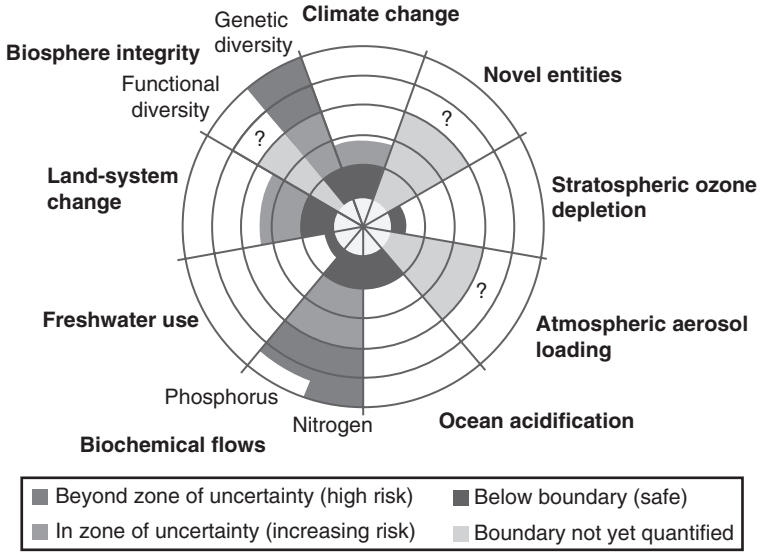


FIGURE 11-1 Nine planetary boundaries determining a "safe operating space" for human well-being, including the current status of control variables for seven boundaries.

Reproduced from Steffen, W., K. Richardson, J. Rockström, S. E. Cornell, I. Fetzer, E. M. Bennett, et al. (2015). "Sustainability. Planetary boundaries: guiding human development on a changing planet." Science (New York, N.Y.) 347(6223): 1259855. Reprinted with permission from AAAS.

The opposite side of this coin is the accelerating spread of invasive species, as long-distance trade, tourism, and migration increase in intensity. For example, the proliferation of water hyacinth (a decorative plant from Brazil) in Lake Victoria, eastern Africa, has extended the breeding grounds for the water snail that transmits schistosomiasis. The planting of *Lantana camerata* as a garden border shrub in Uganda, and its subsequent dispersed spread, has increased the habitat for the tsetse fly, which transmits the trypanosome that causes African sleeping sickness.

As a result of these changes to the ecosystem, serious consequences should be expected, such as changes in patterns of infectious diseases, in regional agricultural and aquatic yields, and in the effects of economic hardship or demographic displacement. Such changes are already beginning to change the conditions of the biosphere—our habitat—and pose long-term, and unfamiliar, risks to human population and ecosystem health.

Recognizing the intertwined nature of economic development, environmental sustainability, and human health, the Millennium Development Goals have recently been superseded by the Sustainable Development Goals, a set of 17 goals that inextricably link economic development, human health, and environmental sustainability (United Nations, 2015b). While all these Sustainable Development Goals have some relevance to modern environmental health, some are of obvious, direct concern to a habitat approach, including sustainable water management (Goal 6); access to affordable, clean energy (Goal 7); resilient, livable cities (Goal 11) with sustainable industrialization (Goal 9) and consumption and production patterns (Goal 12); and ecosystem health (Goals 13, 14, and 15).

Given these considerations, the scope of the environmental health framework must be extended to emphasize the impairment of our global habitat (McMichael & Bambrick, 2011) and its complex relationship with human health. Such a shift in focus should emphasize the positive roles that intact ecosystems and well-designed built environments play in supporting human health. While these "big picture" goals are incorporated into the environmental health framework, "traditional" environmental health priorities must evolve to incorporate modern realities. Hazard-oriented research should continue, but expand to incorporate a more thorough understanding of complex, interacting, cumulative exposures. New linkages need to be explored between urban planning and health, as large populations move into growing cities and face a combination of new and old environmental health threats.

Responses to the need for an expanded philosophical and methodological scope have burgeoned over the past three decades, giving birth to a number of important new approaches to environment and health. The One Health Commission (2017), which emerged from the medical and veterinary sciences (Zinsstag, Schelling, Waltner-Toews, & Tanner, 2011), acknowledges that issues such as zoonotic disease, food safety, and antimicrobial resistance require a greater understanding of human–animal–environment interactions, with a heavy emphasis placed on the human–animal nexus and on interdisciplinary collaborations among the medical, veterinary, and environmental sciences (see the *Public Health Infrastructure* chapter for further information on One Health). Ecosystem Health, or EcoHealth, has been developing in practice and research since the beginning of this century from roots in ecology and public and global health. Charron (2012) synthesizes the following set of EcoHealth research and practice principles, based on values of environmental sustainability and social equity: (1) systems thinking; (2) transdisciplinary research (involvement of policy makers and community representatives with scientists) and participation; and (3) translation of knowledge into policy action.

The evolving global approaches to rabies prevention and management provide a useful contrast between the One Health and EcoHealth methodologies. Since rabies is almost always fatal once contracted, prevention strategies are vital. Partnerships between medical and veterinary scientists in a One Health approach have led to the successful eradication of human rabies in many countries through the development of animal vaccines and mass-vaccination programs for dogs (WHO, 2013c). Further, One Health partnerships between medicine and veterinary science have been used to understand the transmission of rabies from wild carnivores and bats to humans (WHO, 2013c). However, in some parts of the world (such as India and parts of Africa and South Asia), attempts at eliminating rabies through mass dog vaccinations alone have proved unsuccessful. One of these places is Bali, which experienced a resurgence of rabies cases from 2008 despite having been previously rabies-free. Initial centralized mass dog vaccination was unsuccessful at achieving high rates of vaccination (Putra et al., 2013), which led to a project based on EcoHealth principles (Jatikusumah et al., 2013). This program involved wider partnerships among health, veterinary science, local government, livestock management, and communities. A mixture of methods were used to understand free-roaming dog ecology, demographics, and behavior; social and cultural relationships between humans and dogs; and local leadership and governance processes. This information was then used to create a much more context-specific, local, and community-led response to education, dog vaccination and management, dog registration, and rapid response to dog bites.

More recently, the planetary boundaries concept has stimulated renewed discussions in global health about Earth systems, social systems, and health

(Horton & Lo, 2015), with *The Lancet* introducing a new journal on the subject titled *Planetary Health*. This new concept is focused on "the interplay between health and the determinants of health in our living world" (http://www.thelancet.com/lanplh/about) and appears to be bringing ecosystem health concepts into the mainstream global health discourse.

Methods for Environmental Health Research and Practice

Research Scope and Strategies

Environmental health research seeks to understand how the environment influences states of health, to help prioritize and develop appropriate interventions to reduce risks to health, and to investigate the effectiveness of such interventions. Methods derived from a wide range of scientific disciplines are applied to these endeavors. Toxicology and microbiomics, audiology and neuropsychology, ecology and systems science, and others make important contributions.

We focus first on the methods and strategies applied in epidemiology, which has traditionally been the basic quantitative science of environmental health research. On their own, traditional research approaches are insufficient to engage with environmental problems of large scale and high complexity, especially as the field evolves from studies of discrete hazards to investigations of disordered systems. We outline some of the research tools that are being applied to studies of modern environmental health problems such as climate change and loss of biodiversity.

In essence, epidemiologic research describes and explains variations and temporal changes in the patterns of illness and disease between and within populations. Most environmental epidemiology is observational (that is, nonexperimental), which introduces some important issues in research design and data interpretation (Baker & Nieuwenhuijsen, 2008; Morgenstern & Thomas, 1993). However, where health benefits are anticipated from exposure-reducing interventions, experimental studies may be carried out.

Historically, epidemiology played an important role in identifying specific, localized hazards such as severe air pollution (e.g., the "London Fog" of 1952), waterborne infections, and asbestos in workplaces. While problems of this kind persist, we now face more subtle exposures, which are less well defined and more diffuse, such as electromagnetic fields and chemical exposures that mimic hormones and act cumulatively over decades (Diamanti-Kandarakis et al., 2009).

Many environmental exposures occur at levels that are low by comparison with what was experienced in the past in highly polluted settings. For example, in terms of fine particulates and noxious gases, exposures in many cities in high-income countries are commonly two orders of magnitude less than the "London Fog." This makes it more difficult to detect increments in risk that are, in absolute terms, modest. Even so, the effects are important, for the following reasons:

- They typically impinge on many persons, perhaps whole populations, thereby causing a large aggregate health impact (an economic–political criterion).
- They are encountered on an essentially involuntary, and often unequal, basis (an ethical criterion).
- They are often amenable to control at the source (a practical criterion).

The environmental health researcher faces two other recurrent difficulties. First, these real-world exposures are likely to be accompanied (and potentially confounded) by other exposures or risk factors—some of which may be unknown to the investigator or, indeed, to science. Second, the exposure–effect relationships often involve long-term, chronic, and sometimes subtle causal processes.

Because of these complexities, environmental health research must often be tackled in a multidisciplinary fashion so as to develop a sufficiently broad basis of evidence from which to make causal inferences. For example, causal inferences about the effect of low-level environmental lead exposure on the cognitive development of young children required the integrated consideration of the results of epidemiologic studies, animal experimental research, and neuropathological and molecular toxicological studies.

Extra leverage may be gained via interdisciplinary research in which the techniques of several disciplines are combined. For example, the development of molecular biology over the past several decades has yielded many new techniques for measuring internal exposure, especially in relation to carcinogenesis. Despite these challenges, complexities, and advances, there remains an important role for small-scale local studies that identify useful preventive policy recommendations.

Causation and Other Methodological Issues

For a detailed account of epidemiological reasoning, concepts, and methods, see a textbook such as *Modern Epidemiology* (Rothman, 2012). In this section, we cover only the most important elements relevant to environmental health.

Over recent decades, epidemiologists have developed a set of criteria specifically suited to their predominantly nonexperimental, bias-prone, confounding-rich research, with particular emphasis placed on the temporality of the relationship, its strength, the presence of

a plausible dose–response relationship, the consistency of findings in diverse studies, and coherence with other disciplinary findings and biomedical theory (Bonita, Beaglehole, & Kjellstrom, 2007). Nevertheless, etiologic research in environmental epidemiology entails several distinctive methodological issues:

- Choice of study design for data collection and analysis.
- Definition of exposure and choice of the mode of exposure assessment.
  - Choice of the relevant reference exposure (the theoretical minimum exposure level that a society could achieve).
  - Approach to dealing with multiple coexistent, potentially interacting environmental exposures.
  - Choice of the appropriate level of comparison (population, local community, or individual). Many environmental exposures (e.g., ambient air pollution or fluoride levels in drinking water) impinge on whole communities, with minimal exposure differences between individuals.

Study Design Options

The same basic set of study designs that are used in general epidemiology are also used in environmental epidemiology—that is, descriptive, analytic, and experimental (Baker & Nieuwenhuijsen, 2008; Bonita et al., 2007).

Descriptive Studies: Trends and Correlations

In descriptive studies, the pattern of variation in a population's or community's environmental exposure or health status (or both) is described, usually in relation to time, place, or category of person (e.g., age, sex, ethnicity). If the data are appropriate, the relationship between exposure factors and health status may be described. Such studies aid in identifying research priorities and in guiding the design of etiologic studies. For example, a study may show that the exposure levels are not high enough to warrant closer investigation. Time trends may be informative (e.g., seasonal variations in mortality that may or may not be related to temperature). Spatial distributions also provide clues to possible causes and sources of vulnerability.

Descriptive studies may struggle to reach definite conclusions about etiology. Commonly, this difficulty arises because inadequate information is available for confounding factors, or the temporal relationship between exposure and health outcomes is unclear.

Time-series studies have a special role in environmental epidemiology. Some environmental exposures such as urban air pollution and weather conditions vary on a short-term basis. Intrinsically interesting questions may arise, such as whether asthma attacks increase on high-pollution days or whether daily death rates increase on days of extreme temperature. The statistical techniques used within time-series analyses have been acquired largely from econometrics and engineering research; they include tools to adjust for lower-frequency (e.g., seasonal) cyclical variations, background secular trends, and autocorrelation. Time-series studies benefit from the fact that ongoing characteristics of the study population—such as age distribution, socioeconomic profile, and smoking habits—remain essentially constant over time. Further, because the comparison is made entirely within the chosen population, between population confounding factors do not apply.

Analytic Studies

Analytic studies examine formal statistical associations between an exposure variable and a health outcome variable at the level of the individual or a small homogeneous exposure group (Bonita et al., 2007). Are individuals with higher exposure to indoor air pollution more likely to develop respiratory disease than those with low exposure to such pollution? Are individuals who develop diarrheal disease in a coastal city more likely to have been swimming in contaminated seawater recently than individuals without such disease? Studies that seek to answer questions such as these can be designed to start either from exposures (cohort studies, such as the indoor air pollution example described earlier) or from the health effect (case-control studies, such as the diarrheal disease example described earlier).

The study of the relationship of early-life environmental lead exposure to child cognitive–intellectual development, for example, began with various types of cross-sectional studies in the 1970s. However, it was not possible to establish from those studies the temporal relationship between occurrence of exposure and occurrence of intellectual or behavioral deficit. To determine this relationship, cohort studies were required, in which infants and children were followed from birth, with systematic documentation of their early-life lead exposure history and cognitive–intellectual development. An investigation of this kind was carried out in and around the lead smelting town of Port Pirie, South Australia (Tong, Baghurst, Sawyer, Burns, & McMichael, 1998), and provided the data necessary to estimate by how much a given exposure to lead impaired neurologic function among young children (**EXHIBIT 11-2**).

Experimental and Intervention Studies

Experimental and intervention studies begin with sets of reasonably similar populations or groups, which can then be allocated, preferably randomly, to "intervention" or "control" categories. The statistical analysis

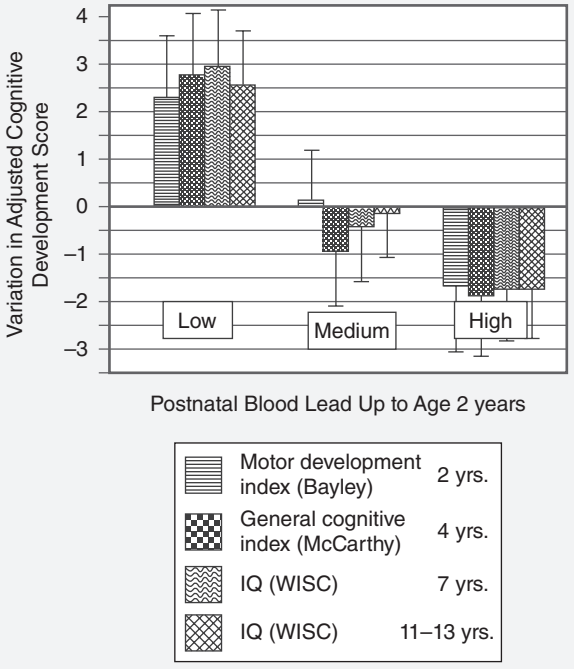
EXHIBIT 11-2 Environmental Lead Exposure and Childhood Cognitive Development

Lead is the most abundant heavy metal and may have been the first metal smelted, around 6500 B.C.E. The ancient civilizations of Phoenicia, Egypt, Greece, Rome, China, and India used lead for vessels, roofs, water ducts, utensils, ornaments, and weights. The use of this metal increased greatly during the Industrial Revolution, given the many uses of lead in manufacturing processes. The rise of the automobile meant that large of quantities of lead were required both in lead-acid batteries and as an antiknock additive in gasoline. This history is evident in the environmental record: The lead content of Greenland ice, for instance, reached 100 times the natural (pre-industrial) background level in the mid-1990s.

Lead affects many organ systems—most importantly, the gastrointestinal tract, central nervous system, kidneys, and blood (through the impairment of hemoglobin synthesis). Very high levels of exposure (leading to blood lead concentrations of 50 to 100 mg/dL) may occur in the workplace, particularly in lead smelting, battery recycling, lead soldering, and various lead-based craft activities. Such exposures are uncommon now in high-income countries, but are widespread in many LMICs.

Epidemiologic evidence shows that exposure to lead in early childhood causes a deficit in neurocognitive development, as illustrated in the nearby figure (Tong et al., 1998). Evidence from animal experimental studies and neuropathologic analyses backs up the epidemiology. A doubling in blood lead concentration from 10 to 20 mg/dL—roughly equivalent to the difference between high and low tertiles in poorly controlled urban environments—is associated with a deficit in intelligence quotient of 1 to 3 points, or 1% to 3% of the expected average IQ score of 100 (Pocock, Smith, & Baghurst, 1994). Subtle effects on IQ may result from blood lead levels as low as 5 mg/dL. Note that a loss of IQ points will have greater impact in children on the threshold of significant neuro-psychological impairment (e.g., mild mental retardation, defined as an IQ score of 50 to 69) than in children with a higher IQ.

Many high-income countries, including the United States and Australia, have set relatively stringent standards for environmental lead levels, in an effort to protect young children from exposure to this metal. Even so, lead may still present a serious environmental health problem, including in wealthy societies. For instance, widespread contamination of the drinking water of Flint, Michigan, occurred in the United States in 2016, caused by a shift to a more corrosive water source in a city with an old reticulation system that included lead piping (Hanna-Attisha, LaChance, Sadler, & Champney Schnepp, 2016). Likewise, childhood lead poisoning occurs in many LMICs. For example, the lead content of gasoline sold in Africa is the highest in the world and is associated with high lead concentrations in the atmosphere, dust, and soils. More than 90% of the children in Cape Province, South Africa, in the 1990s had blood lead levels in excess of 10 mg/dL (Nriagu, Blankson, & Ocran, 1996). In 2017, it was estimated that lead causes approximately 14 million lost DALYs and 500,000 premature deaths each year worldwide (Landrigan et al., 2017).



Lead exposure and cognitive development in childhood. One point approximates to a 1% change. Low, medium, and high lead exposure categories have mean blood lead concentrations of 12.5, 18.5, and 25.9 mg/dL, respectively.

Modified from Tong, S. et al. (1996). Lifetime exposure to environmental lead and children's intelligence at 11–13 years: The Pt. Pirie cohort study. *British Medical Journal*, 312, pp. 1569–1570.

Some difficulties arise in including cognitive and intellectual impairment in the risk assessment equation for evaluating and controlling environmental lead as a public health hazard. This particular functional health deficit—a subtle neurologic impairment that will have its most marked effects on the social and psychological development of children who already have a low IQ score—does not readily translate into the standard currency of deficit due to disease, disability, or death (the DALY). Hence, the burden of disease caused by relatively low but widespread exposures to lead may be underestimated by policy makers. Although overt lead-induced toxicity is apparent in individuals experiencing high levels of exposure, the full public health impact of widespread exposure to a range of environmental lead levels requires evaluation of more subtle health, behavioral, and developmental effects (Moore, 2003).

In developing a policy on an environmental health risk such as lead exposure and taking the evidence, such as that on cognitive impairment, into account, two questions commonly arise. First, does the deficit persist over time? It appears that the effect of lead on the developing brain does, indeed, persist through late childhood and into early adulthood. Second, is there a threshold—that is, an exposure level below which no neurotoxicologic effect occurs? It is difficult to answer this question because few data are available in the very low exposure range, so conclusions about "safe exposures" must be framed cautiously. Nevertheless, a strong case can be made for adopting public health measures to prevent lead exposure in early childhood. Because lead exposure tends to be widespread within a population, even a modest health impact upon each individual could yield a substantial aggregate impact for the total population. For instance, through its effect on blood pressure, it is estimated that lead is responsible for 2.5% of the global burden of ischemic heart disease (Landrigan et al., 2017).

compares outcome rates in the two or more groups (the intervention may be applied at more than one level).

The clinical randomized controlled trial (RCT) is commonly regarded as the "gold standard" for health research, but is seldom applicable to the study of environmental diseases among populations. It was not possible, for instance, to conduct an RCT of the effects of removing lead from gasoline, and indeed such a study was not necessary, given the weight of observational evidence justifying such a policy, and the rapid fall in body lead levels that occurred following its implementation. That said, there are sometimes opportunities for studies with an element of random allocation—for example, testing whether the installation of household humidifiers reduces the prevalence of respiratory symptoms, or whether the provision of masks to reduce inhalation of fine particles prevents acute changes in the cardiovascular system. In these cases, interventions are randomly allocated at the individual or household level. In some circumstances, randomized allocation of interventions at the population level is possible. A well-known historical example from the 1940s was the addition of fluoride to the drinking water of four towns in North America for the purpose of preventing dental caries, but not in four other similar towns (Fawell et al., 2006). However, the effectiveness of random allocation as a device for reducing the influence of confounding is much reduced when the number of observational units is small (8 in the case of the study of fluoride).

The need for a broader range of study designs to explore the effects of interventions becomes more apparent as the focus of environmental health is scaled upward. In the 21st century, studies of discrete toxins and physical exposures must be accompanied by investigations into the health effects of sociotechnical and physical system change. These include social constructs (e.g., the ingredients of a successful city, a well-functioning transport system) as well as elements in the natural world (e.g., the global climate, ecosystems that modulate risk of infectious diseases) and systems which mix the two (e.g., food systems).

Another type of intervention study often utilized in environmental health research is the "before and after" study. With this design, assessments are made before and after the introduction of an intervention. Before and after studies of interventions may struggle to control for time-varying confounders (i.e., factors that may differ before and after deployment of the intervention). However, research that includes multiple sampling points and well-chosen external reference groups can provide high-quality evidence. An example is the investigation undertaken to determine the effect of smoke-free legislation in Scotland on hospital admissions (Pell et al., 2008).

Exposure and Dose: Assessment and Definitions

Paracelsus, the 16th-century German physician/alchemist who is often credited with being the founder of environmental health and toxicology, is credited with writing: "Poison is in everything, and nothing is without poison. The dosage makes it either poison or remedy" (Deichmann, Henschler, Holmstedt, & Keil, 1986). This statement lies at the heart of environmental health science.

Measurements of toxic agents at the source or in emissions or in the ambient environment may be a useful guide, but do not directly indicate how much of the toxin is absorbed and so can cause harm. There is a huge amount of toxic mercury in the oceans, for example, but very little of it reaches people in normal circumstances. Volcanoes emit vast amounts of toxic gases, but fortunately few persons are usually nearby to breathe them. Dose is the amount of toxin that has actually reached

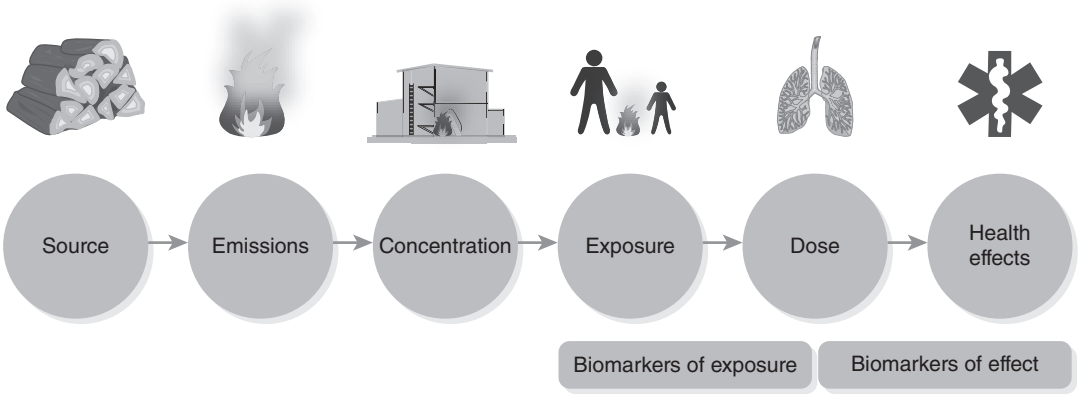


FIGURE 11-2 Environmental pathway.

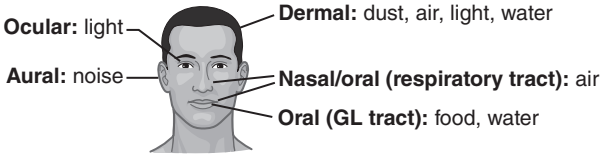

FIGURE 11-3 Routes of exposure.

the vulnerable parts of the body. Unfortunately, it is difficult to measure dose directly for most hazards (whether chemical or physical), either because it involves sophisticated, expensive, and invasive procedures (e.g., extracting and analyzing blood or tissue samples) or because it is beyond current scientific abilities.

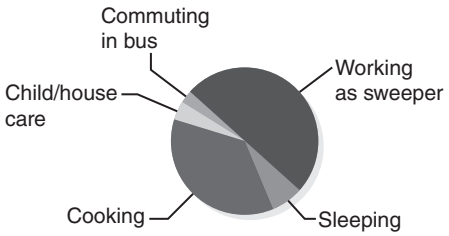
For this reason, scientific and policy attention is mostly focused on the intermediate segment of the environmental pathway—that labeled "exposure" in **FIGURE 11-2**. Exposure refers to the quantity and duration of the hazardous factor that humans encounter in the course of their activities. More explicitly, it is the amount of material or energy in the air, water, food, and soil that reaches the body's protective barriers of the respiratory and digestive systems, skin, eyes, and ears (**FIGURE 11-3**).

Total Exposure Assessment

To understand the full impact of a pollutant, it is necessary to examine all the ways it might reach people, rather than simply relying on measurements made in the most convenient places. This consideration is especially important for pollutants that can reach people through several different routes. For example, lead pollution may affect vulnerable groups, such as children, through airborne dusts or contaminated water, soil, and food. Confining attention to a single route may underestimate the true size of the problem (see Exhibit 11-2): It is total exposure, of course, that determines the risk to health.

Consider, for example, the woman with the daily pattern of activities shown in **FIGURE 11-4**. What is her health risk due to exposure to particulate air pollution? She lives in an urban slum of a low-income country where outdoor air pollution levels are fairly high. Her total exposure is even higher, however, because she spends considerable time in locations where particulate concentrations are even higher than the outdoor levels. During the working day, she works as a sweeper on busy streets, where pollution is especially severe due to large volumes of nearby traffic. In the morning and evening, she is exposed indoors to toxic products of combustion from an unvented cook stove, made worse because her family can afford only low-quality cooking fuels such as briquettes made from coal dust. In the evening, she is also exposed to secondhand smoke from her husband's cigarettes. Her total exposure over the day is best estimated by the sum of the pollutant concentration in each major microenvironment, weighted by the fraction of time she spends in it.

Total exposure assessment is necessary to accurately record the burden of disease attributable to environmental factors. Such information may change the relative importance of sources of pollution, or uncover important new sources of personal risk, such as secondhand smoke, that do not appreciably affect concentrations in the ambient environment. This metric also reveals a new dimension of potential control measures. For example, chimneys for household stoves that would not change emissions at all—and might even increase outdoor concentrations—can lower exposures substantially by separating the people from the pollution. Laws to reduce smoking in public places can lower exposure of the general population to secondhand smoke, even if there are no changes in the amount of smoking overall. In some cases, the cost-effectiveness of such exposure-control measures can be much higher than the exposure reduction achieved through generalized control of outdoor sources. Although ideally all pollution sources should be controlled, in reality there is a limit to what can be achieved in the short term.



Activity	Hours/day	Particulate concentration ($\mu g/m^3$)	Daily exposure equivalent ($\mu g/m^3$)	Proportion of total exposure
Sleeping	7	100	29.2	0.07
Cooking	3	1,200	150.0	0.36
Child/house care	3	120	15.0	0.04
Commuting in bus	1	300	12.5	0.03
Working as sweeper	10	500	208.3	0.50
Total	24	Mean = 415	415	1

FIGURE 11-4 Total particulate exposure for a woman in an urban slum.

Biological Markers of Dose

Environmental health researchers may use many different biological markers of dose: heavy metals in hair, nails, and blood; metabolites in urine of chemicals such as nicotine; chlorinated organic chemicals in adipose tissue; radionuclides in bone; core body temperature after excessive heat exposure; or antibody titers in relation to infectious agents. For instance, fingernails and hair have been used to study exposure to organophosphate compounds and polybrominated ethers (Liu, He, Hites, & Salamova, 2016).

Biological assays integrate the physiological and metabolic processes that influence absorption and clearance. These processes vary between individuals, and even in the same person, there may be fluctuations over time. Biomarkers are attractive ways to assess dose because they provide precise measures and imply plausible pathways for pathogenesis, but their relevance to disease causation and policy requires careful thought. Precise measures of irrelevant parameters are less helpful than imprecise data collected on variables that are directly applicable to research and practice. Useful monitoring and regulation of ambient air pollution, for instance, is more likely to be based on measures of exposure than on bioassays.

Consider the field of molecular epidemiology, which became prominent during the 1990s as an approach to studying the cause—especially the environmental cause—of cancer (McMichael, 1994). This same field has also become important in modern infectious disease epidemiology, particularly for the determination of environmental sources and transmission pathways for infections such as Legionnaires' disease, tuberculosis, influenza, cholera, and food-poisoning organisms.

Molecular biomarkers make use of the variations in the structures of macromolecules, particularly DNA. One area in which DNA measurement has assisted the conventional epidemiologic study of causation has been in investigations of dietary aflatoxin and liver cancer (McMichael, 1994). Aflatoxin is a biotoxin produced by the *Aspergillus flavus* mold in foods stored in warm, humid environments. Initially it was not possible to measure directly an individual's level of aflatoxin intake. Epidemiologists were limited to demonstrating ecological correlations, in eastern Africa and within China, between average aflatoxin concentrations in local diets and rates of liver cancer mortality. Now it is possible to measure the concentration of excised, excreted, aflatoxin-DNA adducts in urine and to use this as a measure of recent individual exposure. Such an approach was taken in a cohort study of 18,000 Chinese men in Shanghai that found a positive association, at the individual level, between adduct level at the commencement of the study and subsequent cancer occurrence (Qian et al., 1994).

Exposure Assessment at Individual and Population Levels

Exposure assessment at the individual level can occur at varying levels of intensity, ranging from exposure inferred via questionnaire, to personal exposure assessment (in which an individual's contact with environmental hazards is quantified, often using measurement devices), to measurement of individual biomarkers in blood, urine, hair, or tissue. Each type of assessment has its advantages and disadvantages.

For example, in studies of the health effects of secondhand smoke, it has been common practice to classify

exposures according to whether an adult has a smoking spouse or a child has a smoking parent. Clearly, someone who lives with a smoker is more likely to be exposed to tobacco smoke than someone who does not, but this is not necessarily so in every case. A child with no smoking parent, for example, may have four smoking grandparents who visit every day. Another child may have smoking parents who are careful to refrain from smoking anywhere near their child. In such cases, classifying children based on the smoking status of their parents would lead to exposure misclassification and, consequently, an attenuated estimate of the true effect. This type of error may be avoided by careful questionnaire design and by use of biomarkers such as cotinine in urine or saliva for at least a sample of the study population.

Often studies are based on a measure of exposure of whole population. This is obviously appropriate if the exposure is truly ecological—that is, it pertains to the whole population rather than individuals. Examples might be the level of income inequality or uptake of immunizations. But if the population measure is a proxy for what is happening at the level of individuals, there is a risk of misclassification, leading to bias in the measure of effect (Blakely & Woodward, 2000). It is common, for example, to conduct air pollution epidemiology studies by dividing urban populations into exposure classes according to the measurements made at the nearest outdoor air pollution monitoring station or even to use one or a few monitors to represent the exposure of an entire city for comparison with other cities. In reality, local exposure sources can contribute to great variation between individual exposures and the estimated population average exposure. The same problem arises in studies of heat, which commonly rely on measures of air temperature taken at a small number of weather stations, as there are many factors in the micro-environment that affect local temperatures and, in turn, an individual's experience of heat (Kjellstrom, Holmer, & Lemke, 2009).

Health Outcome Assessment

Many studies of the health impacts of environmental factors such as fine particles or heat have examined associations with mortality. However, the underlying pyramid of nonfatal health effects has a broad base: A full understanding of the effects of environments on health requires information on hospitalizations, primary care consultations, long-term chronic conditions, impaired organ function, and self-assessed symptoms, to name just a few items.

Researchers and data-collection agencies naturally tend to prefer "hard" endpoints that are well defined clinically and amenable to clear-cut counting or measurement. Yet community surveys indicate that the most commonly experienced effects of environmental exposures are frequently social, behavioral, and psychological disruptions that are not well suited to precise measurement. Examples are the mental stress of noisy environments, symptoms elicited by unpleasant odors, and the constellation of health-damaging exposures that affect children in car-dependent cities (Kjellstrom, Ferguson, & Taylor, 2009).

Environmental Health Indicators and Monitoring and Their Implications for Policy

Environmental health issues are recognized in the UN Sustainable Development Goals as an important part of the broader picture of human welfare, sustainability, and social and economic development (Griggs, 2013). To achieve a lasting improvement in global health, an intervention must influence the factors that created the exposure in the first place.

Most high-income countries have established a range of environmental performance indicators that attempt to be both scientifically robust and readily applicable to policy and practice. For example, the Organisation of Economic Co-operation and Development (OECD, 1993) developed the pressure–state–response (PSR) model to meet these criteria. Other frameworks have been constructed that elaborate the relationships between human activities, environmental change, and human health (Corvalán, Briggs, & Kjellstrom, 1995). It is possible to distinguish "driving forces" that lead to pressures on environments and population health, affecting the state of the environment and resulting in human exposures, and ultimately leading to health effects and actions or interventions in response. This is known as the DPSEEA model, where the acronym stands for the hierarchy of Driving forces, Pressures, State of environment, Exposures, Effects, and Actions (**FIGURE 11-5**).

Driving force indicators are likely to be qualitative and are often expressed as yes/no answers. For example:

- Is there a policy to redirect all storm water to treatment plants?
- Are sedimentation dams in operation upstream in potentially cadmium-contaminated rivers?
- Are safety regulations for nuclear power stations adhered to?

Pressure indicators are usually quantitative. For example:

- The amount of sewage-contaminated storm water entering a beach or river after heavy rain

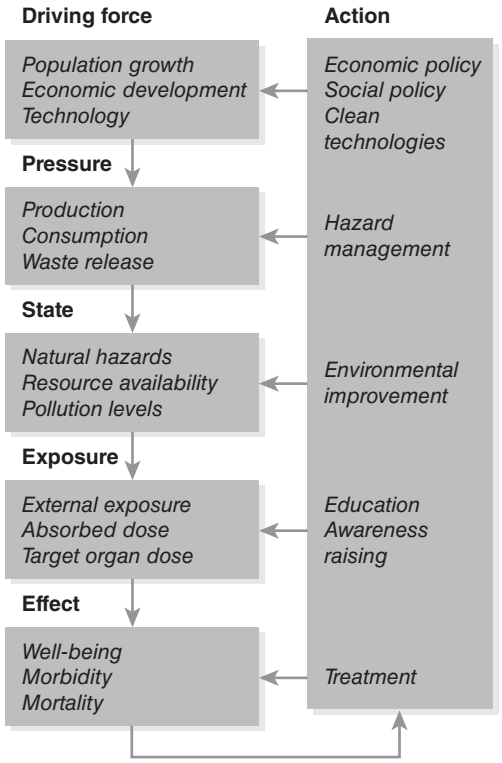


FIGURE 11-5 The DPSEEA framework to define environmental health indicators.

Framework for the development of environmental health indicators. *World Health Statistics Quarterly, 48*, 144–154; Corvalán, C., Briggs, D., & Kjellstrom, T. (1996). Development of environmental health indicators. In D. Briggs, C. Corvalán, & M. Nurminen (Eds.), *Linkage methods for environment and health analysis*, (pp. 125–153). Geneva, Switzerland: World Health Organization. Retrieved from http://apps.who.int/iris/bitstream/10665/62988/1/WHO_EHG_95.26_eng.pdf

- The amount of cadmium transported via river water to paddy fields
- The quantity of radionuclides released from a nuclear power station accident

The most common indicators are direct measurements of the environmental state—the concentration of a hazard in some environmental medium. For example:

- The enterococci concentration in beach water or drinking water
- The concentration of cadmium in rice paddy soil or rice
- The level of radioactive strontium in lichens or reindeer meat

Exposure indicators may be based on exposures calculated from state indicators, as described in the "Exposure and Dose: Assessment and Definitions" section earlier in this chapter. Biological indices add individual-based information and can be used to monitor both exposure (e.g., blood lead concentration, DNA-adduct level) and effects (e.g., enzyme assays for liver function, blood pressure). For example, such indicators were used to identify the marked decline in human milk concentrations of dichlorodiphenyltrichloroethane (DDT) (Smith, 1999).

Assessment of Environmental Health Impacts and Risks

Risk assessment is conventionally viewed as a stepwise sequence (WHO, 2002). It begins with the research-based identification of an environmental hazard. Subsequent studies then estimate, first, the exposure–response or dose–response relationship between the hazard and the specified health outcome, and, second, the distribution of exposure (doses) within the population of interest. Based on these two sets of data, the overall risk to the population is characterized, and risk management strategies are formulated.

Although there is now some agreement about how to calculate risks, there is no completely objective way to compare alternatives with different patterns of risk. This situation is illustrated in **EXHIBIT 11-3**, which presents a choice between two ways of producing electric power with different patterns of risk and explains how consumers with different worldviews could rationally choose either one or the other. This difference in risk perception explains why some people buy life insurance (risk aversion) and others do not, and why insurance companies run profitable businesses (based on expected-value calculations).

Many other considerations would be included in a full assessment of alternative power plants, including various outcomes of social importance other than those directly related to health. Thus, Exhibit 11-3 illustrates that a decision about how much or which kind of risk to take demands substantial scientific input but is ultimately a social and political choice. The extraordinary earthquake and tsunami damage to nuclear power stations in Japan in 2011, and the long-term challenges in rehabilitating and resettling Fukushima in its wake, illustrate just how difficult these decisions can be (Normile, 2011).

Probabilistic Risk Assessment

Because nuclear power plant operation is a relatively new enterprise, few accident statistics are available, particularly for large accidents in modern plants. How, then, can overall risk be determined? For this purpose, a technique called probabilistic risk assessment (PRA) is applied to understand the potential for adverse consequences. Developed originally by the National Aeronautics and Space Administration (NASA) for assessing the risks of manned space flight,

EXHIBIT 11-3 Risk Assessments: Additional Information, But No Substitute for Decision Making

Suppose a proposal has been made to build a large new power plant near your community. Everyone agrees on the need for more power and two options have been presented: coal and nuclear. These options are found to cost about the same. A full probabilistic risk assessment is done to compare the health implications of the two plants, yielding the results described here.

The coal plant, although of the best design, will have impacts in the form of air pollution and mining accidents. There is relatively little uncertainty about these factors—the probabilistic risk assessment finds a 90% chance that 30 persons will die prematurely because of the operation of the plant over its lifetime. Because there might be a large accident at the coal mine or a fire at the coal plant during meteorological conditions that lead to severe local air pollution, there is a 10% likelihood of killing 60 persons.

The nuclear plant is given a 99% chance of doing little damage (i.e., shortening only one person's life from the small amount of radiation released routinely). Unlike the coal plant, however, there is a small chance (here set at 1%) of a terrible accident in which 2,500 persons die from the radiation released.

Which plant is safer? Which would you rather live alongside? There are at least three ways to answer this question—none necessarily right or wrong, but all dependent on the set of values of the people making the decision:

- Maxi-min (maximize the chance of the minimum consequence): Because 99% of the time little damage is done and more may be learned in the future on how to reduce the chance of accidents, choose the nuclear plant.
- Mini-max (minimize the chance of the maximum consequence): Because a nuclear accident would be a tragedy (cause international headlines, go down in history, destroy the community, and so on), coal should be used so as not to have any chance of such an event.
- Expected value (calculate the odds): Because the expected number of deaths from the coal plant is 33 ($0.9 \times 30 + 0.1 \times 60$) and that from the nuclear plant is 26 ($0.99 \times 1 + 0.01 \times 2{,}500$), choose the nuclear plant.

Although the numbers used here are fictional and real probabilistic risk assessments for such facilities are much more complicated (involving hundreds of branches on the risk trees), the overall results are often similar. Nuclear plants generally have a lower expected value of damage but carry a small probability of terrible events (much less than 1%). Coal plants produce more damage on average but do not impose anxiety about large negative events (although growing concerns about possible climate change owing to the release of carbon dioxide from coal plants may change this perception).

The fact that groups of perfectly rational people may apply different decision rules does not mean that any group is right in an absolute sense, but rather indicates that groups start with different values. Indeed, although many other factors must be considered, the big difference in public acceptance of nuclear power between, say, France and Sweden can be partially accounted for by such differences in values.

this technique basically breaks down into subsystems the extremely complicated systems of large-scale technologies for which there is no overall accident information. These subsystems may then need to be broken down even further into even smaller components, until a level is reached for which failure data are available. The failure data for the various subsystems are combined to predict the performance of the total system.

For example, there is no information available that would enable one to predict directly how a new type of nuclear plant will operate over time, but such a facility is made up of thousands of components for which information is available. For example, information will be available about how often pumps of a certain size, switches of a certain voltage, or warning gauges of a particular brand are expected to fail under various conditions. Even if a new type of component is introduced, its failure rate can be experimentally determined without putting anyone at risk, unlike testing the entire power plant.

Such PRAs, of necessity, are extremely complex and difficult for even specialists to evaluate. In particular, it is difficult to tell whether all possible accident scenarios have been taken into account and whether unforeseen events, such as human sabotage, might potentially circumvent many subsystems at once. A PRA also assumes that the context in which each component was originally tested is not materially different in critical respects (e.g., temperature or vibration) from the working context of the assembled plant.

Where an assessment reveals a potential or actual exposure to a chemical for which there is no human exposure history, a similar dilemma results. It would be dangerous and unethical (not to mention time-consuming) to deliberately expose enough people to the chemical to discover its true risk. Instead, various techniques have been developed that can be used to estimate the risks of human exposures in this situation. The most commonly used method is to expose laboratory animals—usually rats and

mice—to high-enough doses of the chemical to observe effects within their relatively short lifespans. When deleterious effects, such as tumors or reproductive failure, are observed, then legitimate concern arises that such effects might also be seen in humans. To quantify that risk, however, requires extrapolating from high doses in animals to (usually) low doses in humans. To do so, researchers use a mathematical model that, ideally, is based on knowledge of metabolism, tumor induction, and other often poorly understood biological processes. Frequently, alternative animal models that are equally plausible biologically will predict different human risks for the same dose of the same chemical. Had the antinausea drug thalidomide been tested in rats, not rabbits, the tragedy of limbless human babies would probably have been averted. It is necessary, therefore, to establish standard conventions for which model will be used in which circumstances so that consistent risk estimates are made. At present, many of the model choices depend more on scientific intuition than on actual demonstrated knowledge. Finding more reliable and scientifically valid ways of performing such assessments is an active research area.

It might seem best to establish the convention of always using the most conservative model—that is, the model that predicts the largest risk. This strategy would seem to fit the classic public health dictum that, in cases of uncertainty, it is better to err on the side of caution than to underestimate potential risk. Indeed, for this reason, such a conservative approach is used in formulating official policy by some regulatory agencies. Unfortunately, and perhaps counterintuitively, if this approach is taken for each chemical independently, it can lead to the opposite effect—that is, exposing the public to unnecessary risks. The degree of conservatism (or the size of the safety factor) for specific chemicals can be quite different, depending on how well their observed effects on animals or humans actually compare with the predictions of the mathematical model employed. As a consequence, society might end up spending vast sums to control one chemical based on a risk assessment that uses a conservative safety factor of 1,000 because it appears to be more dangerous than another chemical that is actually more dangerous, but whose estimated risk is based on a safety factor only 10 times its true value.

Because it is rarely necessary to protect the population from only one hazard at a time, it is preferable to make judgments based on the best estimate of the actual risks rather than incorporating large, but varying, safety factors into the PRA. In the real world, which is characterized by limited resources and time to deal with many possible hazards, an overly cautionary approach might be described as "too safe is unsafe."

Measures of Ill Health for Risk Assessment Purposes

As discussed in the *Measures of Health and Disease in Populations* chapter, various measures of ill health have been proposed to take into account, separately or in combination, the degree of prematurity of death and the time lived with nonfatal disease. Several choices must be made in such calculations— for example, whether to use different life expectancies for men and women or for different regions, how to weigh the severity of different kinds of disease, and whether to discount the value of lost life years in the future (as is the practice in economics). Whatever choices are made, it is evident that measures of lost healthy life years, due to both death and disease, are useful as an indicator of environmental impacts.

As the environmental risk transition progresses, and as the time between creation of a risk factor and its expression as disease tends to lengthen, the need for formal risk assessment increases (Smith & Ezzati, 2005). When evaluating measures to control diarrhea, for example, it is reasonable to monitor diarrhea rates, because the diarrhea of today is due largely to environmental exposures that occurred within a few preceding days. A similar logic can be used for increasing heat exposure due to climate change: Heat exhaustion and heat stroke are due to the exposure during the most recent hours or days (Kjellstrom et al., 2009). In contrast, for controlling environmental carcinogens or greenhouse gases, which have decades-long latency periods, waiting until ill effects start to occur would be far too late. Thus, it is necessary to conduct risk assessments as best we can to make predictions well in advance of the actual events, so that appropriate measures can be taken in time.

Assessing Risk: Compared with What?

Risk assessments, when done in isolation, can be misleading. The following two examples are illustrative. Determining the risk imposed by an activity requires, explicitly or implicitly, choosing an appropriate baseline. In discussing the health effects of smoking, the appropriate baseline may be zero: It is possible for people to quit or not take up smoking. For air pollution, by comparison, the choice is not as clear. Natural sources of many air pollutants exist, and human sources are so difficult and expensive to control that a zero baseline is not feasible in many cases. Which level is then

appropriate: the national standard or the WHO guideline value, or perhaps the level of the cleanest city? It is necessary to choose something, if we are to calculate the risk of the incremental pollution above the baseline.

Most human endeavors that are subject to risk assessment (technologies, industries, chemicals, regulations, and others) actually result in a mixture of risk-lowering and risk-raising effects. A new factory in a low-income country, for example, might impose pollution on the public and accident risk on the workers, but it may provide jobs, housing, training, security, and other benefits that could lead to substantial improvements in health. Just because these effects are less direct than the accident risk does not mean they are small. Indeed, the overall impact of industrialization must be risk lowering—otherwise, the high-income countries would be unhealthy rather than the LMICs without industry.

Such risk lowering also occurs in high-income countries. Consider, for example, a pesticide residue on vegetables. Looked at in isolation, it may appear unacceptably risky. Viewed in terms of the overall impact on food cost and intake for low-income people, occupational risks to farm workers, and other factors, however, it may actually lower the overall risk compared with alternatives. This is not to say that all polluting activities will lower risks, but rather that all technologies should be judged on both their risk-lowering and risk-raising propensities. In addition, important equity and justice issues often arise in relation to who experiences the raised risk and who experiences the lowered risk. Unfortunately, our current risk assessment methods are not well developed enough to determine risk lowering, which is a source of potential bias in the results.

In this chapter, we have focused heavily on the methods for understanding hazards via environmental epidemiology and risk assessment. However, an expanding range of approaches and methods are also being developed in the disciplines of ecosystem health and planetary health. These approaches and methods are being applied to understand environments as habitats, the role of ecosystems and ecosystem services in human health, and the integrated positive and negative health impacts of environmental exposures; they also support decision making for health, equity, and environmental sustainability. Broad approaches include the following:

- Health impact assessment (HIA) of policies and projects outside the health sector, which aim to examine proposals for multiple health effects (Briggs, 2008)
- Health in All Policies, which aims to more deeply integrate health into policy making outside the health sector (including policies governing the natural and built environments) through partnership, co-funding, accountability, and management of vested interests (WHO, 2013a)
- Integrated catchment management, which is described in the "Freshwater" section of the chapter

Methods range from qualitative interviews and narrative methods (Charron, 2012) to community epidemiologic intervention studies examining multiple outcomes, geographic information systems (GIS) mapping and analysis (Delin & Shilong, 2016), and systems thinking and modeling (Brown, Proust, Spickett, & Capon, 2011; Macmillan et al., 2014).

Occupational Health

The workplace environment is generally more dangerous to human health than the ambient external environment. Machinery, chemicals, dusts, ergonomic hazards, and the fact that much work is carried out with the body at its peak performance are all factors that contribute to the overall level of risk. Nevertheless, many of the same specific hazards occur in the workplace and the general environment; hence there are many similarities in how their effects can be monitored and managed (Rosenstock, Cullen, Brodkin, & Redlich, 2005).

A variety of textbooks on occupational health and occupational medicine describe the many workplace hazards to health (e.g., Levy, Wegman, Karon, & Sokas, 2011; Rosenstock et al., 2005; Smedley, Dick, & Sadhra, 2013; Stellman & International Labor Office [ILO], 1998). The issues in LMICs have been highlighted by the web-based detailed handbook by Elgstrand and Petersson (2009), and a detailed treatise is given by Herzstein and colleagues (1998).

The convenient access via the Internet to information about different occupational health hazards has reduced the need for access to major textbooks giving details of each health hazard. One important source is the *Encyclopaedia of Occupational Health and Safety* (ILO, 2012), which is a web-based, updated version of the original report (Stellman & ILO, 1998). Another source of health information for a wide variety of industrial chemicals is the collection of International Chemical Safety Cards, also available via the ILO website (http://www.ilo.org/safework/info/publications/WCMS_113134/lang--en/index.htm). In addition,

the ILO website makes a substantive number of databases and statistics available. In this section, we have kept many of the references from previous editions of this text, and revised or added references only when some important new evidence has become available.

Important phenomena in the workplace environments of LMICs include the problems that occur during a time of rapid industrialization. Agricultural societies are transformed during this rapid transition, but often without the infrastructure for environmental and workplace health protection that was built up in high-income countries over their many decades of industrial development. Sometimes the new industries replace existing cottage industries, and conditions may improve. In other cases, industries with outmoded, dangerous technology are moved from high-income countries, creating new hazards in the receiving LMIC. The phrase "export of hazards" has been used to describe this problem (LaDou & Jeyaratnam, 1994; Moure-Eraso, Wilcox, Punnett, Copeland, & Levenstein, 1994). A new feature of this export of hazard is the transfer of much consumer product manufacturing (e.g., clothes, shoes, furniture, toys) to tropical countries with high ambient heat levels during much of each year (Kjellstrom, Freyberg, Lemke, Otto, & Briggs, 2017; Kjellstrom, Holmer, & Lemke, 2009). Few factories in such countries have efficient air cooling systems, and the resulting workplace heat stress is a major health and productivity threat, becoming worse as global climate change progresses. Another growing occupational health challenge is the increasing use of new migrants and "guest workers" in the economies of many high-income countries. The health and safety management of such workers is often less developed than for native workers (Arcury, Grzywacz, Sidebottom, & Wiggins, 2013).

Agriculture

Agriculture is the most common occupation in rural areas of LMICs, where most of the world's population lives. Most workers are engaged in subsistence agriculture, in which the boundaries between work and other aspects of daily life are fluid. Workplace hazards in this type of situation include generally poor and unhealthy living environments, which are often characterized by unsafe drinking water, poor sanitation, and inadequate shelter.

Specific hazards may also exist in these areas, such as injury hazards from tools used in tilling the soil, vector-borne diseases related to walking in water or mud, hazardous heat exposure under extreme conditions, bites from insects and animals, and falls or drowning from working on hillsides or riversides. The health risks are further increased because subsistence farm work involves the whole family, including children and the elderly. Epidemiologic evidence of these types of health risks is scanty.

As the planting and harvesting processes become more advanced and farmers develop cash crop production, new hazards emerge. The tools involved become more mechanized, which creates new types of injury risks, particularly because the use of these tools is unfamiliar to many of the workers. Pesticides are introduced, but often without the provision of full equipment and training (Thundiyil, Stober, Besbelli, & Pronczuk, 2008; WHO, 1990). As a consequence, an estimated 3 million cases of unintentional pesticide poisoning occur among agricultural workers in LMICs each year (WHO, 2004). In addition, pesticides have been estimated to be used as a deadly poison in 30% of global suicides, with 250,000 people taking their life in this way each year (Gunnell, Eddleston, Phillips, & Konradsen, 2007); the *Unintentional Injuries and Violence* chapter discusses self-directed violence in more detail.

Agricultural work hazards are not only related to planting and harvesting food crops. An important activity is the collection of fuel wood for cooking and heating. Wood and agricultural waste are often collected in local forests by women (Sims, 1994). An analysis of time use for these activities, along with water collection and cooking, in four low-income countries showed that women spent 9 to 12 hours per day engaged in such tasks, whereas men spent 5 to 8 hours. Firewood collection may be combined with harvesting of wood for local use in construction and small-scale cottage industry manufacturing. A number of health hazards are associated with the basic conditions of the forest, including insect bites, stings from poisonous plants, cuts, falls, and drowning.

In countries with tropical heat and humidity, great physiological strain is placed on the body, whereas the cold is a potential hazard in temperate countries and the Arctic area. Excessive heat exposure is not just a health hazard, but also affects work capacity and productivity (Kjellstrom et al., 2017; Sahu, Sett, & Kjellstrom, 2013), which can reduce incomes for already vulnerable low-income workers. In countries with a high sunshine level, ultraviolet radiation can be another health hazard, increasing the risk of skin cancer and cataracts (Gallagher & Lee, 2006).

Most forestry work is hard physical labor that is associated with a risk of ergonomic damage, such as painful backs and joints as well as fatigue, which increases the risk of injuries from falls, falling trees, or

equipment (Poschen, 1998). Women carrying heavy loads of firewood—and also at risk of ergonomic damage—are common in areas with subsistence forestry (Sims, 1994). Further, the living conditions and sanitary facilities of forestry workers are often poor, and workers may spend long periods in simple huts in the forest with limited protection against the weather.

Urbanization typically leads to the development of a commercial market for firewood and larger-scale production of firewood from logs or from smaller waste material left over after the logs have been harvested. Energy forestry then becomes more mechanized, and workers are exposed to additional hazards associated with commercial forestry (Poschen, 1998). Motorized hand tools (e.g., chainsaws) become more commonly used—a trend that leads to high injury risk, noise-induced hearing loss, and "white finger disease" caused by vibration of the hands (Griffin, Bovenzi, & Nelson, 2003). In addition, fertilizer and pesticides become a part of the production system, which results in the potential for pesticide poisoning among sprayers. As the development of forestry progresses, more of the logging becomes mechanized with large machinery, reducing the direct contact between workers and materials. Workers in highly mechanized forestry have only 15% of the injury risk of highly skilled forestry workers using chainsaws (Poschen, 1998). In contrast, firewood production continues to require manual handling and, therefore, may remain a hazardous operation.

The mortality and morbidity data for occupational hazard impacts on populations are in many countries severely underreported. However, based on the statistics reported to the ILO, an idea of the reported mortality can be gleaned (**TABLE 11-3**). Agriculture and fishing have relatively high injury mortality rates in the four countries assessed in Table 11-3, while mining, has even higher rates, particularly in Turkey and the Philippines.

Mining and Extraction

Mining is inherently dangerous to the mine workers, as highlighted by regular media reports of severe incidents in different types of mines. Most countries, including LMICs, have recognized this fact and developed specific legislation and systems to protect mine workers (Eisler, 2003; ILO, 2012; Ramani & Mutmansky, 1999; Stellman & ILO, 1998).

Two major types of mining exist, each with a somewhat different pattern of health hazards: underground mining and open-cast mining. Ergonomic hazards and

TABLE 11-3 Occupational Injury Mortality Rates in Different Economic Sectors, Five-Year Averages for the Latest Years of Reports, 2009–2016

Sector (ISIC Code)	Sweden	United States	Turkey	Philippines
All occupations	1.0	3.4	15	5.4
Agriculture and fishing (A + B)	6.2	24	9.7	29
Mining and quarrying (C)	7.0	16	56	44
Manufacturing (D)	0.8	2.2	13	4.1
Electricity, gas, water supply (E)	1.0	2.8	23	17

Transport (I)	3.2	14	21	18
Financial and business (J + K)	0.0	0.4	0.4	0.0
Administration, education, health, and other (L–O)	0.4	2.1	5.9	1.8

Note: The unit here is the number of deaths per 100,000 economically active workers in the sector.
Data from International Labor Organization statistics (Kjellstrom & Hogstedt, 2009).

physical (accident-inducing) hazards occur in both, but underground work includes the added hazards of being crushed by falling rock, poisoned by gas or dust buildup, or affected by heat or radiation. Each type of mine entails specific hazards associated with the rock from which the ore is excavated. Most types of rock contain high levels of silica, leading to high levels of silica dust in the air of a mine and the risk of silicosis in workers. Certain types of rock (particularly uranium ore) contain radioactive compounds that are emanated as the gas radon, which increases the risk of lung cancer. Other types of rock contain metals that are inherently poisonous (e.g., lead and cadmium) and that in certain conditions can cause dangerous exposures.

According to the United Nations' Demographic Yearbooks, miners constitute a large occupational group on a global level. They represent as much as 2% of the economically active population in some countries. Although in recent years only 1% of the global workforce has been engaged in mining, this industry accounts for 8% of all fatal occupational accidents—approximately 15,000 deaths per year. A detailed review of occupational health and safety issues in mining was performed by Armstrong and Menon (1998).

Clearly, mining is a particularly dangerous occupation. Table 11-3 highlights the high overall occupational mortality rates in selected countries. In LMICs, coal mining employs millions of people. Coal is a major global energy source, contributing 28% of total energy consumption (International Energy Agency, 2017). It was the primary source of energy for the world between 1900 and 1960, but subsequently was overtaken by oil, much of it collected via more difficult extraction, such as "fracking" and tar sands extraction. Coal can be produced through surface mining (open cast) or underground mining. Both operations are inherently dangerous to the health of the workers.

Underground coal miners are exposed to the hazards of excavating and transporting materials underground. These risks include injuries from falling rocks and falls into mine shafts, as well as injuries from machinery used in the mine. There are no reliable global data on injuries of this type from LMICs (Jennings, 1998), but in high-income countries miners have some of the highest rates of compensation for injuries. In addition, much of the excavation involves drilling into silica-based rock, which creates high levels of silica dust inside the mine. As a consequence, silicosis is a common health problem in coal miners (Jennings, 1998). In addition, coal miners with silicosis have an increased risk of lung cancer.

Other health hazards specific to underground coal mining include the coal dust, which can cause "coal worker's pneumoconiosis," or anthracosis, often combined with silicosis. Coal dust is also explosive, so explosions in underground coal mines are an ever-present danger for coal miners. Fires in coal mines are not uncommon, and once started may be almost impossible to extinguish. Apart from the danger of burns, the production of smoke and toxic fumes creates great health risks for the miners. Even without fires, the coal material produces toxic gases when it is disturbed—namely, carbon monoxide, carbon dioxide, and methane. Carbon monoxide binds to hemoglobin in the blood, blocking oxygen transport and causing chemical suffocation. This colorless and odorless gas gives no warning before the symptoms of drowsiness, dizziness, headache, and unconsciousness occur. Carbon dioxide displaces oxygen in the underground air and can cause suffocation.

Mines where materials other than coal are extracted (e.g., iron, copper, lead, zinc, silver, gold) have similar risks of injuries, hot work environments, and exposure to silica dust. An additional health hazard is exhaust fumes from the diesel engines used in machinery or transport vehicles underground. These emissions contain fine particles, nitrogen oxides, and carbon monoxide, all of which can create serious health problems. Underground mining may also expose the workers to extreme heat stress due to high temperature or humidity (Wyndham, 1969). The climatic conditions underground need to be assessed when scheduling work shifts and breaks.

Surface mining avoids the hazards of working underground but still involves risks from machinery, falls, and falling rocks. In addition, mining is energy-intensive work, similar to forestry, and heat, humidity, and other weather factors can affect the workers' health. The machinery used is noisy, and hearing loss is a common effect in miners. Another health hazard is the often-squalid conditions in which many miners in LMICs live, which creates particular risks for the diseases of poverty.

A special type of mining is the extraction of oil and gas to supply the energy needs of societies in the midst of industrialization. Oil and gas exploration, drilling, extraction, processing, and transportation involve a number of the hazards mentioned previously: heavy workload, ergonomic hazards, injury risk, noise, vibration, and chemical exposures (Kraus, 1998). This type of work is often carried out in isolated geographic areas that are subject to inclement weather conditions. Long-distance commuting may also be involved, which increases fatigue, stress, and traffic accident risks. The ergonomic hazards have the potential to cause back pain and joint pain. Injuries may include

burns and those caused by explosions. Workers need well-designed protective clothing to avoid skin damage from exposure to the oil itself and from chemicals used in the drilling processes. In addition, many oil and gas installations have used asbestos for heat-insulating cladding of pipes and equipment, which leads to the hazard of inhalation of asbestos dust in the installation and repair of such equipment, which in turn increases the risk of lung cancer, asbestosis, and mesothelioma (Kamp, 2009; WHO, 1998, 2006).

Much exploration and drilling for oil and gas now occur offshore. This type of mining involves underwater diving work, which is inherently dangerous. In addition, the weather-related exposures can be extreme, particularly because the work often requires continuous, around-the-clock operations (Kraus, 1998).

Construction

Construction work is another dangerous occupation; workers may potentially be exposed to a variety of hazards (Weeks, 1998). Risks include injuries from falls and falling objects, from machinery, or related to excavation or underground work. Because much construction work is carried out in the open, weather conditions may create hazards related to heat, cold, ultraviolet radiation, and dust storms. Construction work also involves heavy lifting of materials and activities in awkward body positions, leading to ergonomic hazards. Injuries, strains, and sprains are common. Many injuries are severe, leading to the high ratio of construction workers in the occupational mortality statistics (see Table 11-3).

In many cases, construction work involves exposures to heat, cold, noise, chemicals, and biological hazards. Much of the machinery used is noisy, and this problem has only increased with the increasing mechanization of the industry. Demolition is a common aspect of construction work, and demolition activities are inherently noisy. As a consequence of these factors, noise-induced hearing loss is common among construction workers. Another aspect of the noisy environment is the increased safety problems caused by the masking of warning calls or other alarms.

Chemical and dust exposures are related to the composition of the building materials. Asbestos, which has long been used as insulation and as a component of asbestos-cement pipes and sheets, is a prime example of a hazardous material. Asbestosis (a form of pneumoconiosis), lung cancer, and mesothelioma (another fatal cancer strongly associated with occupational asbestos exposure) have been found in many construction workers (WHO, 1998). Indeed, mesothelioma is one of the most prominent occupational diseases in most countries where records are kept, while underreporting of asbestos-related lung cancer is common. In high-income countries, as many as 20,000 cases of lung cancer and 10,000 cases of mesothelioma occur each year due to workplace asbestos exposures that took place 20 to 40 years ago (Tossavainen, 2000).

The use of asbestos in LMICs remains widespread (Kameda et al., 2014; Kazan-Allen, 2003; Tossavainen, 2004) and, indeed, is continuing to increase (Le et al., 2010). The epidemic of serious health effects associated with exposure to asbestos takes decades to develop, so preventive actions need to be taken at an early stage. Some LMICs have instituted bans on use of asbestos in construction, which would be the most effective means of prevention. Alternatives to asbestos exist for almost every use, and their cost is often similar to that of asbestos. The epidemic of asbestos-related disease is still on the ascendancy in a number of high-income countries, even though virtual bans were instituted in the 1980s—for example, in New Zealand, where the full epidemic of asbestos cancer over 40 years may kill at least 2,000 to 3,000 workers (Kjellstrom, 2004).

Other chemical and dust exposures in the construction industry include cement dust among bricklayers and concrete workers (Meo, 2004); such dust causes lung disease and dermatitis. Sand-blasting or rock drilling creates silica dust in the air, which can lead to silicosis in exposed workers. Construction work often involves welding, which adds further health hazards, such as inhalation of welding fumes that leads to bronchitis. Paint fumes often contain organic solvents that may cause neurologic disorders. The hazards of dusts and fumes are increased inside confined spaces, where these concentrations can reach extremely high levels.

Because of climate conditions, work in the construction industry is often seasonal, so contract workers may rely on other work during parts of each year. This seasonality is influenced by climate. In tropical and subtropical countries, extreme heat exposure during the hot season may cause major health and productivity issues (Kjellstrom, Holmer, & Lemke, 2009; Nybo, Kjellstrom, Bogataj, & Flouris, 2017). The intermittent character of seasonal work also creates problems in maintaining efficient prevention programs to protect workers against these hazards (Weeks, 1998), especially in LMICs. Subcontracting or informal employment relations often reduce the responsibility taken by the main employer or contractor on a construction site. When the responsibility for health and safety is dispersed among many individuals, the protection against hazards may become insufficient. Thus, in construction work, it is important that

contracts include the necessary safety provisions and that systems be in place for monitoring and enforcing these provisions.

Transport

An important industry in modern society is motorized transport of goods and people. As a country develops economically, transport occupations typically account for an increasing proportion of the workforce. These jobs include drivers of trucks, buses, taxis, trains, airplanes, and other vehicles; people involved inside the vehicles (e.g., conductors, flight attendants); people involved in loading and offloading freight; and people involved in the management of the transport system (e.g., traffic police, air traffic controllers).

The motorized transport system creates several health hazards in communities as described in other sections of this chapter (e.g., air pollution, noise, injury risks). The health risks specific to the people working in the transport industry are also of importance. Table 11-3 shows the relatively high injury and mortality risks for transport workers in four countries. Most of these deaths are likely to be listed as "traffic accidents" in official statistics. Other occupational health hazards include exposures to noise, chemicals, and dusts, as well as ergonomic hazards associated with lifting heavy loads and sitting for hours in the same position while driving a vehicle (Kjellstrom, Ferguson, & Taylor, 2009).

Industry and Manufacturing

Industrialization brings many benefits in the form of income and jobs, but, unless regulated in some fashion, can lead to significant occupational and public health hazards. These health hazards may take the form of releases of toxic or potentially toxic materials—as in the notorious cases in postwar Japan (**EXHIBIT 11-4**).

EXHIBIT 11-4 Minamata and Itai-Itai Disease: Classic Environmental Health Disasters

Environmental health disasters have been important triggers for national and international action to prevent environmental pollution. The best-known such disaster may be Minamata disease, which struck the small coastal town of Minamata, Japan, in 1956 (ILO, WHO, International Program on Chemical Safety, & United Nations Environment Programme, 1990). Hundreds of people were seriously affected by methylmercury poisoning, and many victims died. This type of poisoning affects the nervous system, producing symptoms that range from slight numbness of the fingers to loss of the ability to talk and walk.

The source of the methylmercury in Minamata was a chemical production factory that used mercury as a catalyst in one of its processes. Surplus mercury was discharged via spill water into a nearby bay, and this mercury accumulated in bottom sediments. Microbes in the sediments converted the mercury to methylmercury, which eventually entered the food chain of fish and caused high methylmercury levels in the local fish. Minamata had a substantial population of small family fisheries, and these families were the most affected.

The outbreak of the disease developed over several months, and it was initially thought that a new type of infectious disease affecting the nervous system had appeared. It took months of detailed epidemiologic research to conclude that the cause of the disease was associated with the consumption of fish. Further toxicologic and epidemiologic research over many years eventually identified the specific chemical involved. A second outbreak of similar methylmercury poisoning, in Niigata, Japan, intensified the search for a definite cause. In 1968, the Japanese government committee responsible for elucidating the cause finally incriminated methylmercury—12 years after the disease was first reported.

A similar story can be told about Itai-Itai disease, a form of chronic cadmium poisoning that developed in farmers in Toyama, Japan, at about the same time as the first outbreak of Minamata disease (Friberg, Elinder, Kjellstrom, & Nordberg, 1986; WHO, 1992). Painstaking research identified that the consumption of cadmium-contaminated rice and drinking water was the cause. The cadmium, which came from a mining area and a lead/zinc ore concentration plant, had reached the affected community via a river that residents used to irrigate their rice fields. The farming families in the contaminated area had small subsistence farms, providing for all of their needs. Thus, if a family's farm was contaminated, the family members ended up with high daily cadmium intake. Cadmium is a cumulative poison that eventually damages the kidneys, indirectly leading to bone deformities and fractures because of severe osteomalacia and osteoporosis.

At the time when these two disease outbreaks occurred, Japan was a low-income country trying to recover from the disastrous economic effects of World War II. The living conditions were not dissimilar to those in today's low-income countries undergoing rapid industrialization. Rural populations consumed mainly locally produced food. Only basic healthcare services were available, and the environmental pollution situation was not closely monitored or managed. Local industry discharged wastes into the air, rivers, or sea without much pollution control equipment.

A country that currently has similar conditions to erstwhile Japan is China, which also has lead, zinc, and copper mining; rice farming; and high local food content in the diet. Indeed, cadmium-polluted areas have been found in China (Cai, Yue, Shang, & Nordberg, 1995), and environmental epidemiologic studies have discovered exposures and effects similar to those observed in the polluted areas of Japan.

Some industrial facilities carry the risk of large-scale accidental releases of toxic materials. The biggest such release in world history occurred in Bhopal, India, where an explosion at a pesticide manufacturing plant resulted in some 3,000 deaths caused by the chemical methyl isocyanate and significant health impairment in many tens of thousands of people. The impact of this accident at the facility was exacerbated by the lack of urban zoning controls, with hundreds of households having been built directly adjacent to the plant. There was also inadequate planning for alerting and evacuating the public once the accident had occurred.

Manufacturing workplaces can be the sites of any of a long list of occupational hazards, some of which were mentioned in earlier sections of this chapter. A review of the various hazards is included in the *Encyclopaedia of Occupational Health and Safety*, published by the International Labor Organization (ILO, 2012; Stellman & ILO, 1998). Manufacturing involves ergonomic injury hazards from improper work positions, heavy lifts, and dangerous machinery; physical hazards, such as noise, heat, poor lighting, and, occasionally, radiation; and chemical exposures of many kinds. However, as in the earlier history of today's high-income countries, the major chemical exposure problems in LMICs include lead, cadmium, chromium, mercury, other metals, organic solvents, and welding fumes. Increasingly, the most hazardous industries and processes are being exported from high-income countries to LMICs (LaDou & Jeyaratnam, 1994), but without the technological improvements that have reduced workers' exposures to these risks in the high-income countries. In addition, stress and other psychosocial hazards of long work hours and shift work are common in industries that have made large investments in machinery, from which economic benefits accrue only when the equipment is in operation. Notably, the transfer of consumer products manufacturing (e.g., clothes, shoes, furniture) to low-income countries has created health risks due to limited applications of occupational health and safety management precepts.

Of the various manufacturing industries, some with particular health risks are worth highlighting. In electrical appliance manufacturing (Stellman & ILO, 1998), major risks are found in lead-acid battery manufacturing operations, which produce batteries for vehicles. Because such batteries are too heavy to transport over long distances, local production is usually established at an early stage of the "motor car society." The operation of these factories typically involves many workers who receive unacceptably high lead exposures. The usual approach is to monitor workers' blood lead levels; if the levels exceed the national standard, the worker is taken off lead exposure work for a few weeks. Indeed, this type of risk management is enshrined in occupational health law in many countries. This approach displaces the exposure problem to the individual rather than analyzing the workplace environment as a whole.

Cadmium is another toxic metal of increased importance; it is used in rechargeable batteries in modern electronic equipment such as mobile phones. Unfortunately, the manufacturing of cadmium batteries involves even more risks than lead battery production. Vigilant exposure monitoring and effective protection are essential to avoid chronic poisoning in the form of kidney and lung diseases (Friberg et al., 1986).

Another manufacturing industry commonly found in high-income countries is metal processing and metal working. Smelting and refining of any metal create a major potential for occupational exposures to many types of hazards, especially exposure to toxic metal dusts, sulfur dioxide, and other fumes. Because these industries often involve large-scale operations, even small concentrations of toxic compounds in the processes can yield substantial emissions into the workplace and the surrounding environment. The experience with lead smelters in many countries has produced similar outcomes: high lead exposures for workers and contamination of the local environment. Often the workers and their families live in the vicinity of the industry, and high lead exposures from dust emissions are found in children who live in the area (Baghurst et al., 1992). These exposure situations have been studied in detail in the United States and Australia, and epidemiologic research there has produced some of the most valuable quantitative data on the health risks of lead in children and workers (see Exhibit 11-2).

Service Occupations

Many service industries involve important occupational hazards. The services reviewed by the International Labor Organization include those characterized by specialized and sometimes severe hazards, such as emergency and security services (e.g., firefighting and law enforcement), public and government services (e.g., garbage collection and hazardous waste disposal), and healthcare services (Stellman & ILO, 1998). Occupations that are considered likely to have less severe hazards include retail trades, banking, administrative services, telecommunications, restaurants, education, and entertainment. Nevertheless, stress due to increased mental workload and various

forms of interpersonal conflicts in such settings can become major occupational health hazards.

Firefighting involves exposure to carbon monoxide and toxic fumes, as well as the heat from the fire itself. Injuries from falling debris, falls, or working in awkward positions are also of concern. Protection of workers depends on the availability and use of protective equipment, which may be in short supply in LMICs. Law enforcement is another high-risk occupation, as it involves hostile contacts with persons who may be armed.

Garbage collection exposes workers to risks of cuts and other injuries from the garbage itself, as well as ergonomic hazards (e.g., heavy lifting) and chemical hazards. A notable at-risk group in LMICs is the people who scavenge on garbage dumps for recyclable materials from which to glean a meager existence. Sometimes these scavengers actually live on the garbage dump, where they are subjected to risks of infectious disease, bites from rats and dogs, and other dangers. Because hazardous wastes are not always separated out from general wastes, their presence adds to the risks encountered by the garbage collectors and scavengers. In areas where hazardous wastes are separated, the storage and handling of these materials requires sophisticated protective equipment, detailed information about the hazards, and efficient management systems; these factors are often missing even in high-income countries.

Healthcare workers face hazards such as infections from patients, transmission of HIV or hepatitis from needlesticks, and allergies to medications or to cleaning and disinfection chemicals. More generally, the most common problem faced by these workers is ergonomic hazards from lifting or moving patients, which may lead to back injuries. This type of injury creates great problems for nurses and nurse aides, and in many cases curtails their careers. Another service occupation with particular occupational health hazards is the tourism industry.

One special hazard for people in service trades that involve continuous work at computer keyboards is the development of repetitive strain injury, also known as occupational overuse syndrome (Rosenstock et al., 2005). Repetitive keyboard finger work, or repetitive fine movement of the computer mouse, may create a wear-and-tear reaction in tendons and muscles that can lead to chronic pain. As with back problems, these painful conditions are not always accompanied by measurable anatomic or pathological changes, which has caused substantial arguments among medical practitioners as to the genuineness of the disease. However, as many people using modern computers attest, the short-term pain after intensive use of a keyboard or a mouse is real. Ergonomic design of computer workstations and the provision of regular work breaks are essential for preventing this occupational hazard. The height of the keyboard should be adjusted to the individual user.

Other Occupations

Among the other occupational exposure situations of particular importance, especially in LMICs, are cottage industries of various types. At an early stage of industrialization, small-scale operations based on family members may be the mainstay of certain industries. They may take the form of work contracted out from a larger enterprise, or the businesses may arise directly in relation to the local market. The production of handicrafts, clothing, and consumer items for local households may be the starting point, although more hazardous activities, such as recycling car batteries, may also develop initially as cottage industries. Such work may entail extreme exposures to toxic chemicals, with little or no protection either for the workers or for other family members. Ergonomic hazards, injuries, noise damage, and all other occupational hazards are likely to be a greater danger in these cottage industries than in larger, more organized enterprises.

Major Issues in Environmental Health

The next sections describe five current major issues in environmental and occupational health. These issues illustrate well the measurement, research and practice methods, boundary, and policy challenges that have been outlined so far, as well as including aspects of environmental and occupational health. All combine multiple environmental hazards and multiple sources for those hazards, with complex sources and interactions, acting at a range of scales, from the household to global. These five issues are indoor and outdoor air pollution, freshwater, food production, cities and the built environment, and climate change. The last is the most challenging global environmental health issue of our time, and it potentiates many of the environmental hazards discussed in the remainder of the chapter.

Air Pollution

Air pollution, a complex mixture of gases and particles, is one of the most important risk factors for disease. While thousands of compounds are found in air

pollution, governments tend to focus on a specific subset as indicators of the overall air quality. In this section, we primarily address small particles, one of the most commonly measured and best-understood air pollutants. According to the Institute for Health Metrics and Evaluation's Global Burden of Disease (GBD) study, exposure to small particles contributed to approximately 6.1 million deaths (11% of the total) and 163 million DALYs (6.8% of the total) in 2016 (IHME, 2016).

The discovery and "taming" of fire is an event described as the transition between the prehuman and human periods. Since this development, people have polluted the air both inside and outside of their homes, first for cooking and heating, and later for transportation and as by-products of industrial activity and waste disposal, among other sources. Air pollution now occurs at many scales:

- In households, where biomass fuels are still burned for cooking, heating, lighting, or for other tasks
- At local levels, where numerous sources (automobiles, industry, and natural events) degrade ambient air quality
- Regionally and globally, as transport of pollutants across boundaries results in impacts far from the original sources

The burden of ill health resulting from exposure to ambient and household air pollution estimated in the GBD study focuses on five endpoints: heart disease, stroke, lung cancer, and chronic obstructive respiratory disease in adults and lower respiratory infection in children under 5. The majority of ill health arises from exposure to $PM_{2.5}$—that is, particulate matter, or soot, with an aerodynamic diameter of less than 2.5 μm (depicted next to a human hair and a grain of beach sand for comparison in **FIGURE 11-6**).

Ambient and household $PM_{2.5}$ exposure rank among the top global risk factors for mortality and account for more deaths than many other better-recognized risk factors, including alcohol use, high body mass index, and high salt intake. These estimates most likely underestimate the true global health impact of air pollution, as new evidence points to associations with neurologic and cognitive deficits (Dix-Cooper, Eskenazi, Romero, Balmes, & Smith, 2012; Morales et al., 2009; Perera et al., 2006; Suades-Gonzalez, Gascon, Guxens, & Sunyer, 2015; Suglia, Gryparis, Wright, Schwartz, & Wright, 2008), diabetes (Eze et al., 2015), asthma (Oluwole, Arinola, Huo, & Olopade, 2017a, 2017b; Wong et al., 2013), other cancers (Josyula et al., 2015), and pregnancy and birth outcomes (Amegah, Quansah, & Jaakkola, 2014).

The remainder of this section provides overviews of household and ambient air pollution and briefly discusses regional dispersion of air pollution.

Household Air Pollution

Use of the oldest of human energy technologies—the home cooking and heating fire fueled by wood—began approximately 1.8 million years ago (Wrangham, 2009). As cultivation and farming took hold, so, too, did burning of agricultural waste, including animal dung and crop residues, for heating and cooking. Approximately 1,000 years ago, coal use peaked in several European countries, where it was easily obtained; coal is still used widely in China today (Smil, 1994). The three broad fuel types—coal, wood, and crop residues/dung—are still used as a primary source of energy for cooking and heating by approximately 40% of households globally. They are commonly burned in simple cookstoves, resulting in large amounts of smoke termed "household air pollution."

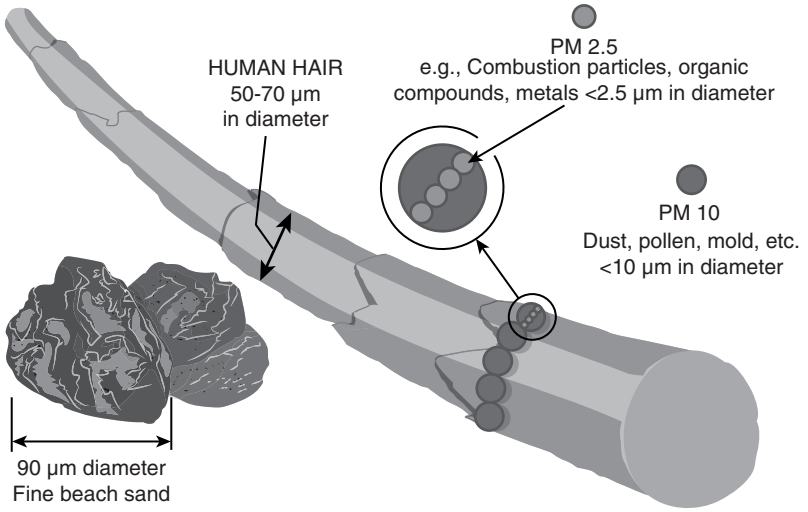

FIGURE 11-6 The size of $PM_{2.5}$ in comparison with a human hair, beach sand, and PM_{10}.

A useful framework for examining the trends and impacts of household fuel use is the "energy ladder." It ranks household fuels along a spectrum running from the simple biomass fuels (dung, crop residues, and wood), through the fossil fuels (kerosene and gas), to the most modern form (electricity). In moving up the ladder, the fuel and stove combinations that represent the higher rungs increase the desirable characteristics of cleanliness, efficiency, storability, and controllability. At the same time, capital cost and dependence on centralized fuel cycles tend to increase with upward movement on the ladder. Although local exceptions are possible, history has generally shown that when alternatives are affordable and available, populations tend to naturally move up the ladder to use of higher-quality fuel and stove combinations. Indeed, 60% of the world's population uses gas or electricity for nearly all of their cooking. The remaining 40% of the world's population is either still using wood or has been forced down the ladder by local wood shortages to crop residues, animal dung, or, in some severe situations, the poorest-quality fuels, such as shrubs and grass.

Exposure to household air pollution arising from cooking resulted in approximately 2.8 million deaths in 2016 (IHME, 2016). **TABLE 11-4** lists some of the many hundreds of health-damaging pollutants (HDPs) emitted as products of incomplete combustion from a range of household solid-fuel stoves. Even though biomass fuels might produce few wastes other than carbon dioxide and water when combusted completely, in practice as much as one-fifth of the fuel carbon is diverted to products of incomplete combustion, many of which are important HDPs (Naeher et al., 2007). Unfortunately, not only do solid-fuel stoves produce substantial HDPs, but a large fraction lack chimneys for moving the emissions out of the living area. Consequently, household air pollution concentrations can reach high levels for many HDPs, including $PM_{2.5}$ and carbon monoxide. For example, fine particulate levels often reach 20 to 40 times the WHO guideline level of 10 $\mu g/m^3$ set to protect health. Furthermore, in areas in which households have chimneys, heavily polluting stoves can produce significant local or neighborhood outdoor pollution. This is particularly true in densely populated urban slums, where such neighborhood pollution can greatly exceed urban average levels. Globally, it is estimated that approximately 12% of total ambient air pollution comes from household sources; in India, this contribution is approximately 26%, while in China it is approximately 10% (Chafe et al., 2014).

Coal, by comparison, not only is difficult to burn completely because of its solid form, but also can contain significant intrinsic contaminants. Most prominent among such emissions from coal are sulfur oxides, but in many areas coal smoke also contains arsenic, fluorine, lead, mercury, or other toxic elements that lead to serious HDPs. Recent meta-analyses provide strong evidence that exposure to hazardous air pollutants from coal smoke increases the risk of lung cancer. In fact, the International Agency for Research on Cancer (IARC) classified coal emissions as a Group 1 carcinogen (Hosgood et al., 2011; Straif et al., 2006; Zhang & Smith, 2007).

China provides a practical example of the dangers of coal smoke exposure and an effective initiative to reduce this exposure. Since the 1980s, this country has introduced more than 180 million improved stoves with chimneys—more than in all other LMICs combined. In Yunnan province, this strategy has led to a 50% reduction in the risk of lung cancer and chronic obstructive pulmonary disease (COPD) (Zhang & Smith, 2007).

Petroleum-based liquid and gaseous fuels, such as liquid petroleum gas and natural gas, may also contain

TABLE 11-4 Major Air Pollutants, Their Physical State, and Their Sources

Pollutant	State	Sources
Ozone	Gas	Generated from other pollutants and natural processes
Sulfur dioxide	Gas	Fossil fuel combustion, natural emissions
Carbon monoxide	Gas	Fossil fuel combustion
Nitrogen oxides	Gas	Combustion processes
Particulate matter	Particulate	Combustion, fertilizer use, dust storms
Hazardous air pollutants, including benzene, formaldehyde, dioxin, and others	Gas	Incomplete combustion, chemical processing, solvent use

Data from *IARC Monographs Volume 109: Outdoor Air Pollution* (2013).

sulfur and other contaminants, albeit in much smaller amounts than in many coals. Further, their physical forms allow for much better premixing with air in simple devices, thereby assuring substantially higher combustion efficiencies and lower HDP emissions. In addition, gas stoves tend to be much more energy efficient. Hence, the HDP emissions per meal from these fuels are at least an order of magnitude less than those from solid fuels.

One of the significant challenges to reducing the burden of disease associated with household air pollution is choosing a set of solutions that both decreases emissions of HDPs and is suitable to the household to the extent that they nearly entirely stop use of the older, polluting traditional stove. Modern, clean fuels—such as liquefied petroleum gas (LPG) or natural gas—or electric cooking are an ideal solution, but may remain out of reach of many households who either cannot afford or access these technologies. A number of improved biomass stoves have been created and have shown promising reductions in HDP emissions in the laboratory, only to perform poorly in the field or to be used only occasionally for specific tasks, negating their benefit. Much emphasis is currently placed on finding ways to make clean, modern fuels available to the poor through innovative policy programs, targeted social welfare investments, and other policy paradigms.

Outdoor/Ambient Air Pollution

Ambient air pollution has, in recent decades, become recognized as a global health problem (Health Effects Institute, 2017; Landrigan, 2016; Pope & Dockery, 2006; WHO, 2016), in large part due to a combination of strong epidemiologic evidence and recent and public air pollution episodes in India and China. Between 1990 and 2015, global, population-weighted $PM_{2.5}$ exposures increased approximately 11% (Health Effects Institute, 2017). This change reflected rapid increases in ambient air pollution in heavily populated areas, including large megacities of India and China, but ambient pollution levels also exceed guidelines in large parts of rural Asia as well. For example, approximately 90% of the global population live in areas where the ambient air pollution exceeds WHO's exposure guideline of 10 $\mu g/m^3$. Approximately 85% of those living with the most extreme average concentrations (greater than 75 $\mu g/m^3$) reside in China, India, Pakistan, and Bangladesh (Health Effects Institute, 2017). Note that the mortality impacts of air pollution are increased by high environmental heat exposures, as happened during the European heat wave in August 2003 (Dear, Ranmuthugala, Kjellstrom, Skinner, & Hanigan, 2005).

Unsurprisingly, there are differences in the patterns and levels of exposure to air pollution globally. In high-income countries, industrial and hazardous air pollutants from coal burning that proliferated in earlier eras has been largely replaced by pollutants from motorized transport that form photochemical smog, including ozone (a strong irritant that affects the eyes, upper airways, and lungs) in summer and a heavy haze of particulates and nitrogen oxides in winter (see Table 11-4 for common pollutants of concern and their major sources). Although many industrialized cities do not yet meet annual standards for every pollutant, conditions are generally much better than in the past, with cleaner cities becoming even cleaner, primarily in high-income countries.

In contrast, in LMICs, urban air pollution has reached alarming levels in many cities. In New Delhi, Beijing, and several other Indian and Chinese cities, for example, the annual average concentrations of particulates have been 5 to 15 times greater than the WHO guideline. In China, the main source of pollution is combustion of coal, though the transportation sector and household biomass combustion make only slightly smaller contributions to the deaths attributable to $PM_{2.5}$ pollution (GBD MAPS Working Group, 2016). Both the morbidity and the mortality in Chinese cities due to air pollution are estimated by some observers to be increasing (Chen et al., 2017).

Studies relating ambient air pollution levels to health risks were, until the 1970s, largely confined to examining the health impacts of particular extreme episodes of high outdoor air pollution levels. Subsequent studies, based on daily mortality time series, have elucidated the role of respirable particulates, including black carbon, ozone, sulfates, and nitrogen oxides in acute mortality (Schwartz, 1994). The advantages and attractions of daily time-series statistical analysis were discussed in the section "Study Design Options" earlier in this chapter. Long-term follow-up studies of populations exposed to different levels of air pollution, especially $PM_{2.5}$, indicate that the higher the levels of exposure, the greater the mortality risk.

For example, a 16-year follow-up of 550,000 people in the United States was used to link urban air pollution exposures to mortality with appropriate control of confounding factors (Pope et al., 2002) as part of the American Cancer Society cohort study. An increased mortality in cardiopulmonary diseases was identified, and the strongest relation to air pollution (indicated by exposure to $PM_{2.5}$) was found for lung cancer. Further quantification of the exposure–response relationships based on the same cohort and other studies is now available (Pope, 2009; Pope et al., 2004; Pope, Ezzati, & Dockery, 2009). Since the original study, numerous updates and continued follow-up have occurred (WHO, 2013b), with all showing

remarkably consistent findings. Additional cohort studies from Asia, Canada, and Europe have provided further evidence of the impact of long-term exposure to $PM_{2.5}$ on mortality.

Asthma, whose prevalence has been increasing in high-income countries for three decades, has a still unresolved relationship to external air pollution (Guarnieri & Balmes, 2014). A 2009 meta-analysis found that traffic-related air pollution (TRAP) contributed to the development of asthma symptoms in healthy children (Bråbäck & Forsberg, 2009; Pollock, Shi, & Gimbel, 2017), as did a 2017 systematic review and meta-analysis (Khreis et al., 2017), but other studies and reviews have yielded less conclusive results for ambient air pollution writ large. The apparent increase in the susceptibility of modern generations of children to asthma may derive from changes in human ecology that have altered early-life immunologic experience, such as reduced exposure to childhood infections (due to smaller family sizes) or increased allergenic exposures (e.g., house-dust mites or fungal spores).

Epidemiologists have developed a diverse, sophisticated set of methods for assessing the health impacts of air pollution. Nevertheless, the measurement issue remains bedeviled by difficulties in exposure assessment, the uncertain differentiation of acute and chronic effects, the need to sort out independent and interactive effects between air pollutants that are often highly correlated, and the fact that the air pollution profile keeps evolving as human activity patterns change. Although many uncertainties remain, there is agreement that significant health effects occur at pollutant concentrations that were previously considered benign. In the case of small particulates, which can penetrate deeply into the respiratory system, there is no evidence of a threshold exposure below which no effect occurs. As a consequence, policy makers are forced to decide which level of health risk is acceptable to determine an appropriate exposure standard.

Traffic and Transport

As cities grow in size, their urban transport systems expand and evolve. In particular, private car ownership has increased spectacularly over the past half-century, creating new opportunities and freedoms—and a new raft of social and public health problems (London School of & Tropical Medicine Public Health, 1997; Nieuwenhuijsen, 2016; Nieuwenhuijsen, Khreis, Verlinghieri, & Rojas-Rueda, 2016).

Transportation is one of the key polluters in the process of economic development, urbanization, and industrialization. In traditional subsistence agricultural societies, the community's basic needs could be met within a relatively localized distance. Increases in population size and density meant that specialized resources for the community, such as firewood, had to be acquired from increasingly distant sources, which creates transportation needs. Modern economic development has accelerated this process through further specialization of economic tasks and dependence on resources from distant areas. Energy sources, such as coal, must be transported from afar to sustain local cottage industries; such is also the case with food items to sustain people in places where little can be grown or gathered for much of the year.

Today, the automobile has become the dominant source of air pollution in many cities. The World Bank and IHME estimate that pollution from vehicles is responsible for 184,000 deaths globally (Bhalla et al., 2014). Current technical solutions to this problem include making car engines more energy efficient and using pollution-control devices, such as catalytic converters. The obvious, more radical solution is to reduce dependence on car traffic by encouraging people to walk and to travel by trains, buses, or bicycles. Such measures, carried out as part of a clean air implementation plan, can significantly reduce automotive air pollution, as has been shown in certain towns in the United States and Germany (WHO, 1997). The unprecedented action to reduce emissions that took place during the 2008 Beijing Olympics provides a profound example of the potential efficacy of clean-air implementation plans. Pollution-control measures instituted during that period included limiting automobile usage, closing heavy industrial facilities, and pausing construction work. Collectively, these strategies resulted in a 54% reduction in particulate matter of 10 μm or less and subsequently a 46% reduction in outpatient visits for asthma during the two weeks of the Olympics (Li, Wang, Kan, Xu, & Chen, 2010).

In cities in LMICs, transportation problems have grown even faster. Whereas in Europe a local transport infrastructure based on railways, trams, and buses was already in place when the car boom emerged in the 1960s, LMICs often have negligible transport infrastructure. Hence, with increasing affluence and urbanization, the automobile is seen as the best solution for individual families. As a consequence, cities such as Mexico City experienced a rapidly deteriorating air pollution situation during the 1980s and 1990s (Davis, 2017). However, the recent experience of Mexico City also provides a case study of attempts to reduce car-generated air pollution (Davis, 2017).

Since the first oil crisis in the 1970s, the average fuel efficiency of the world's automobiles has increased substantially, largely through major improvements in North American car manufacturing through the mid-1990s that brought these vehicles' efficiencies nearly

to European levels. Emissions of air pollutants have also been greatly reduced, partly through combustion modifications and partly through extensive application of end-of-pipe controls, in the form of catalytic converters. Nevertheless, if the number of automobiles in LMICs continues to grow as it has in recent years, unacceptable air pollution levels will undoubtedly persist for many decades despite the application of even the best current automotive pollution-control technologies.

Regional Dispersal of Air Pollutants

Following the surge of industrial growth in high-income countries following World War II, the transboundary problem of acid deposition (commonly referred to as "acid rain") became increasingly problematic. It was featured prominently at the 1972 United Nations Conference on the Human Environment in Stockholm. By that time, eastern Canada was experiencing problems from acidic emissions traveling northeast from the United States, and Scandinavia was exposed to emissions from the United Kingdom and highly industrialized areas of West and East Germany. More recently, the strong increase in China's industrial production has subjected Japan to acid deposition from that source. Acid levels are also rising in other parts of Asia as energy use grows across the entire region.

The hazards to human health from this source are neither extreme nor direct. Nevertheless, the acidification of waterways and soils has demonstrably increased the mobilization of various elements—particularly heavy metals and aluminum—that enables them to enter the drinking water and the food chain. Human exposures to these elements have, therefore, increased in several regions.

The El Niño event of 1997–1998 created unusually strong drought conditions in Southeast Asia, which exacerbated the size and duration of forest fires originally lit to clear land. The result, in addition to extensive damage to the forests, was regional air pollution in the form of wood smoke plumes that extended over thousands of miles and could readily be seen by satellites. The forest fires raised outdoor particulate levels to several times the acceptable upper limit in a number of large cities in the region for a period of days to weeks, apparently with significant accompanying adverse health effects. Although it was larger in 1997–1998 than in previous years, the same phenomenon has actually been occurring for decades in the region, and is likely to be repeated in the future unless land-use practices are drastically modified.

Another issue of importance is the development of atmospheric "brown clouds" caused by the confluence of urban air pollution from the numerous cities and major industries in Southeast Asia, India, China, and elsewhere in the world (Ramanathan et al., 2005; Ramanathan & United Nations Environment Programme [UNEP], 2008). These high-level "clouds" result from ground-level emissions, which also cause outdoor air pollution levels to exceed air quality guidelines in large areas of Asia, even those regions located far from cities.

Freshwater

Ever since hunter-gatherers turned to cultivation and settled living, sanitation and unsafe drinking water have been health problems for human societies. Further, although nearly two-thirds of the Earth's surface consists of water, only 2.5% of this is freshwater, and only 11% of this freshwater is available for human use. Political and institutional factors operate on top of this scarcity to create a global water shortage. As the global population grows, direct pressures on local sources of fresh drinking water increase, as do indirect pressures, particularly from the increases in agricultural production required to support the ever-growing population. Despite efforts to mitigate unsafe sanitation and drinking water having been associated with the largest reductions in deaths and DALYs over the past decade, these problems remain among the top 30 risk factors for early deaths and disease, with unsafe water ranked number 16 and unsafe sanitation ranked number 21 on that list (Gakidou et al., 2017).

The management of freshwater perhaps demonstrates most clearly the addition of habitat approaches to existing and ongoing efforts dealing directly with environmental hazards. Clean water and sanitation is one of the 17 Sustainable Development Goals, as well as having a role in Goal 1: No poverty (United Nations, 2015b). Specific targets by 2030 under Goal 6 reflect an ongoing need to improve sanitation (e.g., Target 6.2: Achieve access to adequate and equitable sanitation and hygiene for all and end open defecation), reduce hazardous pollution (e.g., Target 6.3: Improve water quality by reducing pollution, eliminating dumping, and minimizing release of hazardous chemicals and materials), and ensure integrated management of water ecosystems (e.g., Target 6.5: Implement integrated water resource management at all levels, and Target 6.6: Protect and restore water-related ecosystems).

Hazards from Poor Sanitation and Contaminated Drinking Water

Unsafe sanitation and drinking water remain widespread health hazards in the world, particularly in LMICs in semiarid regions. More than 840 million people, almost all in LMICs, have inadequate access to water, and 2.3 billion people still lack basic sanitation (WHO &

UNICEF, 2017). In 2016, a lack of access to clean drinking water, appropriate sanitation, and hygiene facilities resulted in more than 1.6 million deaths from diarrheal diseases around the world (Gakidou et al., 2017) (see also the *Infectious Diseases* chapter).

Two factors need to be taken into account when evaluating the relationship between health outcomes and access to clean drinking water. Most prominent are the linkages between household water availability and the health burden attributable to diarrheal diseases. In addition, intense rainfall and drought play crucial roles in facilitating waterborne outbreaks of diseases through both surface water and piped water supplies (Confalonieri et al., 2007).

Diseases related to water supply can be classified based on their route of transmission. Waterborne diseases, such as cholera and campylobacteriosis, are a result of the ingestion of contaminated water. Water-washed diseases, such as *Chlamydia* infection and scabies, are caused by a lack of hygiene secondary to a lack of water. Some classifications also include categories for water-based diseases, which include schistosomiasis, and diseases transmitted by water-related vectors, with malaria being the typical example.

A lack of sanitation may lead to the contamination of drinking water, highlighting the intertwined nature of these two problems. The waterborne illnesses associated with poor sanitation make the greatest contribution to the overall economic costs of sanitation. In 2015, India suffered the greatest costs associated with health spending, productivity losses, and labor diversions due to inadequate sanitation and clean drinking water, with these costs exceeding $100 billion, more than 5% of India's gross domestic product (GDP) (Lixil, WaterAid Japan, & Oxford Economics, 2016). This figure outstripped the total aid flows and debt relief provided to the country in that year.

The main barrier to improving sanitation facilities is a lack of political will. By ensuring access to clean water and adequate sanitation facilities, the fecal–oral transmission pathway is interrupted, resulting in an enormous flow of improvements in health, poverty reduction, and economic development.

Fecal contamination of drinking water is not isolated to LMICs. Rising income inequalities and poverty in the United States have meant that some low-income populations in southern states continue to have poor sanitation and hygiene. A recent prevalence study of infection with the intestinal nematode *Necator americanus* (American hookworm), focusing on one of the poorest counties in Alabama, found that more than 30% of those people tested were infected with hookworm or other gastrointestinal parasites (McKenna et al., 2017). The implications for anemia, childhood stunting, and poor education make this a significant environmental justice issue.

Although most short-term illness from contaminated drinking water comes from microbial contaminants, chemical pollution of freshwater is another significant issue, often having longer-term impacts on victims following prolonged exposure. These impacts are difficult to quantify because of the long lag between exposure and outcomes, multiple sources of exposure to the same chemicals, and multiple chemicals with similar effects being present in water sources. In addition, only a minority of the more than 140,000 chemicals that have been manufactured since 1950 have been tested for their effects on human and ecological health, either singly or in combination (Landrigan et al., 2017). Chemical contaminants can occur naturally as a result of geological factors (arsenic in the groundwater of Bangladesh, Nepal, and West Bengal is a good example; Argos et al., 2010), or they can be anthropogenic, resulting from industrial or agricultural pollution or from the water treatment and distribution system itself. The WHO (2017) guidelines for drinking water quality include specific guideline values for 8 naturally occurring chemicals, 21 industrial chemicals (of which mercury has the greatest health burden), and agricultural source chemicals (nitrate, nitrite, and 25 agricultural pesticides).

Land Use and Water Engineering

Regional tensions over freshwater supplies are increasing in many locations as population pressures increase and an increasing proportion of agricultural production comes to depend on irrigation (Grimm et al., 2006). Water is essential for household hygiene, communal sanitation, and economic vitality.

During the third quarter of the 20th century, it became clear that large-scale human interventions in the natural environment—dams, intensification of livestock agriculture, irrigation schemes, land reclamation, road construction, and population resettlement programs—often affected infectious disease patterns. In particular, the composition of vector species generally changes following alterations in environmental conditions. Such large-scale developments in the eastern Mediterranean, Africa, South America, and Asia have been consistently associated with increases in vector-borne diseases, especially schistosomiasis and filariasis. In the Sudan in the 1970s, for example, schistosomiasis appeared soon after the start of the Gezira scheme, a large irrigated cotton project; the prevalence of malaria also increased markedly in this region (Fenwick, Cheesmond, & Amin, 1981; Gruenbaum, 1983). In Africa, the building of large dams in the Sudan, Egypt (the Aswan High Dam),

Ghana, and Senegal caused the prevalence of schistosomiasis in the surrounding populace to increase from very low levels to more than 90% (WHO, 1997).

Again, these interactions between land use and infectious disease patterns are not limited to LMICs. As a salutary example, in 2015 New Zealand experienced the largest waterborne campylobacteriosis outbreak in its history, when more than 5,000 people had a notified gastrointestinal illness in the town of Havelock North (population 13,000). The outbreak involved a complex interplay of factors: An extended period of drought was followed by a heavy rainfall event; poor groundwater management left an insecure water bore; and the area had seen increasingly intense development of sheep and dairy farming, with agricultural run-off as the source of contamination (Government Inquiry into Havelock North Drinking Water, 2017).

Integrated Catchment Management

While there has appropriately been a heavy focus on improved sanitation, and on the regulation, monitoring, and treatment of individual hazards in drinking water, it is increasingly being recognized that protecting source waters from contamination is both a crucial and cost-effective step to improve human and ecological health (WHO, 2017). Increasingly, this involves considering and planning the management of water catchments and surrounding land uses together.

Developing integrated catchment and land-use management plans requires a significant shift from top-down, centralized, regulatory approaches to significant intersectoral and *transdisciplinary* effort, bringing policy, community, and scientific citizens together. Behind these more integrative approaches is the understanding that watersheds have a range of influences on health that are wider than the physical health impacts of drinking water contamination, encompassing the social, ecological, economic, and cultural building blocks of health (Parkes, 2016). Often these implications for health are not explicit in integrated catchment planning, but instead remain hidden among discussions about "ecosystem services" (Stosch, Quilliam, Bunnefeld, & Oliver, 2017), "social outcomes" (Bunch et al., 2014), or ecological "conservation," which also must encompass protecting ecological integrity for human health (Horwitz & Finlayson, 2011). These interconnected ways of considering integrated catchment management have been described as facets on a prism (Bunch et al., 2014), as shown in **FIGURE 11-7**. When only a limited number of these perspectives are included in planning, then crucial aspects are likely to

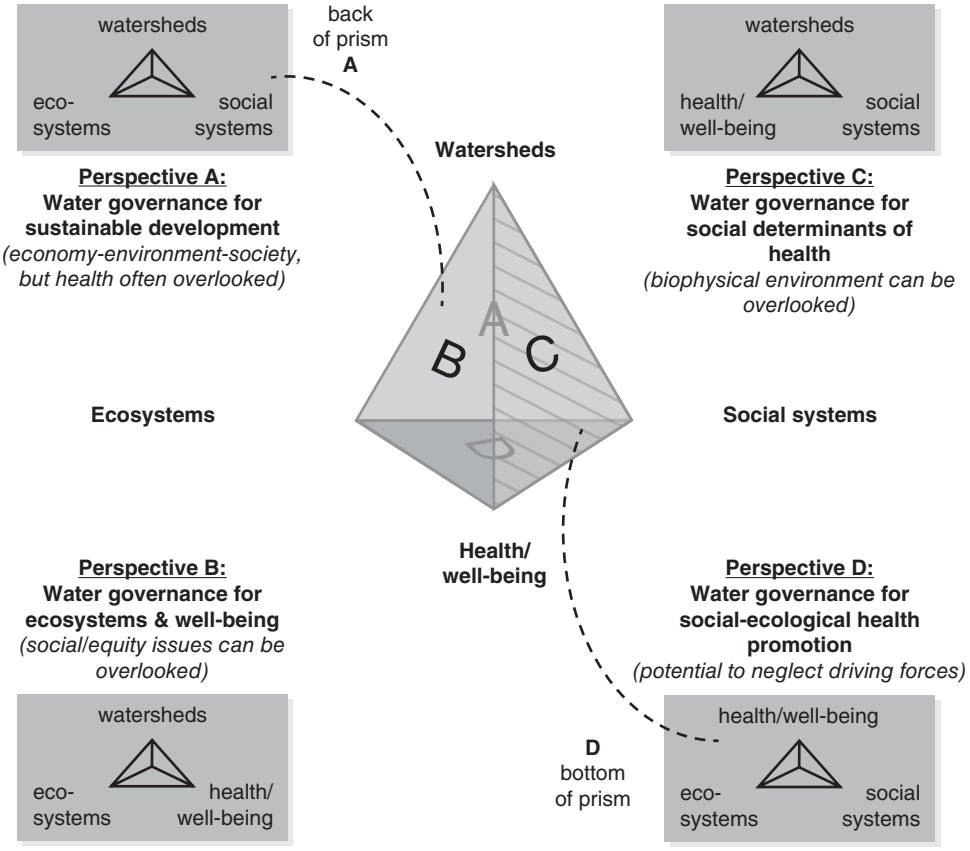

FIGURE 11-7 Watershed governance prism for integrated catchment management.

be overlooked. Unfortunately, examples where health systems, social systems, and ecological systems come together in catchment and land-use planning are generally lacking, despite ongoing recommendations and the development of tools to facilitate such collaboration (Horwitz & Finlayson, 2011; Stosch et al., 2017).

One successful example of integrated catchment and land-use management with the objective of protecting health through drinking water is New York City's Watershed Protection Program (Smith & Porter, 2010). Unfiltered and untreated water from reservoirs in three major catchments supplies New York City's 9 million residents. The water supply has been able to avoid filtration and disinfection requirements through a Watershed Agricultural Program (Watershed Agricultural Council, 2017) voluntarily involving 90% of farmers in the catchments (with funding to minimize agricultural sources of pollution and create run-off barriers), land acquisition, and wider community-based water protection through partnerships between community representatives, local and regional policy makers, and scientists to manage local septic systems, storm water, agriculture and forestry, and riparian planting. As a result of the program, two catchments supplying New York City's drinking water have been able to meet national quality standards without needing to be treated (NYC Environmental Protection, 2017).

Food Production

The world's population continues to grow, projected to reach 9.8 billion people in 2050 and 11.2 billion in 2100 (United Nations, Department of Economic and Social Affairs Population Division, 2017). The overall production of food has so far kept pace with levels of population growth, though it is distributed unevenly among countries. In addition to population growth, economic development, per capita food consumption (particularly of meat and dairy), and the increasing use of food crops for biofuel are currently putting pressure on global food production systems. Environmental factors such as soil, climate, and water supply are all central to the success of food production. Agriculture and fisheries workers are exposed to a wide variety of occupational hazards, many of which were described in the "Occupational Health" section of this chapter.

The "Green Revolution," which has to date allowed food production to increase with population growth, has involved increased mechanization, chemical inputs, monoculture cropping, and livestock intensification. All of these advances have had complex implications for environmental health as a by-product of their inarguable and measurable improvements in overall global nutrition. While industrialization and commodification of agriculture and livestock production have occurred in high-income countries, much of the world's population continues to rely on small-scale subsistence farming. The Green Revolution depended on the introduction of laboratory-bred, high-yield cereal grains, along with fertilizers, groundwater, and arable soils. In retrospect, the productivity gains associated with this agricultural trend appear to have come substantially from using up exhaustible ecological capital—especially topsoil and groundwater. Even as greater food yields to feed ever more people are pursued, almost one-tenth of the world's population remains malnourished in ways that impair health.

Meanwhile, at sea, since the 1970s an increasing proportion of wild-caught marine fish stocks have been overfished. The Food and Agriculture Organization (FAO) of the United Nations estimates that approximately 90% of marine fish stocks are now either overfished or fully fished, with nearly one-third of stocks currently fished at unstainable levels (FAO, Fisheries and Aquaculture Department, 2016).

The increasing length of food supply chains and the greater movement of food between countries have also meant food contamination can be spread rapidly across borders, while investigating and addressing the contamination source has become more difficult. Climate change will both impact global food production (see the *Nutrition* chapter) and require a transition to net zero-carbon food production systems as part of the needed low-carbon society, while continuing to accommodate increasing demand from growing populations. At the same time, it is increasingly being recognized that the intake side of the obesity equation is in major part the result of a complex interplay among physical, social, and policy environments shaping the availability, affordability, attractiveness, advertising, and hidden content of unhealthy and healthy foods (Allen, Prosperi, Cogill, & Flichman, 2014).

In synthesizing these issues, the FAO in 2010 published a scientific consensus definition of sustainable diets:

> [T]hose diets with low environmental impacts which contribute to food and nutrition security and to healthy life for present and future generations. Sustainable diets are protective and respectful of biodiversity and ecosystems, culturally acceptable, accessible, economically fair and affordable; nutritionally adequate, safe and healthy; while optimizing natural and human resources.

Land-Use Change

Increases in the amount of land available for growing crops and livestock in response to population and

consumption pressures have most often come at the expense of natural habitats, inevitably reducing indigenous biodiversity. We currently use half of all global vegetated land for food production (Searchinger et al., 2013). On a worldwide scale, the increased proportion of land used for crops and livestock is the main driver of deforestation, especially in tropical and subtropical regions (FAO, 2017). This trend has had complex and often significant negative effects on local disease patterns, though surprising positive effects have occasionally been noted.

For example, deforestation has had variable effects on malaria mosquito vectors. In some parts of Southeast Asia, deforestation has enabled malaria-transmitting *Anopheles punctulatus* species to become established. In contrast, several *Anopheles* species, including *A. dirus* in Thailand and *A. darlingi* in South America, have disappeared following deforestation that removed the flora and fauna on which they depended for feeding.

In South America, forest clearance during recent decades to extend agricultural land has also mobilized various viral hemorrhagic fevers that previously circulated quietly in wild animal hosts. For example, the Junin virus, which causes Argentine hemorrhagic fever, naturally infects wild rodents. Extensive conversion of grassland to maize cultivation stimulated a proliferation of the reservoir rodent species, which in turn exposed human farmworkers to this "new" virus. In the past 35 years, the land area where this new human disease is endemic has expanded many-fold, with several hundred cases of infection occurring annually, as many as one-third of whom die (Chomel, Belotto, & Meslin, 2007).

Deforestation also disrupts hydrological cycles, most markedly those governing tropical rainfall. At a more local scale, reductions in rainfall and increased probability of drought can undermine the productivity of the newly available farmland and threaten drinking water supplies (Lawrence & Vandecar, 2015). At a much larger scale, the Amazon rainforest, which accounts for 40% of the total global tropical forest area, has undergone rapid land-use change, with more than 20% of its original area lost by 2017. This has had an aggregate regional impact by creating greater divergence in rainfall patterns, with some areas becoming wetter while others become drier (Khanna, Medvigy, Fueglistaler, & Walko, 2017).

Fertilizer Use and the Nitrogen Cycle

Nitrogen is a vital input in food production. Until the beginning of the 20th century, farmers relied on crop rotation, nitrogen-fixing crops, and animal manures to increase the amount of nitrogen in their soil and maintain crop production. The Green Revolution was largely a result of development of the Haber-Bosch nitrogen fixation technology, which allowed ammonia to be produced so that bioactive nitrogen could be applied to soils in the form of synthetic urea fertilizers. Human production and application of nitrogen fertilizers now roughly equals the total natural amount fixed by all non-agricultural organisms on Earth, fundamentally altering the global nitrogen cycle, together with fossil fuel use more generally (Bouwman, Beusen, & Billen, 2009).

Although this has largely been a positive development for human health, with as much as half of global dietary protein now reliant on synthetic fertilizers, there are also significant negative impacts as nitrogen (and phosphorus) is washed into ground and surface waters, including drinking water. Groundwater contamination with nitrates exceeding the WHO guidelines is common as a result of increasing agricultural intensity, which requires concomitant increases in fertilizer use. The most well-established direct health effect is methemoglobinemia, particularly in infants, although further research is needed to understand the long-term health effects of exposure (Villanueva et al., 2014; Ward et al., 2005). Further, multiple indirect pathways between nitrate contamination of freshwater ecosystems and health exist. Increased levels of nitrogen in freshwater increase toxic cyanobacteria blooms (O'Neil, Davis, Burford, & Gobler, 2012), which can also facilitate the rapid growth of *Vibrio cholerae*, precipitating cholera outbreaks (Constantin de Magny et al., 2008). These ecosystem impacts are potentiated by climate change influences on freshwater, including rising water temperatures and changing rainfall patterns.

Microbiological Contamination of Food

Diarrheal disease from contaminated water and food remains one of the world's great global health problems, as discussed earlier in the section on household-related risks. Although this hazard is, in a sense, generated at the household level, failure to initiate community controls can lead to large-scale outbreaks.

An important example is cholera, whose incidence spread worldwide during the 1990s. During that decade, the largest ever cholera pandemic caused cases throughout Asia, the Middle East, Europe (occasionally), Africa (where the disease became endemic for the first time), and Latin America (where it spread widely during the 1990s), affecting more than 1 million people and causing 10,000 deaths. Meanwhile, an apparently new epidemic of cholera was detected in the early 1990s, appearing first in southern India and caused by a new strain (number 0139) of *V. cholerae*. The spread of cholera has been greatly enhanced by the increasing number of slum dwellers in LMICs, the speed and

distance of modern tourism, and an apparent increase in extreme weather events, such as the massive El Niño–associated floods in Kenya in 1997 that caused epidemics of cholera in two regions of the country. In addition, the aftermaths of earthquakes, such as the one in Haiti in 2010, have led to local epidemics of cholera because of poor water and sanitation facilities.

In the villages and slums of LMICs, poor household water quality and sanitation often lead to food contamination. The widespread and unregulated commercial street-food sector in cities offers additional opportunities for exposure. Food contamination remains a concern even in high-income countries, where food is supplied to most of the population via long agriculture, processing, and distribution chains.

The reported rates of food poisoning have increased in high-income countries during the past two decades. The spread of the potentially lethal toxin-producing *Escherichia coli* in North America and Europe in the mid-1990s appears to have accompanied beef imported from infected cattle in Argentina. As long-distance trade expands, as commercial supply lines lengthen in large cities, and as people more frequently opt for convenience or fast foods, the opportunities for foodborne illness increase.

The intensification of meat production is another hotspot for infectious disease problems, as evidenced by three examples: the development of "mad cow disease" in Great Britain and its human counterpart (a variant of Creutzfeldt-Jakob disease); the outbreak of a new strain of influenza in chickens in Hong Kong in 1997; and the surprise appearance in 1999 of the newly named (and often fatal) Nipah virus in intensively produced Malaysian pigs and in several hundred human contacts, many of whom died (Weiss & McMichael, 2004).

Chemical Contamination of Food

Chemical contamination of food derives from three sources: (1) industrial wastes and emissions and household and agricultural chemicals (**EXHIBIT 11-5**); (2) chemicals that form during the storage and handling of food, such as the biotoxin aflatoxin; and (3) natural chemical contaminants. Because changes in land-use patterns are typically accompanied by changes in population density, population mobility, pesticide usage, and regional climate, it is difficult to state with authority any specific causal explanations for chemical contamination of food. Indeed, many of the health outcomes result from interactions between these various change processes.

Several major food contamination episodes in which chemicals were implicated have occurred in Europe. Most recently, in 2008 in China, baby milk formula supplied by a company owned by the New Zealand dairy giant Fonterra was contaminated with melamine, resulting in the deaths of 6 children from kidney disease, and the hospitalization of more than 50,000 children (Ingelfinger, 2008). In 2017, eggs from the Netherlands were contaminated with the insecticide fipronil and then shipped to 15 European Union countries, prompting a recall. These two examples demonstrate the potential for the rapid globalization of such environmental problems in the modern free-trading world.

EXHIBIT 11-5 Learning from Bitter Experience: The Banning of Methylmercury Fungicides

The infamous methylmercury poisoning catastrophe in Minamata, Japan, in 1956 highlighted the severe health problems that could occur after environmental pollution with organic chemicals (ILO, 1990). The same chemical was used in the 1950s and 1960s to prevent fungal growth, which has the potential to impair crop-seed viability and cause mold damage in paper pulp. The use of this fungicide in the paper industry increased the concentrations of mercury in paper manufacturing factories' wastewater, which in turn led to methylmercury contamination of fish. In the late 1960s, Swedish ornithologists had identified both this source and the use of fungicide-treated seeds as a potential cause of infertility in wild birds. A major environmental pollution debate followed, and eventually these fungicides were banned—not only in Sweden, but also in most countries with functioning regulatory systems.

In 1971, Iraq received a large consignment of fungicide-treated wheat seeds from USAID. The shipments arrived when much of rural Iraq was suffering from severe drought, and farming families had little food. The seeds for planting had been dyed red to indicate that they should not be eaten, but the farmers soon found out that washing the seeds in water eliminated the dye. Unfortunately, the fungicide stayed in the seeds. The farmers then used the seeds to make bread, and about 2 months later a major epidemic of serious neurologic diseases began. Eventually 500 people died and approximately 5,000 were hospitalized from eating the tainted seeds.

The Iraqi disaster was the largest known epidemic of this type. Previously some smaller outbreaks had occurred in Africa from the same seed fungicide. After the Iraqi epidemic, a new level of awareness arose about such problems, and the use of this fungicide was subsequently banned in most countries. This intervention represents an example of successful chemical safety management, based on the scare caused by a major epidemic of toxicity.

In the future, addressing the environmental health challenges of the food system while continuing to increase production will require more integrated thinking about land use and farming practices, as well as a global redefinition of healthy diets to incorporate sustainability. Such a dietary shift will need to involve reductions in the consumption of resource-intensive calories and animal-based proteins (especially beef), While realistic targets to increase food production are needed, these must be accompanied by a range of ecological limits and targets—for example, for water pollution, land degradation, deforestation, nitrates use, and greenhouse gas emissions (Hunter, Smith, Schipanski, Atwood, & Mortensen, 2017). Environmental health researchers and practitioners, together with ecologists, have a role in identifying the human health elements of such targets, integrating environmental and health impacts in agricultural and nutrition research, and ensuring the findings are centralized in agriculture and food policies.

Cities and the Built Environment

Across the world, most people spend most of their time inside artificial structures or in other environments that have been deliberately shaped by human design. The importance of the built environment is likely to grow in the future. All around the globe countries are experiencing a spectacular shift of their populations into cities, an environment par excellence that is shaped by human design: The urban population has roughly doubled since 1990, and now includes more than half the people on the planet (UN Habitat, 2016). The damage to health caused by hazards in the built environment is enormous, but so are the gains that can be achieved by wise action. In other words, this aspect of environmental health deserves attention because the stakes are high and the causes of illness and injury are amenable to change.

In the space of half a century, the city has become the predominant human habitat. Indeed, urbanization is one of the defining features of the great acceleration of production, consumption, drawdown on natural resources, and pollution on a global scale (Steffen, Broadgate, Deutsch, Gaffney, & Ludwig, 2015). In official terms, cities are "large settlements," with the size of the settlement that qualifies for city status varying from one jurisdiction to another. In New Zealand, the minimum number is 50,000; the largest Chinese city by the end of the century will contain more people than the present population of Japan.

What defines a city more precisely is the social dynamic. According to Giovanni Botero (1544–1617), the city is "an assembly of people, a congregation drawn together to the end that they may thereby the better live at their ease in wealth and plenty" (Botero & Symcox, 2012). In other words, in cities the whole is greater than the sum of the parts. These are venues of opportunity. Cities thrive according to the density, variety, and connectedness of their populations, and the novel and creative outcomes that emerge when these elements are combined. "Great cities," wrote Jane Jacobs (1916–2006), "are not like towns, only larger. They are not like suburbs, only denser. They differ from towns and suburbs in basic ways, and one of these is that cities are, by definition, full of strangers" (Jacobs, 1961). Cities benefit human health and well-being in many ways, as is evident in the widening gap in the United States and other countries between the life expectancies of urban and rural populations; in the United States in 2005–2009, these were 79.1 and 76.7 years, respectively (Singh & Siahpush, 2014). Better access to education, employment, and health care are part of the explanation for this phenomenon, as are the chances available in cities for social mobility and economic advancement.

However, the features of cities that draw people in and help explain their astonishing productivity (in 2025, the largest 600 cities are projected to generate more than 60% of global GDP) also warrant health warnings. More people closer together, for instance, offers opportunities for the emergence and spread of infectious disease. What is important in this context is not only the population density (from the pathogen's point of view, this means the distance to the next host), but also the population size, the turnover, and the proportion of susceptible individuals: Ultimately, what matters most to the pathogen is the distance to the next *non-immune* host.

The history of cities includes the arrival of pathogens, their establishment, and eventually, in some instances, coexistence with human hosts and declining virulence. For instance, measles and rubella require large, close-living populations (in the range of 100,000 to 500,000 people) to be sustained. For this reason, it is unlikely they were endemic (i.e., established without the need for reinfection from outside) before about 5000 BP, when human settlements reached critical size. The first cities enabled economic specialization and innovation, but at the same time "opened up new niches for nimble microbes" (Woodward, 2014). Modern cities, particularly those distinguished by poverty, conflict, and pollution, continue to provide fertile environments for modern diseases such as HIV/AIDS, cholera, dengue, and tuberculosis (TB).

Other products of dense urban environments include noise, air pollution, and road traffic crash injuries; all of these health risk factors are described in detail elsewhere in this chapter. Heat waves are often more threatening in city centers, where temperatures may be higher than in the leafier suburbs and the surrounding countryside, and where the relief of nighttime cooling is lessened (Hajat, O'Connor, & Kosatsky, 2010). The "heat island" effect is not a necessary consequence of cities: It is typically associated with large heat-retaining structures and treeless asphalt expanses. Cities that feature abundant large street trees, green roofs, urban wetlands, and widespread use of reflective building materials are less likely to be affected.

Basic requirements of healthful living such as provision of shelter, clean water, and sanitation are still a challenge in many cities. UN Habitat (2016) estimates that the proportion of the urban population living in slums in LMICs fell from about 39% in 2000 to 30% in 2014, but the absolute number of people in these environments increased from 791 million to approximately 881 million over the same period. Improvements in sanitation and water supplies have been uneven, with lower coverage in sub-Saharan African cities and south Asia. Conflict and war still cause enormous health problems: The fastest-spreading outbreak of cholera in modern history occurred in 2017 in Yemen, due to population displacement, destruction of homes and infrastructure, and failure of health services. Farther afield, the surge in involuntary migration has placed extraordinary pressures on cities in many countries (UN Habitat, 2016).

The health risks of modern cities apply not just to local populations, but worldwide. Cities generate most of the pressures that today jeopardize the sustainability of current human ecology (Rees, 1996). Urbanism provides opportunities to improve environmental efficiency, including economies of scale in heating, lighting, and waste disposal; shared use of resources; and potential for reuse and recycling. Unfortunately, these opportunities have not matched the rate of growth in people and consumption. The highly urbanized Netherlands, for example, consumes resources from a total surface area approximately 20 times larger than its own geographical footprint. In the 1990s, the estimated consumption of resources—wood, paper, fibers, and food (including seafood)—by 29 cities of the Baltic Sea region, and the absorption of their wastes, depended on a total area 200 times greater than the combined area of those cities (Folke, Larsson, & Sweitzer, 1996). In 2016, UN Habitat estimated that cities account for 60% to 80% of energy consumption and approximately 70% of greenhouse emissions worldwide. The scale of these externalities of urbanism is growing, and includes massive contributions to global greenhouse gas accumulation, stratospheric ozone depletion, land degradation, and coastal zone destruction. The air pollution externalities were described earlier in this section.

A good deal of thought is now applied to building healthier places with an eye toward co-benefits. This means moderating urban form and function to achieve local health gains (by reducing particulate pollution, for instance), while simultaneously shrinking the ecological footprint. Urban transport systems offer many opportunities for win–win interventions of this kind (Shaw, Hales, Howden-Chapman, & Edwards, 2014). City planning and land-use regulations may be deployed to cut vehicle traffic, promote positive social interactions, improve access to social services, and increase opportunities for physical activity. Cities that have to some extent achieved these goals include Bogota, New York, and Seoul (Montgomery, 2013). Recent investments in Copenhagen in blue-green infrastructure along the coast are expected to take the edge off heat waves, improve air quality in the city, promote biodiversity, reduce storm run-off, increase local amenities for residents and visitors, and boost tourism (Institute for European Environmental Policy et al., 2016).

Housing

Housing is a basic human necessity, and its lack, or deficiency, affects environmental health in complex, interactive ways (Macmillan et al., 2016). These impacts may be direct, resulting, for instance, from exposures to physical hazards such as smoke from unvented stoves or allergens released from damp, moldy walls. There may also be less direct, but equally important, effects of inadequate housing on mental health, social functioning, and educational opportunities. In many cities, the high cost of housing is one of the most common causes of financial hardship, with negative consequences for health.

At a basic level, healthy housing depends on ventilation, drainage, lack of crowding, materials that resist pests, design that limits injuries, and insulation from sun, wind, cold, and heat. All of these factors have a significant influence on health. Indeed, much of the improvement in health that occurred in western Europe and North America during the latter part of the 19th century and early part of the 20th century may be attributed to improvements in what have been called "dreadful enclosures"—the urban slums built early in the industrial era to provide for the factory workforce (Preston, 1991).

Because the home is where much human activity takes place, the potential for damaging exposures in households is high if pollutants are present. Two of the most fundamental and mundane human household activities—defecation and cooking—produce significant volumes of potentially health-damaging waste products. When human waste is not removed completely, there is a risk of contamination and outbreaks of diarrhea and other waterborne diseases. As described in the "Air Pollution" section, when the smoke from cooking fires fueled with wood, coal, and other low-quality fuels is released indoors, this pollution may lead to respiratory diseases and other adverse health effects. Indeed, collectively these two environmental health factors account for a substantial fraction of the total environmental burden of ill health globally (Prüss-Üstün et al., 2016).

In some parts of the world, housing conditions substantially influence the risk of infectious diseases spread by vectors. In tropical countries, residences should be situated so that they avoid breeding sites for insect vectors of disease. Good drainage around the home and elimination of any sites where water can stagnate and mosquitoes can breed are of great importance in preventing malaria and dengue fever. In parts of Latin America, the prevention of Chagas disease (South American sleeping sickness) and the elimination of its vector, the triatomine bug, depend on the use of solid ceiling and wall materials without cracks. In the Pacific islands, leptospirosis has become a recurrent health problem among populations in informal settlements where rats are prevalent.

A poorly designed or maintained home may not provide sufficient shelter from extreme weather, protection from neighborhood environmental hazards, or safety in the case of natural disasters. A large literature describes the links between poor housing and ill health, but fewer reports have discussed successful interventions. Nevertheless, a small number of community trials have shown that housing improvements lead to a demonstrable gain in the health of inhabitants. These interventions include removal of injury hazards, installation of clean heating and cooking systems, insulation of walls and ceilings, removal of disease vector breeding sites, and establishment of secure safe water supplies and effective sanitation (Thomson, Thomas, Sellstrom, & Petticrew, 2013).

Transport

The transport system is an important element of the built environment because it has direct impacts on health, arrangements for transport dominate the urban landscape in health-damaging ways, and these systems are heavy users of energy, mostly in the form of fossil fuels. As a result, transport systems contribute substantially to global perturbations such as climate change.

The direct health risks of transport systems have been detailed in a review for Sweden by Kjellstrom, Ferguson, and Taylor (2009). Most obvious, on a global scale, is the large, and increasing, burden of road traffic injuries—which is why halving road traffic injury deaths is a Sustainable Development Goal target (Target 3.6) (United Nations, 2015b). According to the latest Global Burden of Disease analyses, almost 1.5 million people die each year from road traffic injuries, and such injuries are a leading cause of death among young adults (15–29 years) (Naghavi et al., 2017).

Approximately 90% of the road traffic injury fatalities occur in LMICs, even though these countries have only half the world's vehicles (WHO, 2015). Rates per 1,000 vehicles are approximately 30 times higher in Africa than in Norway, the United Kingdom, and the United States. These differences highlight the injury risks at an early stage of motorization, when roads are undeveloped, a safety culture has not taken hold in government, vehicles are frequently old and relatively poorly maintained, vulnerable road users such as pedestrians and cyclists are more numerous and not protected from fast-moving motor vehicle traffic, laws such as compulsory seat-belt use and drink driving are seldom enforced, and emergency services are rudimentary (see the *Unintentional Injuries and Violence* chapter).

Noise is a significant environmental health issue in many parts of the world, and motor vehicle traffic is the most common cause of noise pollution. Approximately 100 million people in Europe are exposed to noise above 55 dB, according to an EU report (European Environment Agency, 2017). Harmful effects arise from the stress of loud and frequent noise, occurring at any hour of the day, and links have been established between noise pollution and sleep disturbances, high blood pressure, weight gain, cardiovascular disease, and premature mortality.

The proliferation of roads and highways can also disrupt social interactions within communities. Unless town planning attends to the needs of pedestrians, cars and roadways tend to dominate the built-up landscape. In Great Britain, for example, the proportion of primary school children walking to school has declined dramatically over the past two decades from a clear majority to a shrinking minority, as traffic has become more intense and walking along roads less safe.

Transport systems that favor the private motor vehicle reduce the opportunities for physical activity. This is an important aspect of the "obesogenic environment," contributing to the global epidemic of obesity and associated disease problems (Kjellstrom, van Kerkhoff, Bammer, & McMichael, 2003). Changing the built environment to promote active transport (walking and cycling) may reduce vehicle use, increase healthy levels of physical activity, and reduce emissions of greenhouse gases (Kelly et al., 2017).

It is challenging to identify effective policies to achieve increases in active transport, and to demonstrate such effects in cities that are dominated entirely by cars and trucks and roads. Nevertheless, interventions have sought to modify road spaces to protect walkers and cyclists, provide alternative routes for active transport away from cars, and discourage use of private motor vehicles (for instance, through congestion charges). In turn, these programs have been linked with favorable changes in modes of transport and risk of disease and injury (Panter, Heinen, Mackett, & Ogilvie, 2016; Smith, M. et al., 2017). Based on existing evidence, integrated health, social, and environmental effects of specific policies have also been modeled using ecosystem health principles (as outlined earlier in the chapter) and complex systems modeling (Macmillan et al., 2014).

Road building and car parking lead in many cities to large land areas covered in tar-seal, which constitute environmental hazards in two respects: They add to the urban "heat island" effect, and they greatly increase storm water run-off during heavy rains. This latter effect was illustrated by the devastating floods that occurred in Houston, Texas, in August 2017 associated with Hurricane Harvey. Harvey brought heavier rains than seen previously in the United States, but the effects were compounded by lack of permeable surfaces across the city.

Climate Change

From an environmental and occupational health viewpoint, climate factors (temperature, humidity, air movement, and heat radiation) are important physical factors affecting individual and population health (Rosenstock et al., 2005), although it remains difficult to link a particular shift in health parameters to long-term climate change. A major review of the health impacts of climate change in the journal *The Lancet* (Watts et al., 2015) concluded that climate change is a very significant and growing global health risk.

The overall links between underlying factors, specific climate exposures, and the health impacts are shown in the DPSEEA framework (**FIGURE 11-8**) developed by WHO in the 1990s (Corvalán et al., 1995). This framework demonstrates that a broad range of climate factor exposures and health effects are likely to occur, and the overall picture has not changed much since the first detailed report on the health impacts of climate change was published in 1996 (McMichael, Haines, Sloof, & Kovats, 1996).

The United Nations' Intergovernmental Panel on Climate Change (IPCC) concluded in 2013 that there is a significant human influence on global climate (Collins et al., 2013). Further, trends in greenhouse gas emissions will, in the IPCC's estimation, cause an increase in average world temperature of approximately 1.8°C to 4°C over the coming century. Rainfall patterns will also likely change, as will the variability of weather patterns. All of these changes are expected to vary considerably by region. The health effects of climate change are expected to encompass both direct and indirect effects, as well as immediate and delayed effects (Smith, K. R. et al., 2014), and have been organized into primary, secondary, and tertiary effects (Butler & Harley, 2010).

The impact of regional climatic variations on human well-being and health has attracted great research interest in recent years. As a consequence of these investigations, there is new understanding about the regional pattern of storms, floods, cyclones, and droughts in response to these quasi-periodic cycles. Indeed, advance warning of interannual variations in rainfall and drought conditions (with their implications for regional food production and outbreaks of certain infectious diseases) is now becoming possible. The distribution of heat on Earth is indicated in **FIGURE 11-9**. The tropical and subtropical areas are most affected, as would be expected, and climate change will make the heat exposure situation worse.

Figure 11-9 indicates that heat stroke and heat exhaustion are important direct effects of increasing heat exposure. These heat stress impacts are boosted by physical activity, because exercise creates surplus heat inside the body. Thus, working populations are vulnerable to climate change health effects (Kjellstrom, Holmer, & Lemke, 2009). The negative effects of daily heat on daily life activities have not been sufficiently analyzed to date, but given that they depend on the physiological limits for coping with heat (Parsons, 2014), one can classify these impacts as health effects even though the outcomes occur at the social level. In tropical and subtropical countries, heat stress effects are not only a problem during "heat waves," but are also related to daily levels of typical heat.

Part A: Global and sectoral aspects. Contribution of Working Group II to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change*. (Chapter 11). Cambridge, UK: Cambridge University Press. pp. 709–754.

The predicted global annual mortality due to climate change in 2030 and 2050 (WHO, 2014) is expected to increase in a major way owing to the direct effects of heat on elderly people. By comparison, the other mortality risks (e.g., malnutrition, vector-borne diseases, diarrheal diseases) may be stable or even decrease due to adaptation possibilities. The dramatic effects on mortality during the severe heat wave in Europe in 2003 and subsequent heat waves bear witness to the severe consequences for the health of older people (WHO, 2004).

The increasing temperatures will boost the local production of ozone from nitrogen oxides emerging from motor vehicle exhausts. This may lead to additional health effects of air pollution, as well as the combined effects of heat and air pollutants (Dear et al., 2005). Proposed interventions to mitigate climate change include replacing fossil fuel–burning vehicle engines with cleaner electric engines, in a move that should have important health co-benefits (Haines et al., 2009).

Many indirect health threats emerge from problems with food storage, food production, drinking water quality, disease vectors, sea level rise, impacts on livelihoods, conflict, and migration. The health outcomes of these events in relation to climate change will depend on the application of adaptation methods. As pointed out in the IPCC's assessment of the health threats (Smith, K. R. et al., 2014), the future strengthening of general public health programs and facilities will reduce these threats. This is one reason why the WHO mortality impact assessment predicted reductions of climate change–induced mortality via indirect health effects between 2030 and 2050 (WHO, 2014). The links between climate conditions and vector-borne diseases have attracted substantial attention, but demonstrating the pathways from exposure to effects has proved to be quite complicated (see **EXHIBIT 11-6**). Although certain health outcomes in selected areas would be beneficial—some tropical regions may become too hot for mosquitoes, for example, and winter cold snaps would become milder in temperate-zone countries where death rates typically peak in wintertime—most of the anticipated health effects would be adverse (Smith, K. R. et al., 2014).

Direct health effects from climate change include changes in mortality and morbidity from an altered pattern of exposure to thermal extremes; the respiratory health consequences of increased exposures to photochemical pollutants and aeroallergens; the physical hazards of the increased occurrence of storms, floods, or droughts, in at least some regions; and the increased direct heat exposure on people working in situations without cooling systems (Kjellstrom, Holmer, & Lemke, 2009). Intensified rainfall, with flooding, can overwhelm urban wastewater and sewer systems, leading to contamination of drinking water supplies. This outcome is most likely in large crowded cities where infrastructure is old or inadequate, as illustrated by an outbreak of typhoid in Tajikistan in 1994, when the city's wastewater system flooded during torrential rains.

Indirect health effects are likely to have a greater aggregate impact over time. They may include alterations in the range and activity of vector-borne infectious diseases (e.g., malaria, dengue fever, and leishmaniasis). These diseases are spread by vectors (e.g., mosquitoes) that are sensitive to climatic

EXHIBIT 11-6 Modeling the Future Impacts of Climate Change on Malaria Transmissibility

Mosquitoes—the vector organisms for malaria—are very sensitive to temperature and humidity. Further, patterns of rainfall, river flow, and surface water affect their opportunity to breed. Given these facts, scientists anticipate that a change in world climatic conditions during the 21st century will affect the pattern of potential transmission of malaria (Martens et al., 1999).

Both temperature and humidity affect the growth, biting rate, reproductive cycle, and longevity of the mosquito. Mosquitoes are most comfortable in a temperature range from 20°C to 30°C and at approximately 60% humidity. The malarial parasite, a single-celled sexually reproducing plasmodium, is also affected by temperature during the extrinsic phase of its complex life cycle, when sporozoites are forming within the mosquito.

From studies done during the 1980s and 1990s, it is clear that malaria outbreaks are closely related to interannual climatic variations in many countries. Studies in India, Pakistan, and Sri Lanka all reveal strong associations between malaria outbreaks and El Niño events and the associated monsoonal changes. A correspondingly strong correlation with interannual variations in temperature and rainfall has been reported for outbreaks of dengue fever (a mosquito-borne infectious disease) in Pacific island populations (Hales, Weinstein, & Woodward, 1996).

Because other determinants of malaria occurrence will also inevitably change over coming decades (e.g., vaccine efficacy, human demography, land-use patterns, or parasite resistance to drugs), the modeling of climate change impacts typically indicates only changes in potential transmission.

conditions, as is the parasite's development while incubating in the vector. Scenario-based mathematical modeling has suggested that the geographic zone and seasonality of potential transmission of malaria or dengue fever will increase in many parts of the world in the coming century (McMichael et al., 2003). In temperate Europe and North America, climate-sensitive, vector-borne infections include tick-borne encephalitis and Lyme disease.

Other indirect effects may include altered transmission of person-to-person infections (especially summertime foodborne and waterborne pathogens). Of great potential importance to population health would be the adverse nutritional consequences of the likely regional declines in agricultural productivity (McMichael, Powles, Butler, & Uauy, 2007), which are forecast to reach 10% to 20% by the latter half of the 21st century in many already food-insecure populations in low-latitude regions. Livestock production, particularly of ruminant, digastric animals (sheep, cattle, buffalo, goats, and others), contributes substantial emissions of methane, a potent greenhouse gas, which are adding significantly to ongoing climate change (Friel, Marmot, McMichael, Kjellstrom, & Vagero, 2008; McMichael et al., 2007). Finally, climate change will inevitably result in adverse physical and psychological health consequences from population displacement and economic disruption due to rising sea levels (e.g., small island states, coastal Bangladesh, and the Nile Delta), declines in agroecosystems, and freshwater shortages. Most of these negative health impacts, along with the heat-induced reductions of the work capacity of working people (Kjellstrom, Holmer, & Lemke, 2009), are expected to have their greatest effects in low-income populations (Friel et al., 2008; Patz, Gibbs, Foley, Rogers, & Smith, 2007).

An analysis of different potential health effects enables the identification of gaps in the current presentations in major international reports. **TABLE 11-5** uses heat impacts to demonstrate that a number of effects are suggested by focused studies, but have not yet been quantified at global level. This table could be expanded to all climate effects, but further research is clearly needed to do so.

On the positive side, a growing body of research has identified potentially significant benefits for health and health equity of well-designed actions to

TABLE 11-5 Climate Change–Related Health Impacts of Heat According to IPCC, WHO, and Other Sources

Hazard Exposure	Health Impact	Confidence* of This Impact	Specific Effects at Organ Level	Source
Intense heat	Heat stroke death	Very high	Heart strain; central nervous system (CNS) malfunction; dehydration	IPCC (Smith K. R. et al., 2014) WHO (2014)**
	Heat stroke morbidity	Very high	Heart strain; CNS malfunction; dehydration	IPCC (Smith K. R. et al., 2014)
	Heat exhaustion Work capacity loss	High	Heart strain; mental fatigue	IPCC (Smith K. R. et al., 2014)
Forced migration	Undernutrition; infections; mental stress; injuries	High	Work capacity loss, heart disease, fatigue	IPCC (Smith K. R. et al., 2014)
Health Concerns Not Mentioned in Detail in the IPCC and WHO Reports				
Intense heat	Chronic kidney disease linked to dehydration		Wesseling et al. (2013)	
	Increased incidence of violent crimes		Gamble & Hess (2012)	
	Increased incidence of suicides		Berry et al. (2010); Kim et al. (2016)	

	Teratogenic effects of high body temperature in pregnant women; damage to development of brain	Edwards et al. (1995)
	Interactions with prescription drugs	Vanakoski & Seppala (1998)
	Deteriorated clinical status in chronic noncommunicable diseases	Parsons (2014)
	Increased damage due to head trauma	Titus et al. (2015)

TABLE 11-6 Health and Health Equity Co-Benefits of Sector Actions to Mitigate Climate Change

Emissions Reduction Measure (Mitigation)	Health and Equity Co-benefits
Investments in low-carbon public and active transport	Increased physical activity; reduced air pollution; reduced road traffic injuries; improved equity of access to employment, education, and health-promoting goods and services
Housing insulation and clean, dry, low-carbon, energy-efficient heating and cooking	Reduced respiratory infections, cardiovascular disease, and asthma; improved housing affordability for low-income households; reduced lung cancer
Lowering livestock production and consumption of animal products	Reduced cardiovascular disease and cancer (especially bowel cancer); improved freshwater quality; reduced deforestation; improved availability of grains for direct consumption
Phasing out fossil-fuel energy generation, particularly coal	Reduced air pollution; reduced mining and oil-drilling occupational deaths, injuries, and chronic diseases

Modified from Haines, A., McMichael, A. J., Smith, K. R., Roberts, J., Woodcock, J., & Markandya, A., et al. (2009). Public health benefits of strategies to reduce greenhouse-gas emissions: Overview and implications for policy makers. *The Lancet 374:* 2104–2114; Bennett, H., Jones, R., Keating, G., Woodward, A., Hales, S., & Metcalfe, S. (2014). Health and equity impacts of climate change in Aotearoa-New Zealand, and health gains from climate action. *The New Zealand Medical Journal (Online), 127*(1406), 16–31.

mitigate climate change (Haines et al., 2009; Watts et al., 2015). These co-benefits can be achieved across all the major sectors producing greenhouse gas emissions—agriculture and food, energy supply, transport, and housing. Reducing air pollution–related deaths by phasing out coal burning has drawn the largest amount of attention in recent years, because of the potential to save a significant proportion of the 9 million lives lost from this cause each year in LMICs, particularly China and India. **TABLE 11-6** summarizes these co-benefits by sector.

In the last few years, research on the global, regional, and national impacts of climate change on health has intensified. A major effort to monitor the emerging health trends has been initiated by the highly respected medical journal *The Lancet*. Its Countdown project (Watts et al., 2017), which aims to show climate change–related trends from 2000 to the most recent year, includes a large number of indicators (**TABLE 11-7**) covering not only a variety of health impacts, but also adaptation and mitigation actions, as well as economic and policy issues.

The first Countdown report with data has a number of gaps (Watts et al., 2017), but additional material is expected to be included as the project progresses. It is clear from the report that the risks of health impacts are increasing, and students of climate change and health need to look for the latest impact assessments

TABLE 11-7 Indicators for Climate Change and Health from *The Lancet* Countdown

Section 1: Climate change impacts, exposures, and vulnerability
1.1. Health effects of temperature change
1.2. Health effects of heat waves
1.3. Change in labor capacity
1.4. Lethality of weather-related disasters
1.5. Global health trends in climate-sensitive diseases
1.6. Climate-sensitive infectious diseases
1.7. Food security and undernutrition
1.7.1. Vulnerability to undernutrition
1.7.2. Marine primary productivity
1.8. Migration and population displacement

Section 2: Adaptation planning and resilience for health
2.1. National adaptation plans for health
2.2. City-level climate change risk assessments
2.3. Detection and early warning of, preparedness for, and response to health emergencies
2.4. Climate information services for health
2.5. National assessment of vulnerability, impacts, and adaptation for health
2.6. Climate-resilient health infrastructure

Section 3: Mitigation actions and health co-benefits
3.1. Carbon intensity of the energy system
3.2. Coal phase-out
3.3. Zero-carbon emission electricity
3.4. Access to clean energy
3.5. Exposure to ambient air pollution
3.5.1. Exposure to air pollution in cities
3.5.2. Sectoral contributions to air pollution
3.5.3. Premature mortality from ambient air pollution by sector
3.6. Clean fuel use for transport
3.7. Sustainable travel infrastructure and uptake
3.8. Ruminant meat for human consumption
3.9. Healthcare-sector emissions

Section 4: Economics and finance
4.1. Investments in zero-carbon energy and energy efficiency
4.2. Investment in coal capacity
4.3. Funds divested from fossil fuels
4.4. Economic losses due to climate-related extreme events
4.5. Employment in low-carbon and high-carbon industries
4.6. Fossil fuel subsidies
4.7. Coverage and strength of carbon pricing
4.8. Use of carbon pricing revenues
4.9. Spending on adaptation for health and health-related activities
4.10. Health adaptation funding from global climate financing mechanisms

Section 5: Public and political engagement
5.1. Media coverage of health and climate change

The Future of Environmental Health in an Unequal World

Sometimes LMICs are criticized for not imposing stricter environmental and occupational standards in tandem with efforts to pursue economic development. There are indeed many situations where minimal efforts could achieve great reductions in health risks. In addition, given the likely increase in public willingness to pay for stricter standards applied in conjunction with economic development, the early imposition of regulations and standards can often be cost-effective using standard economic criteria. Nevertheless, most large LMICs today have standards that are much stricter than those found in high-income countries when they were at the equivalent level of development. Indeed, although cases involving the export of environmental hazard and the degradation of local environments by exploitative and destructive commercial practice can be cited (see "The Export of Hazard," later in this chapter), in the right circumstances the overall impact of globalization can be a net export of positive environmental health. That is, through education, political and public pressures, technology transfer, trade agreements, and other initiatives, LMICs may have, on average, better environmental quality than would otherwise be the case.

Setting Standards: Too Safe Can Be Unsafe

Setting and enforcing environmental standards for protection of the public and workers is a difficult exercise, even in high-income countries that have substantial resources. In LMICs, which face a number of critical needs with few resources, this process is even more challenging. Although official rhetoric about setting standards often states that the only concern is protection of health, in reality there are always economic and other tradeoffs involved. It is too expensive and there are too many other demands on resources to bring every pollutant under the maximum control quickly. Politically, however, it is often difficult for governments in LMICs to set standards that are significantly less stringent than those in high-income countries. As a result, sometimes standards are unrealistically strict and cannot be met or enforced. This disparity between the standards and the reality leads to graft, cynicism, apathy, and, too often, levels of exposures and ill health greater than what could be achieved by adopting more realistic approaches.

One way out of this dilemma is to emphasize environmental health protection and standards setting as dynamic, evolutionary processes rather than as static, one-time-forever efforts. For example, a country might set 20-year goals for its standards that are as strict as any in the world, while establishing interim objectives that become progressively more strict. Thus, pollutants and industries that pose the most risk can be emphasized first, while control over other pollutants and industries (of the kind that now attract attention in high-income countries) can be postponed until a later period. No hazard is ignored with this approach, but merely put into a rational order of priority. Industrial interests are likely to be more willing to accept stricter standards under such a scheme because they tend to have shorter-term financial goals, which are facilitated by clarity of the regulatory environment, whereas they are unsettled by longer-term uncertainty. A recurring problem, however, is attaining sufficient stability within governments to implement such a long-term approach.

The Export of Hazard

In recent years, concern has risen about the potential export of environmental hazards that may be occurring as part of the globalization of the world economy (LaDou & Jeyaratnam, 1994; Leichenko, 2008). Because environmental and occupational standards and enforcement tend to be less strict in LMICs, one might expect that polluting activities would tend to migrate to those countries, thereby imposing excess risk on their workers and public. On the whole, labor costs and tax regimes often appear to be a stronger driver of industry shifts from higher- to lower-income countries. Further, as noted earlier, nations at different stages of development may be juggling multiple tradeoffs between environmental health and occupational standards, job creation, and infrastructure development. The most outrageous examples of injustice arise where decisions about such tradeoffs are made by a small oligarchy without considering the needs and wishes of the population as a whole. In these cases, perhaps the only way to protect the interests of all workers and residents would be to establish international norms.

Some stark examples of problems created by the exporting of hazard between high-income and LMICs can be cited, however. On the Mexican side of the long U.S.–Mexican border, for example, one can find many highly polluting industries with poor occupational safety and health conditions relative to standards on the U.S. side of the border (Moure-Eraso et al., 1994). Because of the proximity of these operations, both the pollution and health problems tend to cross the border, frustrating attempts by U.S. border communities to maintain acceptable conditions. Attempts to impose U.S. standards on Mexican facilities understandably create friction. There have been some encouraging successes in joint efforts by neighboring Mexican–U.S. communities to address these issues in a way that takes into account the need for jobs and for clean working and living conditions on both sides.

The export of plastics and electronics recycling is another example of the export of hazard. China has for many years been the largest importer of wastes for recycling, including from the European Union, the United States, and Japan, with multiple attendant environmental and occupational health risks (Velis, 2014). As a result of the negative environmental and health impacts, in 2017 China notified the World Trade Organization that it would no longer be accepting 24 classes of plastics for recycling.

The political and moral dilemmas associated with industrialization of LMICs are widely recognized. On the one hand, today's high-income world followed a path to development and wealth that put economic gains ahead of human welfare and environmental conservation for most of the 19th century. On the other hand, today's LMICs are dissuaded, if not formally barred, from following the same pathway because (1) their populations have access to more information and hence have higher expectations; (2) the high-income world has a moral obligation to assist them via the transfer of knowledge, wealth, and technology; (3) it is now clear that the integrity of the biosphere at large is jeopardized by the prospect of huge populations in these countries accruing wealth via environmentally damaging behaviors; and (4) there is pressure from public opinion in industrialized countries to achieve higher standards.

Environmental Hazards Resulting from Forms of Globalization

A dominant trend in the global economic environment over the past 50 years has been the rapid growth in international trade in goods, services, and human resources. The globalizing processes of the past quarter century have transformed patterns of connectedness around the world and have created new power relations among countries, international and national governance, and the public and private sectors (see the *Global Health Governance and Diplomacy* chapter).

In traditional agrarian-based societies that produce, consume, and trade on a local basis and with relatively low-impact technologies, the effects of those activities on the environment are predominantly local. Few such societies remain today, in the face of the strong and pervasive economic, technologic, and cultural influences now spanning the globe. The industrialization of the past century and the more recent globalizing processes have altered the scale of contact between societies, intensified environmental impacts, and extended the health impacts of one society on another. In the name of economic development and free markets, LMICs have come under pressure to grant unrestricted access to their resources, workforces, and consumer markets. This process has been associated with increasing poverty in many parts of the world, exacerbating inequalities between and within countries, expanding pressures to reduce the power of the state, and subordinating national programs of social welfare and environmental protection to the agenda of economic growth.

Following the international debt crisis of the early 1980s, many struggling LMICs were obliged to accept the economic stringencies mandated by the World Bank's structural adjustment program. These dictates included a reduction in spending on health throughout the 1980s and into the 1990s. Growing evidence suggests that these structural adjustment policies adversely affected environmental health, including through degradation of freshwater, a shift from mixed agriculture to cash cropping, and rapid, poorly controlled urbanization (Kentikelenis, 2017). In its current form, the world's globalizing economy operates to the general disadvantage of LMICs. The exacerbation of land degradation, rural unemployment, food shortages, and urban crowding all contribute to health deficits for the rural dispossessed, the underfed, and the slum dweller. The health and safety conditions of working people can create particular threats to occupational health (Kjellstrom & Hogstedt, 2009).

In addition, many features of today's globalizing world contribute to the spread of infectious diseases (Weiss & McMichael, 2004). Human mobility has escalated dramatically, in volume and speed, between and within countries in recent decades. Long-distance trade facilitates the geographic redistribution of pests and pathogens—a phenomenon well illustrated in

recent years by the HIV pandemic, the worldwide dispersal of rat-borne hantaviruses, and the rapid dissemination of a new epidemic strain of bacterial meningitis along routes of travel and trade. Likewise, transport on ships has facilitated the introduction of the Asian tiger mosquito, *Aedes albopictus*—a vector for yellow fever and dengue—into South America, North America, and Africa (Morse, 1995) and of the cholera bacterium into South American coastal waters (Colwell, 1996). In an analysis of cholera outbreaks since 1817, Lee and Dodgson (2000) argue that the current (seventh) pandemic is clearly different from earlier ones, reflecting the unprecedented scale of social and environmental change in the world over recent years, the exacerbation of urban poverty, and the rapidity and intensity of intercontinental contacts.

One aspect of globalization that may have negative effects on environmental health is the harmonization of trade-related rules and legislation via the World Trade Organization (WTO). Recent multilateral trade and investment agreements, such as the Trans-Pacific Partnership Agreement, contain clauses that allow multinational corporations to sue governments for loss of profits, including those losses incurred because of governments' new regulations to protect environmental health (Keating, Freeman, Macmillan, Neuwelt, & Monasterio, 2016).

Similar situations may develop with the banning of hazardous products such as asbestos. If, for example, there is no international health guideline banning the use of asbestos, then any country taking a unilateral decision to ban asbestos use would risk trade sanctions from other countries wanting to export asbestos. If the trend in international environmental and occupational health guidelines went toward stricter prevention, this harmonization via trade rules could be good for health and the environment. In reality, the intense lobbying from those commercial groups and countries that would benefit from lax rules makes it likely that the opposite will happen—meaning that compromises veering toward less protection will be made (LaDou & Jeyaratnam, 1994).

Population Health: Index of Social and Environmental Sustainability

Current models of government reflect the compartmentalization of knowledge and policy that grew out of the classic development of scientific disciplines in the 19th century. To deal with a multifaceted world, our predecessors defined various sectors of knowledge, policy, and social action: environment, industry, agriculture, transport, health, social welfare, and education. Subsequently, one of the great lessons to emerge from 20th-century science, which had its origins in the realm of physics (the 1920s debate about quantum mechanics and uncertainty), was that the complexities of the real world require us to think in more integrative ways, across disciplines and topics, elevating holism (or ecological thinking) above mechanistic, reductionist thinking.

It is within this type of integrative framework that population health can be understood as part of the total social experience, a manifestation of how well the social and natural environments are being managed. Population health should be a primary criterion for all social policy making, but particularly in relation to the goal of achieving the "sustainability transition." Health is not just a type of sideshow in the policy arena, but rather is affected by the social, environmental, and (in the longer term) ecological consequences of policies in all sectors. For all these reasons, population health should be an integrating index of social policy across all sectors.

Conclusion

The perceived importance of environmental exposures as health hazards—at local, regional, and global levels—has increased steadily over the past several decades. Currently, scientists estimate that one-fourth to one-third of the global burden of disease and premature death is attributable to ambient (including household) environmental risk factors.

In high-income countries during much of the past four decades, the generally greater ease of measurement of specific exposures relating to individual lifestyle factors (eating, smoking, and sexual behaviors) and the workplace, compared with the more diffuse, lower-concentration exposures in the external environment, resulted in the latter topic area attracting less attention and having lower credibility. More recently, improvements in exposure assessment, the harnessing of time-series analyses, the advent of spatial analytic techniques, the recognition of the legitimacy of population-level analyses, and the extra leverage afforded by molecular biological indices of exposure, susceptibility, and biological damage have all helped reveal the range and extent of ambient environmental risks to health.

Meanwhile, in LMICs, the age-old scourges of diarrheal disease, acute respiratory infections, tuberculosis, and vector-borne infections have remained the dominant health problems. The ascendancy of specific health system interventions for those

problems—sanitation, household hygiene, vaccination, pesticides, and drug treatment— has led to their wider ecological dimensions being somewhat overlooked. Many problems of environmental contamination have their origins in poverty; deficient regulation of mining, industry, and agriculture; and mismanagement of surface water and groundwater supplies. Differences in household exposure to indoor air pollution reflect the traditional division of labor (women are mostly exposed), the ongoing use of low-grade technology, and the persistence of the biomass fuels of poverty. Infectious diseases are often spread by environmental encroachments—land clearing, water damming, irrigation, and expanded trade.

The environmental health agenda is widening. Today, the burden of the growing human population and its aggregate consumption and waste generation is beginning to overload various aspects of the planet's great natural systems. The resultant global environmental changes, signifying that the biosphere's human population carrying capacity is being exceeded, pose further risks to human health. Therefore, even as environmental health scientists strive to improve their research methods for characterizing the health risks associated with local physical, chemical, and microbiological hazards, they must also extend their ideas and methods to encompass larger-scale environmental hazards and the health consequences of disrupted ecosystems. Policy makers, in many sectors, must understand the tendency of human-wrought changes in the social, built, and natural environments to affect health—if not immediately, then in the longer term, and sometimes via pathways with which we yet have little familiarity.

Discussion Questions

1. What should be the scope of the term "environment"?
2. How do conceptualization and methodological approaches change with a shift from thinking about environmental hazards to thinking about human habitats?
3. Which methodological problems are particularly characteristic of environmental epidemiology?
4. How might differences be explained in the profile of environmental health problems between high-income countries and LMICs?
5. What are the characteristics of particular environmental health problems that render them more, or less, tractable to amelioration or elimination?

Acknowledgments

We wish to thank the four Master of Public Health students at the University of California, Berkeley, who kindly reviewed the previous edition of this chapter: Miriam Magaña Lopez, Maximo Prescott, Luciana Rocha, and Morgan Westfall. Their constructive comments assisted with improvements.

CHAPTER 12

Complex Emergencies

Michael J. Toole and Ronald J. Waldman

Introduction

This chapter focuses on public health emergencies that arise from complex political crises but draws, in places, on lessons learned from humanitarian responses to natural disasters. Terminology changes frequently in this area, and different definitions emphasize different aspects of a concept. The term *complex humanitarian emergencies* came into popular use following the Kurdish refugee exodus during the Gulf War in 1991. It was defined by the Centers for Disease Control and Prevention (CDC) as "a situation affecting large civilian populations which usually involves a combination of factors including war or civil strife, food shortages, and population displacement, resulting in significant excess mortality" (Burkholder & Toole, 1995, p. 1012). Goodhand and Hulme (1999) defined *complex political emergencies* as conflicts that combine a number of features: They often occur within but also across state boundaries; they have political antecedents, often relating to competition for power and resources; they are protracted in duration; they are embedded in and are expressions of existing social, political, economic, and cultural structures and cleavages; and they are often characterized by predatory social formations. This latter definition clearly locates the causes and effects in the political sphere—a point echoed by numerous other writers, and one that has considerable implications for those working in these settings with a primarily public health agenda. In the new millennium, these terms have merged into *complex emergencies* (CEs), the term that we use in this chapter to maintain simplicity and consistency.

This chapter grapples with current understanding of CEs and their political causes, and considers their impact on populations and health systems. It incorporates new knowledge and experience gained in the past six years, including the massive humanitarian crisis resulting from the civil conflict in Syria. It highlights current knowledge in humanitarian assistance and indicates that effective technical interventions are possible to help alleviate suffering and limit adverse effects on the health of populations. We draw attention to current efforts by the humanitarian community to improve the effectiveness, efficiency, and equity of humanitarian responses, and consider how the pattern of early responses may influence the longer-term survival of populations and systems and the nature of any post-conflict society established. We are acutely aware, however, that the solutions to CEs are political and not humanitarian, and that it is in the political sphere that both upstream and downstream responses to complex emergencies must receive priority.

Many of the public health interventions currently promoted as best practices were developed and tested during the 1970s and 1980s, when most conflict-affected populations were accessed in relatively secure refugee camps in low- and middle-income countries (LMICs) administered by the Office of the United Nations High Commissioner for Refugees (UNHCR). Recent changes in the nature of conflicts have introduced a great deal of complexity into these responses.

Most contemporary wars are of "protracted duration, intrastate, fought by irregular armed groups, and fueled by economic opportunities and ethnic rivalry" (Spiegel, Checchi, Colombo, & Paik, 2010, p. 341). Many recent displaced populations are in or fleeing from middle-income countries, such as Syria. The populations most in need are often trapped by the armed conflict, unable to flee, not residing in organized camps, and, therefore, need to be accessed by relief agencies "in situ." Such "trapped" populations can be found in northeast Nigeria, Central African Republic, Somalia, Syria, and Yemen.

The conditions experienced by those who manage to flee their country and obtain refugee status have also changed significantly. Since 2011, most Syrian and Iraqi refugees have been housed outside camps. For example, in 2017, the majority of the 3 million Syrian refugees in Turkey were living in urban areas, with only 260,000 accommodated in the 21 government-run refugee camps (UNHCR, 2017a). In Jordan, more than 655,000 Syrian men, women, and children were trapped in exile. Approximately 75% of them lived outside camps, while more than 140,000 found sanctuary at the camps of Za'atari and Azraq. There were no formal refugee camps in Lebanon; as a result, more than 1 million registered Syrians were scattered throughout more than 2,100 urban and rural communities and locations in Lebanon, often sharing small basic lodgings with other refugee families in overcrowded conditions.

Although the impact of natural disasters is not the subject of this chapter, we have made two important exceptions: the destructive tsunami that originated off the coast of Indonesia on December 26, 2004, and the earthquake that devastated Port-au-Prince, Haiti, and its environs on January 12, 2010. We include these catastrophic events because they had many elements of a complex emergency.

The tsunami caused more than 228,000 deaths in 14 countries and displaced more than 1.5 million people from their homes (ReliefWeb, 2009). Two of the areas most severely affected—the Aceh province of Indonesia and northeast Sri Lanka—had experienced several decades of armed conflict. More than 127,000 Burmese refugees were living in the 5 Thai provinces affected by the tsunami: At least 1,000 perished (United States Committee for Refugees, 2005). The massive displacement and disruption to food and water supplies, shelter, and sanitation created conditions similar to those experienced by refugees and internally displaced persons (IDPs) fleeing armed conflict.

The Haiti earthquake killed 230,000 people, injured an approximately equal number, left 604,000 people homeless in Port-au-Prince, and caused the flight of an additional 598,000 residents from the capital city to the countryside. Its impact on the only major city in the poorest country of the Western Hemisphere, including the government paralysis that followed in the earthquake's wake, the massive international relief effort that included interventions by armed forces from many different nations, and the difficulty that is foreseen in returning people to their homes is, again, similar to what might be encountered in conflict settings.

In the period from the end of World War II to the end of the Cold War, most conflicts took place in the developing regions of the world, primarily in Africa, the Middle East, Asia, and Latin America (**FIGURE 12-1**). The end of the Cold War, the break-up of the Soviet Union, and the pace and intensity of globalization led, in the 1990s, to major conflicts in Europe and the former Soviet Union—most notably in Tajikistan, Chechnya, Georgia, Abkhazia, and the former Yugoslavia. The number of armed conflicts globally reached a peak of 52 in 1991. This point was followed by a steady decline until 2012, when an upswing began in part due to conflicts following the so-called Arab Spring, reaching 50 again in 2015 (Uppsala Conflict Data Program, 2016).

Modern-day conflicts are increasingly internal, rather than between states, and often have as a prime objective, alongside the quest for economic and political power, the undermining of the lives and livelihoods of civilian populations associated with opposing factions. As many as 90% of those persons affected in recent conflicts have been civilians, with all ages and both sexes suffering the effects. The distribution of impact and health outcomes vary substantially, however, and depend on the nature of the conflict and its history, its extent and form, and the prior health and health system status.

Many CEs and major natural disasters have attracted considerable media attention and have caused people to seek to promote availability of at least a basic degree of humanitarian assistance, even if fundamental political solutions are not sought. Other ongoing crises, despite causing massive loss of life, population displacement, and infrastructure destruction, are not necessarily explicitly recognized as CEs; as a result, they have attracted few resources and attention. These "hidden emergencies" nevertheless pose fundamental challenges to the health and well-being of affected populations. For example, the ongoing conflicts in Central African Republic, northeast Nigeria, and the Democratic Republic of the Congo (DRC) have drawn little attention and responses from the rest of the world: Such discrepancies are likely to

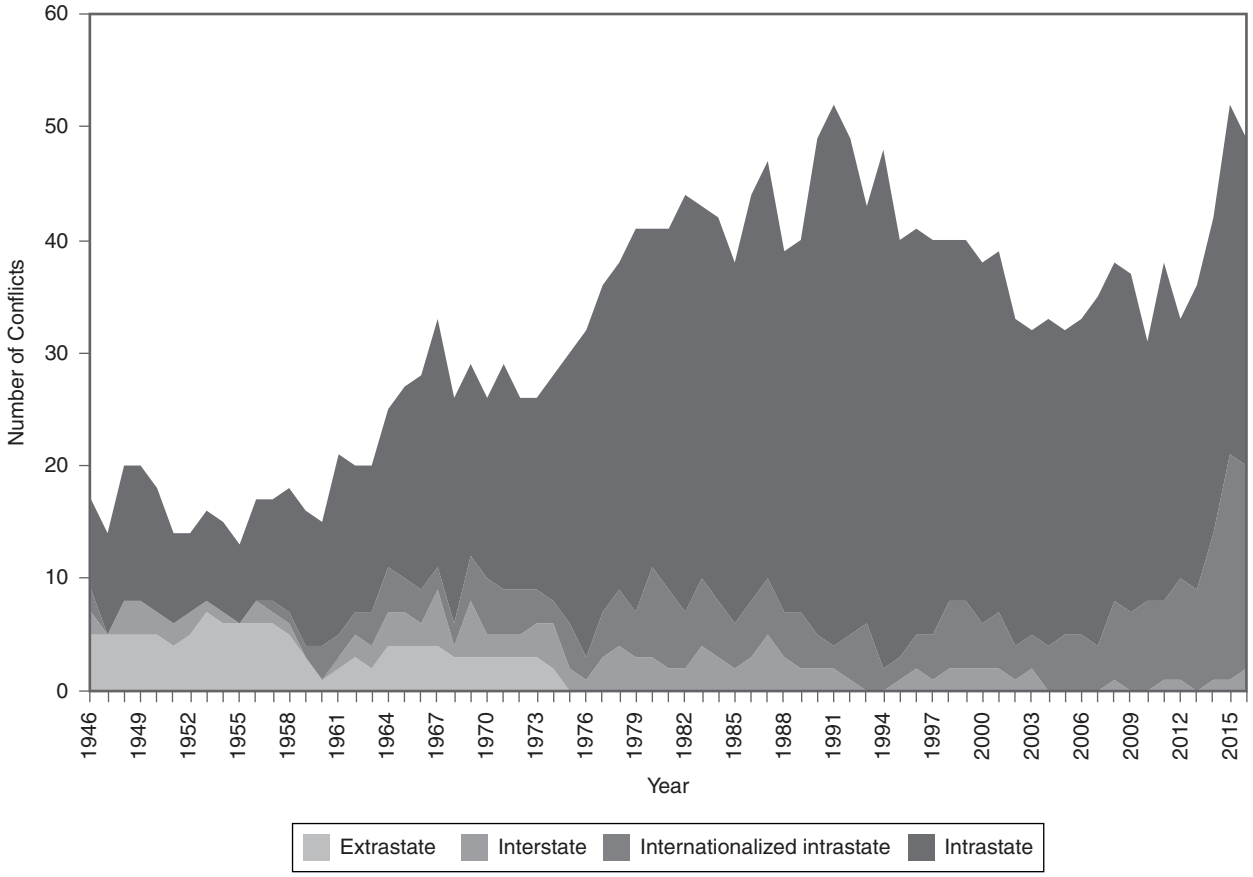

FIGURE 12-1 Armed conflict by type, 1946–2015.

Reproduced from Uppsala Conflict Data Program (2016). Retrieved from http://ucdp.uu.se/.

result from geopolitical concerns, media interest, and economic factors.

In the aftermath of the September 2001 terrorist attacks on New York City and Washington, D.C., United States–led coalitions have used military force to change the regimes in Afghanistan and Iraq. These two conflicts have been "internationalized" and represent a new trend in modern wars, given the huge disparities in military resources between the warring parties. These two conflicts were ongoing in 2018 with intensification of fighting in both countries and, in Iraq, the additional brutality of the radical jihadist movement Islamic State of Iraq and the Levant (ISIL).

During the decades since the Holocaust, numerous episodes of massive human rights atrocities and genocide have been committed against particular groups: Pol Pot's killing fields in Cambodia, the genocide against Tutsis in Rwanda, and "ethnic cleansing" in the former Yugoslavia. Other conflicts, such as that in West Darfur, Sudan, which began in 2004, highlight the brutal nature of internal wars, including the use of repressive techniques to evict people from their homes and to undermine their sense of security and safety, accompanied by the targeted use of force to destroy social, political, and economic structures.

A particularly insidious development is the targeting of violence toward individuals and groups on the basis of their ethnicity or religion. Such conflicts have occurred frequently enough that the term "ethnic cleansing" has entered the language. However, the reality has been that opportunistic politicians have often inflamed the perceived differences between groups, especially during times of economic and political uncertainty, resulting in open armed conflict.

In Syria, Iraq, and other countries, ISIL has taken violence against civilians to a new level. Targeting Shia Muslims, Christians, and Sunni Muslims who oppose them, members of ISIL have engaged in brutal torture and killings and led to massive movements of internally displaced persons and refugees. Other radical jihadist groups in Somalia (Al Shabab) and Nigeria (Boko Haram) have employed similar violent tactics.

In the same conflicts, we see evidence of other key features of modern-day CEs:

- The willingness of powerful segments of the international community to intervene in internal conflicts, and to do so in a way that minimizes their exposure to risk
- The changing nature of humanitarian assistance, which increasingly forms only one dimension of the management of conflicts, alongside political, economic, and military responses
- The changing role of the private sector, as well as the increasingly important role of local and global media
- Trends in globalization that simultaneously integrate peripheral areas within the global economy, yet contribute to their fragmentation as elites compete for access to the economic and political resources associated with integration in the global political economy

One consequence of the targeting of entire communities and their livelihoods has been a dramatic rise in the number of forcibly displaced people. By the end of 2016, 65.6 million individuals were forcibly displaced worldwide as a result of persecution, conflict, violence, or human rights violations (UNHCR, 2017a). That number represented an increase of 300,000 people over the previous year, and the world's forcibly displaced population remains at a record high. Globally, in December 2016, there were an estimated 22.5 million refugees, 2.8 million asylum-seekers (those seeking refugee status), and 40.3 million IDPs, the vast majority of whom were fleeing conflict zones.

Although refugee numbers are typically assessed to plan and provide relief, relatively little attention has been devoted to developing the most appropriate methods for establishing the precise composition of refugee and IDP populations, whether in terms of age, sex, religion, local geographic origin, or ethnicity. This imposes constraints given the differing needs and roles of groups within populations and may make it easier for the more complex issues of dealing with gender, equity, and ongoing intergroup rivalry to be overlooked. Particular groups, such as older adults, refugees not in camps, and IDPs, may neither be identified nor receive the required attention for their differing needs.

The changing pattern of conflict has been accompanied by significant changes in the delivery of humanitarian assistance. On the one hand, the number of agencies operating in these complex settings has increased dramatically; for example, more than 240 nongovernmental organizations (NGOs) were working in and around Rwanda in the aftermath of the genocide and more than 100 agencies were working with the Kosovar Albanians during 1999. On the other hand, lower-profile CEs may be as severe and life threatening to large populations, such as that in Sierra Leone in 1999, yet attract much less media attention and intergovernmental and humanitarian responses. New NGOs established in response to a specific conflict may be short-lived, inexperienced, and unable to cope with the challenges they face in providing services in complex political environments. The principle that such an organization must do more good than harm must underlie all interventions.

Every conflict has winners and losers. Predators identify opportunities amidst the turmoil to further enrich themselves and entrench their political position; thus, these players may have an interest in perpetuating the conflict. Humanitarian aid itself may become a resource over which groups compete, and such assistance and resources may directly or indirectly stoke the conflict. In some distressing circumstances, humanitarian aid has been used unwittingly to attract populations that were subsequently targeted by combatants, as in the DRC and Sudan. Humanitarian workers have increasingly been directly targeted in latter-day conflicts, leading to increased efforts to work closely with the military and security sector. Despite some benefits, such as improved logistics support, this trend may bring negative consequences and additional dangers and may threaten the neutrality and impartiality to which many agencies aspire.

In recent conflicts, health facilities, including those supported by international NGOs, have been targeted by combatants. For example, between 2015 and 2017, nearly 100 medical facilities supported by Médecins sans Frontières (MSF) were bombed (ReliefWeb, 2017a). The vast majority of these sites were in Syria, but facilities in Yemen, Afghanistan, Ukraine, and South Sudan were also hit.

NGOs are not a homogeneous community. Although some are highly professional and have given considerable thought to the development of humanitarian and technical policies and programs, the way in which humanitarian assistance has been provided has brought some negative consequences. Recognition by the humanitarian community of these problems has led to a great deal of evaluation and introspection, along with measures to improve practice, including the development of codes of conduct for humanitarian agencies, the promotion of minimum standards for service provision, and debate regarding enhancing accountability to affected populations. The most widely used minimum standards have been compiled

by the Sphere Project, which is in the process of producing its fourth edition (Sphere Project, 2011).

The first-ever World Humanitarian Summit took place in Istanbul in May 2016. As part of the lead-up to the summit, a number of donors and NGOs negotiated what was known as the "Grand Bargain"—a commitment from donors and aid organizations to provide 25% of global humanitarian funding to local and national responders by 2020, along with more non-earmarked money, and increased multiyear funding to ensure greater predictability and continuity in humanitarian response, among other commitments. The Grand Bargain was endorsed at the World Humanitarian Summit.

Promoting the derivation and uptake of good practices is particularly difficult in humanitarian agencies given their rapid staff turnover, unwillingness to publicly acknowledge failures and limitations because of the possible funding consequences, and a culture of doing rather than reflecting. Interventions are sometimes not evidence-based, and, despite most agencies valuing the concept of coordination, few wish to be coordinated. Poor-quality services have significant adverse consequences: increased morbidity, mortality, and disability; further spread of communicable diseases; community dissatisfaction and breakdown; and psychosocial distress. Clear policy objectives for interventions are often lacking, and mechanisms for working with new players such as the military and the private sector remain inadequately developed. Despite recognition that the accountability of relief efforts to affected populations should be enhanced, mechanisms to assure this relationship is honored are in their infancy.

Ongoing humanitarian challenges include understanding how best to upgrade host population health services alongside efforts to improve those services made available specifically to refugees, how best to ensure that urban refugees can access effective and affordable health care, how to most humanely and efficiently provide good-quality services, and how to maintain the role of communities in structuring both the determination of priorities and the pattern of service provision. A key issue relates to how and whether to bolster and support resilient health and social systems and individual adaptations to conflict. Our level of knowledge regarding these responses, and the potential to further support them, is weak. A persistent challenge for humanitarian workers is the quest to institutionalize a sensitive and inclusive evidence-based culture and to build sustainable mechanisms for crystallizing policy advice from the vast and valuable foundation of field experience.

Direct Public Health Impact of War

Measuring the impact and hidden costs of conflict is complex for a variety of reasons—methodological and theoretical shortcomings, inconsistencies in definitions and terms, restricted access to areas of conflict and sources of information, the rapid evolution of many emergencies, political manipulation of data, resource constraints, and the hidden or indirect nature of the impact. One of the consequences of the data-related limitations is difficulty in identifying more precisely which sections of the population are at greatest risk so as to develop more appropriate responses. Most poor countries lack reliable health information and vital registration systems, the absence of which increases the difficulties of determining the conflict-associated costs in terms of morbidity, mortality, and disability. Furthermore, CEs may seriously disrupt any surveillance and information systems that do exist.

Lack of consistency in definitions used makes it difficult to compare data within and across populations. Different agencies may define refugees and IDPs in different ways, case definitions for particular conditions vary, and techniques for estimating nutritional deficiencies, for example, may vary among different agencies working with the same population. Data are at times incomplete because impartial observers who attempt to provide more accurate figures may not have access to witnesses or other reliable sources of information.

During the last 20 years, a number of expert meetings have been held to develop more reliable methods of measuring both direct and indirect mortality resulting from CEs. Some of their proceedings have been published (Reed & Keeley, 2001; Working Group for Mortality Estimation in Emergencies, 2007). Other publications have sought to help non-epidemiologists analyze and use mortality data (Checchi & Roberts, 2005). Cross-sectional retrospective mortality surveys have been increasingly employed to measure conflict-related mortality. In 2004 alone, large mortality surveys were conducted in three conflict zones: Iraq, the DRC, and the West Darfur region of Sudan. All of these surveys used cluster sampling methodology.

Between 2000 and 2007, the International Rescue Committee (IRC), an international NGO, conducted a series of mortality surveys to evaluate the humanitarian impact of the conflict in DRC. The third nationwide survey in 2007 found that the crude mortality rate (CMR) remained elevated at a level almost 70% higher than that reported in the 1984 national census

and more than 55% higher than the reported baseline for sub-Saharan Africa (Coghlan et al., 2009). Fewer than 10% of deaths documented in the studies were directly attributable to violence. Instead, most were due to the indirect public health effects of conflict, including higher rates of infectious diseases, increased prevalence of malnutrition, and neonatal conditions. The authors of these studies concluded that security interventions, rather than health, would have the greatest impact on reducing mortality rates.

Although innovative techniques may be used to try to build up a picture of what transpired during a particular CE, the needs that arose during the CE, and the nature of the response, the sources of data may be biased, as may the ways in which information has been collected. Despite these challenges, innovative groups—often NGOs without a political agenda linked to any of the key players in the conflict—may be able to play a valuable role in documenting precisely what occurred and what the nature of present needs is. MSF has taken an innovative approach to documenting the impact of CEs through its MSF Speaking Out series, in which extracts from all relevant internal and external MSF documents are collated and annotated to form a compelling chronicle of a crisis and published both in hard copy and on the "MSF-CRASH" website (http://www.msf-crash.org/en). One example is the book published in 2017: *Humanitarian Aid, Genocide and Mass Killings: The Rwandan Experience, 1982–97* (Bradol & Le Pape, 2017).

Even where huge numbers of people are involved in a CE, agreement on the magnitude of impact varies. For example, the reported numbers of deaths in Syria since the beginning of the civil war have varied between government and opposition sources. The most reliable estimate is probably the December 2016 estimate of the Syrian Centre for Policy Research, which suggested that 470,000 direct or indirect deaths had occurred due to the Syrian conflict since it began in 2011, and 11.5% of the population had been killed or injured. Approximately 10% of these deaths occurred among IDPs. The annual CMR in Syria increased from 4.4 deaths per 1,000 in 2010 to 10.9 deaths per 1,000 in 2014, accounting directly and indirectly for the death of approximately 1.4% of the total population.

Data on numbers of IDPs and refugees may be manipulated by states and organizations in an attempt to make a political point or to maximize access to resources. It has been alleged that some refugee camp administrators and refugees report fewer deaths than actually occur so as to maintain levels of international assistance—having fewer beneficiaries could result in less assistance. In Nepal, in an attempt to encourage reporting of deaths among Bhutanese refugees, free funeral shrouds were offered to relatives of the deceased together with assurances that the reporting would not result in decreases of rations; this approach has also been used elsewhere.

Physical Impact

Political conflicts in the latter half of the 20th century were mostly waged between armies and trained combatants. The main direct results, in the form of deaths, morbidity, and disability, reflected the nature of the conflict, the level of technology and the nature of weapons, the prior preparation and protective clothing available to military personnel, and the quality of emergency medical care and evacuation facilities.

In the vast majority of latter-day conflicts, however, the entire population is often targeted, in part directly, but also with massive and sustained efforts at reducing the viability and integrity of the affected community. Injuries and disabilities may follow the use of firearms, but technology levels need not be high to achieve terrible levels of destruction. For example, the Rwandan genocide was largely committed with a combination of guns and machetes.

Antipersonnel land mines have also been responsible for significant population burdens, especially in a small number of heavily infested countries such as Angola, Cambodia, and Afghanistan. Despite a global ban, land mines have been deployed in recent conflicts. One of the most notorious examples was the Syrian town of Madaya in 2016. Syrian government forces had laid siege to the town, in the Rural Damascus Governorate, depriving roughly 40,000 residents of food and medicine for almost a year. The town was surrounded by an estimated 12,000 land mines. Between November 2015 and May 2016, 86 people died from siege-related causes, including 14 from land mines and 6 from snipers (Physicians for Human Rights [PHR] & Syrian American Medical Society, 2016).

Sexual Violence

Rape is increasingly recognized as a feature of internal wars, but has been present in many different types of conflicts. In some conflicts, rape has been used systematically as an attempt to undermine opposing groups. For example, an estimated 215,000 to 257,000 women were victims of sexual violence during the civil war in Sierra Leone (Project Ploughshares, 2002). The effects of gender-based violence (GBV) in conflict and post-conflict areas are numerous and severe. Sexually transmitted infections are a lasting

consequence of GBV and are a major health concern for women in conflict areas. Physical harms such as injury to reproductive organs, traumatic fistulas, and infertility often accompany brutal or repeated rapes. Attempts at abortion following an unwanted pregnancy from rape may also have severe medical complications.

The widespread sexual violence associated with armed conflict in eastern DRC has led it to be named the "rape capital of the world." A 2014 survey conducted in North Kivu Province showed that 22% of women were victims of sexual violence within the conflict (European Parliament, 2014). In addition, 50% of women had experienced sexual violence in a domestic context, evidence of the spread of what some call a "rape epidemic."

The findings of a systematic review in 2014 suggested that approximately one in five refugee or displaced women in complex humanitarian settings had experienced sexual violence (Vu et al., 2014). A study in Uganda found that despite widespread rape, few women spoke of their victimization (Bracken, Giller, & Kabaganda, 1992). Women of all ages had been targeted by sexual violence, but only few of those—and many of them only after several years—sought medical care and psychological help. Interestingly, recent studies have shown that during conflict a surprisingly high proportion of sexual violence is perpetrated on women by domestic intimate partners (Stark et al., 2017).

UN peacekeepers have been hit by a series of accusations of sexual exploitation and abuse of civilians across the globe. At least 55 UN peacekeepers were accused of sexual exploitation and abuse of civilians across UN missions around the globe during the first half of 2017, including a number of allegations against UN peacekeepers in Central African Republic (Essa, 2017).

Women who are on their own during a CE may find it more difficult to assure their safety and that of their children. They may become targets of violence from three sides: from the opposing army, from the armed forces in the country to which they have fled, and sometimes from their own community (Palmer & Zwi, 1998). They may be forced to provide sex in exchange for food, shelter, or other necessities for self and family survival. The experience of Afghan refugees is illustrative: "In the camps in Pakistan, most of which are controlled by one or other of the warring Afghan factions, women have been attacked, particularly those who are unaccompanied by men. If they refuse sexual favors, they are often denied access to vital rations" (Amnesty International, 1995, p. 15).

The issue of safety of women should be carefully considered when planning camp and other facilities: The siting of water, latrines, and cooking fuels should be undertaken in such a way as to reduce risks of abuse and violence, as described in the Sphere Project guidelines.

Human Rights

In times of war, the Universal Declaration of Human Rights and other laws, covenants, declarations, and treaties that constitute the body of human rights law are complemented by international humanitarian law. The latter is "a set of rules aimed at limiting violence and protecting the fundamental rights of the individual in times of armed conflict" (Perrin, 1996, p. 381). These rules are intended to govern the conduct of war by banning the use of certain weapons and by minimizing the effects of armed conflicts, whether international or internal, on noncombatants. The protection of the rights of noncombatants in wartime is based primarily on the Geneva Conventions of 1949 and the two Additional Protocols of 1977. Yet, despite the existence of both of these bodies of international law, CEs are consistently associated with serious infringements of the dignity of individuals and, more specifically, with a major impact on the health status of affected individuals and populations.

General practices that can be considered clear violations of international humanitarian law include the intentional targeting of civilian noncombatants, medical personnel, and civilian health facilities. Protection is also conferred upon prisoners of war, wounded and ill combatants, and military medical installations. Violations by states and individuals occurred with great frequency during the second half of the 20th century. One of the most prominent example was the genocidal activities perpetrated upon the Tutsi population of Rwanda in 1994. In the 1990s, the governments of Serbia and Croatia pursued ethnic cleansing policies against the populations of neighboring republics of the former Yugoslavia and, in the case of Serbia, the province of Kosovo. Arab militia in western Sudan, known as the Janjaweed, terrorized the Zaghawa, Masaalit, and Fur peoples between 2003 and 2005 with active support from the government of Sudan. This overt support led to the issuance in March 2009 of an arrest warrant by the International Criminal Court for the president of Sudan, Omar Hassan al-Bashir. Between 2011 and 2017, numerous human rights abuses were committed by all sides of the Syrian conflict, including torture, summary executions, and sexual violence.

Although violations of human rights law and international humanitarian law are crimes, the legal systems for punishing the perpetrators and compensating the victims are grossly inadequate. To date, four international tribunals have been established to prosecute war criminals from the former Yugoslavia, Rwanda, Cambodia, and Sierra Leone. Although these courts help to move the punishment of war criminals from theory to practice, they have been slow to act and expensive to implement. The establishment of an International Criminal Court—a permanent standing body dedicated to the trial and punishment of individuals accused and convicted of violations of human rights law—is, at least conceptually, another step toward strengthening what has in many respects been a legal system without law enforcement capability.

Reporting and responding to reports of human rights violations pose major problems. Although wars and internal conflicts have been proximate causes of most humanitarian emergencies, few of the individuals and agencies that have been involved in providing relief to the individuals affected are trained in the recognition of human rights violations or know where and how to report them. Until more widespread attention is paid to these crimes against humanity, the victims will continue to suffer from preventable acute and chronic morbidity, and the perpetrators will largely go unpunished. It would be useful to treat human rights violations as a major cause of morbidity and mortality during wars and their aftermath and to establish the epidemiologic characteristics of their distribution (Spirer & Spirer, 1993).

Indirect Public Health Impact of Civil Conflict

This section focuses in detail on the impacts on the health of populations that are not directly consequences of violence. Although the chapter as a whole focuses on the public health consequences of armed conflict, there is a phased evolution of public health effects as a country or region moves from political disturbances, economic deterioration, and civil strife through armed conflict, population migration, food shortages, and the collapse of governance and physical infrastructure. Thus, this section attempts to frame the indirect consequences of civil conflict in the changing context of evolving humanitarian emergencies.

Food Scarcity

As political disturbances evolve in a country, there is generally a significant effect on national and local economies. Under such scenarios, especially in LMICs, one of the first health effects is undernutrition in vulnerable groups, often caused by food scarcity. Local farmers may not plant crops as extensively as usual, or may decrease the diversity of their crops due to the uncertainty created by the economic or political situation. The cost of seeds and fertilizer may increase, and government agricultural extension services may be disrupted, resulting in lower yields. Distribution and marketing systems may be adversely affected. Devaluation of the local currency may drive down the price paid for agricultural produce, and the collapse of the local food processing industry may further diminish demand for agricultural products.

If full-scale armed conflict occurs, the fighting may damage irrigation systems, crops might be intentionally destroyed or looted by armed soldiers, distribution systems may collapse completely, and there may be widespread theft and looting of food stores. In countries that do not normally produce agricultural surpluses or that have large pastoral or nomadic communities, the impact of food deficits on the nutritional status of civilians may be severe. Such has been the case not only in sub-Saharan Africa, but also in Yemen (**EXHIBIT 12-1**). If adverse climatic factors intervene, as often happened in drought-prone countries such as Sudan, Somalia, Mozambique, and Zimbabwe, the outcome may be catastrophic famine.

Famine may be defined as high malnutrition and mortality rates resulting from inadequate availability of food. Lack of food availability may result from either insufficient production or inadequate or inequitable distribution.

EXHIBIT 12-1 Yemen

The civil war in Yemen has exacerbated the country's preexisting challenges, including poverty, poor health, and shortages of basic necessities such as water, fuel, and medications. By late 2016, the price of food had increased by 55% in that country and the gross domestic product (GDP) had contracted by almost 33%. Moving safely and freely was impaired, and access to clean water was a complicating barrier. An outbreak of watery diarrhea that caused much morbidity and mortality in Yemen was attributed to cholera. An estimated 14.4 million people, almost half of whom were severely affected, were unable to meet their food needs (Action Against Hunger, 2017). UNICEF estimated that approximately half of children in Yemen were affected by stunting (chronic malnutrition), and nearly 460,000 of Yemen's children were suffering from severe acute malnutrition (Eshaq et al., 2017).

When food aid programs are established, there may be inequitable distribution due to political factors, food stores may be damaged or destroyed, food may be stolen or diverted to military forces, and the distribution of food aid may be obstructed (Macrae & Zwi, 1994). The resulting food shortages may cause prolonged hunger and eventually drive families from their homes in search of relief. There have been many examples of food aid diversion, including in Sudan, Somalia, and the former Yugoslavia in the 1990s and in South Sudan and Yemen in the 21st century. Indeed, in latter-day CEs, targeting of relief assistance and the use of humanitarian aid as a resource that enables the warring parties to continue their violence is an ongoing challenge for humanitarian agencies.

Population Displacement

A common response by families and communities to civil conflict is to flee the violence. Individuals may flee because they fear persecution due to their particular political beliefs, ethnicity, or religion. In some societies, migration of part of the family to a safer area may be a traditional coping mechanism, with adult males staying behind to care for their land and animals. Some of these men may also be directly involved in the conflict. Mass migration and food shortages have been responsible for most deaths following civil conflicts in Africa and Asia.

Refugees

Refugees are defined under several international conventions as persons who flee their country of origin through a well-founded fear of persecution for reasons of race, religion, social class, or political beliefs (but not for economic reasons).

A number of large mass migrations occurred in the last decade of the 20th century, such as the 1 million Kurdish refugees who fled Iraq for Iran or Turkey in 1991; the 1.5 million refugees or displaced persons within the republics of the former Yugoslavia in 1993; the estimated 2 million Rwandan refugees who fled into Tanzania, Eastern Zaire, and Burundi in 1994; and the approximately 780,000 ethnic Albanians who fled the then Serbian province of Kosovo in 1999. The number of dependent refugees under the protection and care of the UNHCR steadily increased from approximately 6 million in 1980 to more than 17 million in 1992. However, during the first decade of the new millennium, the number of refugees and internally displaced persons remained relatively stable.

This situation changed dramatically following the Arab Spring in 2011, especially in Syria, Iraq, Libya, and Yemen, where fierce armed conflict erupted and continues to this day. In March 2017, the number of registered Syrian refugees exceeded 5 million, with the majority residing in Turkey, Jordan, and Lebanon (UNHCR, 2017b). In addition, an estimated 6.6 million Syrians were internally displaced. Other major sources of refugees and internally displaced persons in 2017 were chronically conflict-affected Afghanistan, Somalia, the DRC, and Colombia, as well as countries recently affected by conflict, such as South Sudan, Central African Republic, and Yemen (UNHCR, 2017a). **TABLE 12-1** notes major refugee populations as of December 2016.

TABLE 12-1 Origins of 10 Major Refugee Populations (Plus Palestinians), December 2016

Refugee Origin	Host Country	Number
Palestinians	West Bank, Gaza, Jordan, Lebanon	5,300,000
Syria	Turkey, Lebanon, Jordan, Egypt	5,500,000
Afghanistan	Iran, Pakistan, India	2,500,000
South Sudan	Ethiopia, Uganda, Kenya, Sudan	1,400,000
Somalia	Kenya, Sudan, Yemen, Djibouti	1,000,000
Sudan	Chad, South Sudan	650,000
Democratic Republic of Congo (DRC)	Uganda, Rwanda, Tanzania	537,500
Central African Republic	Cameroon, Chad, DRC	490,900
Myanmar	Bangladesh, Malaysia	490,300
Eritrea	Ethiopia, Sudan, Saudi Arabia	459,400
Burundi	Tanzania, Rwanda, Uganda	408,100

Data from United Nations High Commissioner for Refugees. (2017). *Global trends: Forced displacement in 2016*. Geneva, Switzerland: Author.

In 2016, the countries hosting the largest numbers of refugees were Turkey (2.9 million), Pakistan (1.4 million), Lebanon (1 million), Iran (980,000), Uganda (940,800), Ethiopia (791,600), Jordan (685,000), and Germany (669,000).

Internally Displaced Persons

In addition to those persons who meet the international definition of refugees, millions of people have fled their homes for the same reasons as refugees but remain *internally displaced* in their countries of origin. Ascertaining the number and location of the world's IDPs presents a stiff challenge due not only to definitional difficulties, but also as the result of institutional, political, and operational obstacles. Despite these difficulties, there is a broad consensus that the global population of IDPs has increased from somewhere in the region of 20 million at the end of 2000 to more than 40 million at the end of 2016.

IDPs lack the protection afforded by the international conventions and protocols on refugees. Nevertheless, the Geneva Conventions and certain articles of the United Nations Charter provide some protection to these individuals. Since 2005, UNHCR has been officially responsible for providing assistance to IDPs.

During 2016, 5.5 million IDPs were newly displaced by conflict and violence in their countries, according to data reported by UNHCR. At the end of 2016, the largest IDP populations were in Colombia (7.4 million), Syria (6.3 million), Iraq (3.6 million), DRC (2.2 million), Sudan (2.2 million), Nigeria (2.2 million), Yemen (2.0 million), South Sudan (1.9 million), Ukraine (1.8 million), Afghanistan (1.8 million), and Somalia (1.6 million). **FIGURE 12-2** shows the trend in IDP and refugee numbers between 1996 and 2015.

The final stages of the Sri Lankan civil war created 250,000 internally displaced persons who were transferred to camps in Vavuyina District and detained against their will for many months (see **EXHIBIT 12-2**).

During the 1990s, the United Nations Security Council sanctioned some extraordinary measures to protect displaced populations in southern Sudan, northern Iraq, the republics of the former Yugoslavia, Somalia, and Timor-Leste. There have been few such United Nations interventions since 2000. One notable exception has been the United Nations–African Union Mission in Darfur (UNAMID), which at the end of 2016 had almost 20,000 uniformed personnel from 116 countries.

Until the past decade, the most common response to mass population movements, either across international boundaries or within countries, had been to establish camps or settlements. In Eastern Europe, many refugees and IDPs have been housed in hotels, resort camps, schools, and hostels, where environmental conditions have been relatively good. In contrast, in LMICs, most refugees and displaced persons have been placed in camps located in inappropriate border areas. Conditions in camps have varied enormously; in general, camps with fewer than 20,000 residents have had more favorable environmental conditions than larger camps. Camps for Rwandan refugees in eastern Zaire in 1994 contained up to 300,000 persons; they were poorly planned and laid out, with inadequate sanitation and poor access to

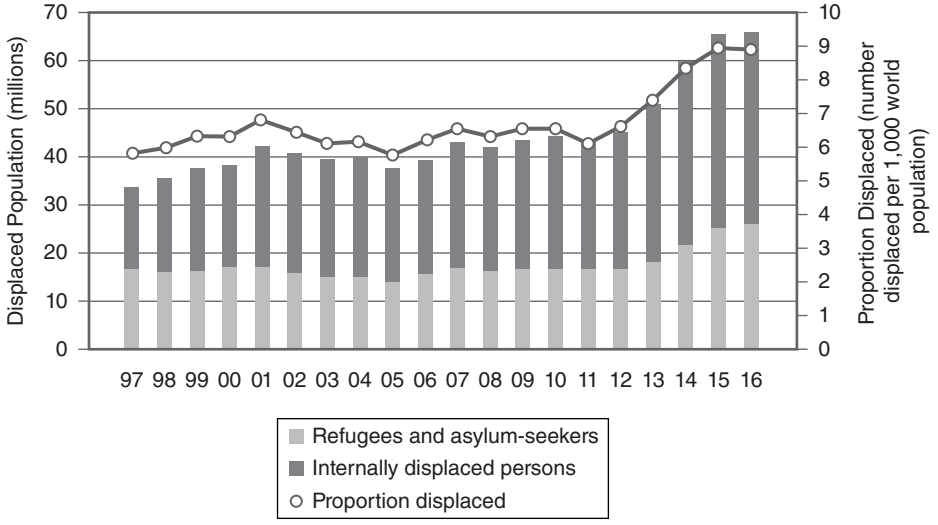

FIGURE 12-2 Estimated global number of refugees and internally displaced persons (millions), 1997–2016.

Reproduced from United Nations High Commissioner for Refugees. (2017). *Global trends: Forced displacement in 2016*. Geneva, Switzerland: Author.

EXHIBIT 12-2 Crisis Traps IDPs in Sri Lanka

During the first half of 2009, Sri Lanka's 26-year conflict in the north of the country intensified. Fighting between the Sri Lankan army and the Liberation Tigers of Eelam (LTTE) trapped approximately 70,000 civilians in a small coastal stretch of land in the north Vanni region. The United Nations estimated that 4,500 civilians were killed and 12,000 injured during the final stages of the conflict. The International Committee of the Red Cross (ICRC) was the only humanitarian aid agency permitted access to the area.

Eventually, LTTE forces were defeated and the fighting ceased. In the immediate aftermath, approximately 250,000 civilians were displaced and held in camps for up to 12 months. In 6 days alone, from May 16 to May 20, 77,000 people emerged from the former conflict zone in northern Sri Lanka and arrived in Vavuniya district, where MSF was one of the aid agencies working. MSF provided surgical and medical support to the 400-bed Vavuniya Hospital, which at one point housed 1,900 inpatients. To ease the congestion, MSF established a 100-bed field hospital. The main cause of hospitalization among the 3,000 patients admitted to the MSF hospital from June to the end of November 2009 was trauma and wounds. In total, more than 1,350 surgical procedures were performed during that time in the MSF hospital.

Data from Medical emergency in Sri Lanka. (2009). *The Lancet*. 373:1399; MSF Australia. (2009, December 14). Field News. Sri Lanka: Situation Retrieved from www.msf.org.au

clean water. Relief program managers found it difficult, if not impossible, to establish equitable systems of distribution of commodities, such as food and shelter materials, and there was a high frequency of violence and other crimes. By contrast, smaller refugee camps in Burundi were more easily managed and the residents there suffered fewer health consequences related to environmental conditions.

In addition to poor environmental conditions, crowded camps promote the spread of many communicable diseases, such as measles, meningitis, and acute respiratory infections. The overwhelming nature of these large camps also tends to create a sense of loss of dignity and independence among mostly rural refugees, and induces mental health disorders such as anxiety and depression.

As noted earlier, in 2016, more than 50% of the world's refugees and IDPs were in urban areas, which has both positive and negative implications for their quality of life and health status. The positives include a diminished risk of communicable diseases; the negatives include difficulties in accessing health services that may rely on user fees. For example, most health services in Lebanon are provided by private practitioners.

Destruction of Public Utilities

Wars often involve the intentional or accidental destruction of public utilities, such as water and sewage systems, electricity sources and distribution grids, and fuel supplies. Although these disruptions mainly affect urban areas, local water supplies have also been destroyed in rural conflicts, such as in Somalia during the early 1990s.

Between 1992 and 1995, in Sarajevo, the capital, and other large cities in Bosnia and Herzegovina, municipal water supplies were destroyed by shelling; similar breakdowns in sewage systems and cross-contamination of piped water supplies led to widespread contamination of drinking water. These problems were compounded by the lack of electricity and diesel fuel needed to run generators.

During a conflict, hospital generators are often able to supply only operating rooms and emergency rooms, further promoting a concentration of services in the area of trauma management. In this kind of environment, routine surgical procedures, inpatient medical care, and pediatric, obstetric and gynecologic, and perinatal care services deteriorate. In addition, the cold chain required to maintain immunization programs is not sustainable.

The Effects of Armed Conflict and Political Violence on Health Services

The model presented in **FIGURE 12-3** offers a framework for describing the health service impact of conflict and CEs. The focus is on the health services within the countries affected by CEs; there are also related pressures and constraints on the health services of host countries to which refugees may flee.

Access to Services

The impact of conflict on health facilities and services depends on their prior availability, distribution, and utilization patterns. Where services

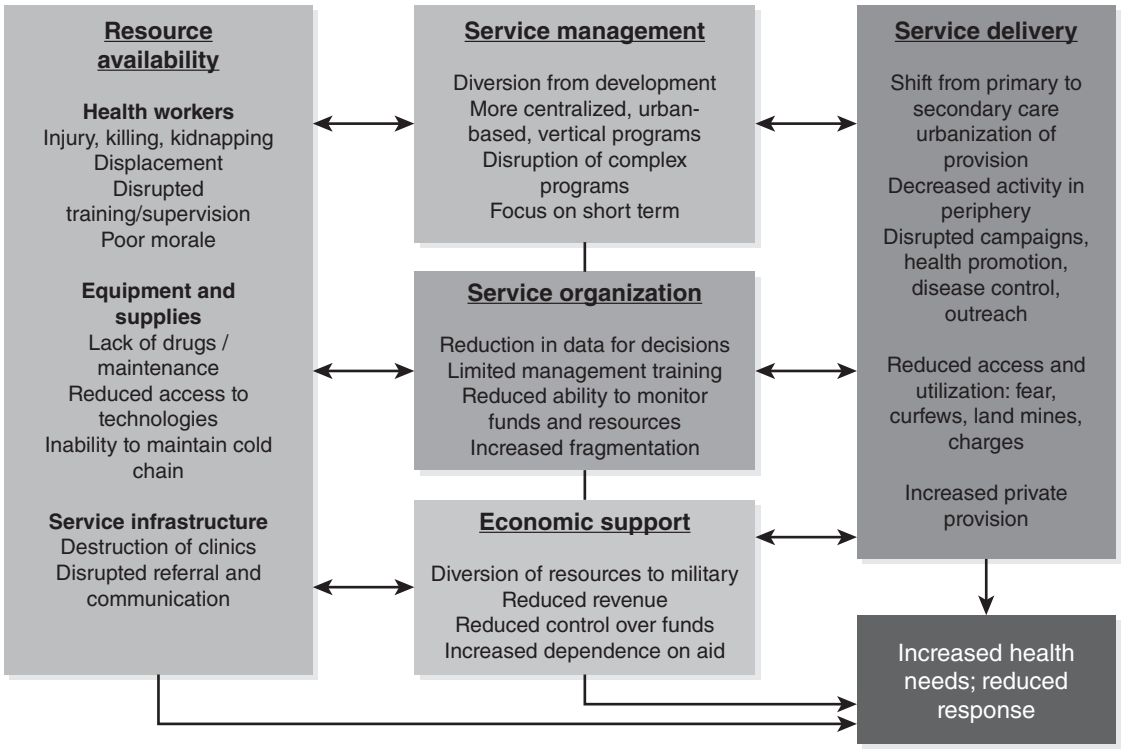

FIGURE 12-3 Impact of conflict and complex emergencies on health.

were originally available, as in Iraq (prior to 1991) and Syria (prior to 2011), the conflict may cause rapid deterioration as a result of infrastructure and distribution systems damage, resource constraints, declining health personnel availability and morale, and reductions in access. The prewar health system in Iraq was extensive, accessible to 90% of the population, and reached 95% of the children requiring immunizations (Lee & Haines, 1991). By the end of the Gulf War, many hospitals and clinics had been severely damaged or closed, those operating were overwhelmed with work, and damage to infrastructure, water supplies, electricity, and sewage disposal exacerbated problems in population health and health services activity.

Six years of civil war in Syria have taken a devastating toll: thousands of lives lost, forced migration at levels unseen since World War II, homes and infrastructure obliterated, health facilities and workers targeted in attacks. Access to basic health care, including surgical care, is severely hampered by restricted ability to move, the destruction and breakdown of health infrastructure, shortage of medical supplies, lack of human resources and threats of kidnappings and killings by different armed groups on medical staff. By the end of March 2015, out of 113 public hospitals in Syria, 44% were reported fully functioning, 36% partially functioning (i.e., shortage of staff, equipment, or medicines, or damage of the buildings in some cases), while 20% were reported to be nonfunctioning (Eastern Mediterranean Regional Office [EMRO], 2015). Reports estimate that more Syrians have died due to health complications resulting from inadequate healthcare services than as a direct consequence of the conflict (European Commission, 2015).

Utilization is determined by geographic access (i.e., the services are not too far away), economic access (i.e., the services are affordable), and social access (i.e., no psychological or other barriers prevent use of services)—all factors that may be disrupted during CEs. Service access may be limited by fear of physical or sexual assault or by physical restrictions on access as a result of antipersonnel land mines, curfews, and, in some cases, the encirclement of areas. In Afghanistan, the Taliban imposed constraints on women accessing services that were previously available to them.

Conflict may seriously disrupt links between services operating at different levels: Referrals will be disrupted by logistical and communication constraints, as well as physical and military barriers to access. Health workers may move to urban areas to seek protection, other opportunities to make a living, or opportunities to provide health services privately with greater financial returns. Towns and cities may be besieged, with entry and exit controlled by militias, as in Aleppo (Syria), Mosul (Iraq), Sanaa (Yemen), and Juba (South Sudan).

Equipment and Supplies

Access to medicines and supplies is typically disrupted during conflicts. Drug shortages, especially where they were previously available, may lead to an increase in medically preventable causes of death, such as asthma, diabetes, and infectious diseases. The Eastern Mediterranean Regional Office of the World Health Organization (WHO) reported from Syria that owing to the reduction of locally produced medicines by 70% of the pre-conflict levels, which led to higher costs for medicines, there were increasingly high numbers of vulnerable people suffering from noncommunicable diseases (NCDs) who could not be adequately treated (EMRO, 2015).

The quality of care available may also suffer greatly during CEs. In Somalia, amputations performed without intravenous antibiotics led to higher rates of infection. In the former Yugoslavia, operations were performed with inadequate anesthesia. Healthcare technologies, including x-rays and laboratories, are undermined through lack of maintenance, spare parts, skilled personnel, chemicals, and other supplies.

Additional problems may emerge as a result of the humanitarian response. Drug donations, if poorly coordinated and standardized, may lead to a large number of expired and inappropriate drugs being offloaded in countries experiencing CEs. These medications may not be usable, but require safe and efficient disposal, placing an additional burden on the recipient country's pharmaceutical services.

Human Resources

Injury, killing, kidnapping, and exodus of health workers are all common events during CEs. Evidence indicates that health workers have been specifically targeted in many recent conflicts; this has been particularly well documented in Syria. Physicians for Human Rights estimates that between 2011 and 2015, at least 610 medical personnel were killed, and there were 233 deliberate or indiscriminate attacks on 183 medical facilities (PHR, 2015). PHR claims that the Syrian government was responsible for 88% of the recorded hospital attacks and 97% of medical personnel killings in that country.

Even if not directly targeted, health workers may flee in search of safety and security. Thousands of physicians once worked in Aleppo, formerly Syria's most populous city, but the assault has resulted in an exodus of 95% of them to neighboring countries and to Europe. Across Syria, millions of civilians have no access to care for chronic illnesses, and the health ministry routinely prevents UN convoys from delivering medicines and surgical supplies to besieged areas.

New Actors

During internal conflicts, due to scarcity of resources and government difficulties in accessing populations under the control of insurgents, NGOs usually fill part of the vacuum left by the public sector. For example, NGOs such as MSF and the Syrian American Medical Society Foundation have been remotely supporting clandestine hospitals and surgical facilities inside Syria. In recent conflict-related emergencies, various military forces have played a direct role in providing relief (e.g., northern Iraq, 1991), as have private companies contracted by government or UN agencies (e.g., Albania and Macedonia, 1999). The entry of these new players has further complicated the response to CEs.

The role of NGOs is extremely important both during and in the aftermath of ongoing conflict. During conflicts, indigenous NGOs and church groups may be among the few service providers that continue to operate during the conflict, especially in rural areas and those more directly affected by violence. A key problem, however, is that these NGOs often provide a patchwork of services that are relatively independent of the state and do not necessarily fit in with other service provision approaches or priorities. They may communicate poorly with one another, adopt different approaches and standards of care and of health worker remuneration, and focus attention mostly at a local level, with some impact on the equity of service availability across large regions.

A key research challenge is to understand how health systems adapt and respond to conflict and to determine whether positive developments can be further reinforced and sustained. Mechanisms to protect and maintain key elements of service provision and functioning, including information systems and supplies, are crucial to assuring ongoing system functioning. How best to promote this state requires further exploration.

Specific Health Outcomes

Mortality

In this section, the impact of civil conflict and humanitarian emergencies on mortality rates is confined to indirect causes, such as food scarcity, population displacement, destruction of health facilities and public utilities, and disruption of routine curative and preventive services. Mortality directly caused by the violence of war was discussed earlier.

The most severe health consequences of conflict—population displacement, food scarcity, and siege situations—have occurred in the acute emergency

phase, during the early stage of relief efforts, and have often been characterized by extremely high mortality rates. Although the quality of the international community's disaster response efforts has steadily improved, death rates associated with forced migration have often remained high, as demonstrated by several emergencies during the 1990s. For example, the exodus of almost 1 million Rwandan refugees into eastern Zaire in 1994 resulted in mortality rates that were more than 30 times the rates experienced prior to the conflict in Rwanda. Most deaths were caused by communicable diseases, such as cholera and dysentery.

In Darfur, Sudan, death rates among civilian populations were as high as 9.5 per 10,000 per day (20 times higher than baseline mortality rates) in 2003, with most deaths being due to violence (Depoortere et al., 2004). However, a study published in 2010 reviewed 63 retrospective mortality surveys conducted after the Depoortere study, spanning from early 2004 to the end of 2008 (Degomme & Guha-Sapir, 2010). The highest CMR was 4 per 10,000 per day in early 2004, when the most common cause of death was still injuries due to violence. The study showed significant reductions in mortality rates from early 2004 to the end of 2008, although rates were higher during deployment of fewer humanitarian aid workers. Also, the main causes of death evolved from violence to communicable diseases. The study estimated that almost 300,000 excess deaths related to conflict and displacement occurred during the 4-year study period.

CMRs have been estimated from burial site surveillance; administrative, hospital, and burial records; community-based reporting systems; and population surveys. The many problems in estimating mortality under emergency conditions have included the following:

- Poorly representative or inaccurate population sample surveys
- Failure of families to report all deaths for fear of losing entitlements
- Inaccurate estimates of affected populations for calculating mortality rates
- Lack of standard reporting procedures

In general, however, mortality rates may be underestimated because deaths are usually underreported or undercounted, and population size is often exaggerated.

Early in an emergency, when mortality rates are elevated, the CMR is usually expressed as deaths per 10,000 population per day (CDC, 1992). The median annual CMR in developing countries is approximately 9 per 1,000, corresponding to a daily rate of approximately 0.25 per 10,000 (Reed & Keeley, 2001). A threshold of 1 per 10,000 per day typically has been used to define an elevated CMR and to characterize a situation as an emergency (CDC, 1992). In one of the most severe refugee emergencies of the 1990s, the CMR among Rwandan refugees during the first month after their arrival in eastern Zaire was between 27 and 50 per 10,000 per day (Goma Epidemiology Group, 1995).

The most reliable estimates of mortality rates have come from well-defined and secure refugee camps where there is a reasonable level of camp organization and a designated agency has had responsibility for the collection of data (**TABLE 12-2**). The most difficult situations have been those where IDPs have been scattered over a wide area and where surveys could take place only in relatively secure zones (**TABLE 12-3**). These safe zones have sometimes acted as magnets for the most severely affected elements of a population. For example, in 1998, a survey in Ajiep, southern Sudan, found that the CMR increased from 17.8 per 10,000 per day during the period June 3 to July 11 to 69.7 per 10,000 per day between July 12 and July 20 (Brown, Moren, & Paquet, 1999). On the one hand, this increase may have been due to an influx of displaced persons reaching Ajiep in a poor condition or to a decrease in the food available within the town. On the other hand, it is possible that the worst affected communities were in areas that were inaccessible to those performing the surveys. In either case, it has proved difficult to extrapolate the findings of surveys on mortality conducted in specific locations to broader populations in conflict-affected countries.

Extensive differences in mortality survey methods have also been identified. For example, an evaluation of 23 field surveys performed in Somalia between 1991 and 1993 found wide variation in the target populations, sampling strategies, units of measurement, methods of rate calculation, and statistical analysis (Boss, Toole, & Yip, 1994).

Since the mid-1990s, CMRs among refugees have tended to be relatively low. In fact, a study found that in conflict-affected emergencies, CMRs are highest among IDPs, followed by nondisplaced residents, followed by refugees who fled to other countries (Heudtlass, Speybroeck, & Guha-Sapir, 2016).

Trends in death rates over time have varied from place to place. In refugee populations where the international response has been prompt and

TABLE 12-2 Estimated Daily Crude Mortality Rates (Deaths per 10,000 per Day) in Selected Refugee Populations, 1991–2013

Period	Country of Asylum	Country of Origin	Mean CMR for Period

effective, as was the case for Cambodians in eastern Thailand (1979) and Iraqis on the Turkish border (1991), death rates declined to baseline levels within 1 month. By comparison, among refugees in Somalia (1980) and Sudan (1985), death rates were still well above baseline rates 6 to 9 months after the influx of refugees occurred (Toole & Waldman, 1990). In the case of 170,000 Somali refugees in Ethiopia in 1988–1989, death rates actually increased significantly 6 months after the influx. This increase was associated with elevated malnutrition prevalence rates, inadequate food rations,

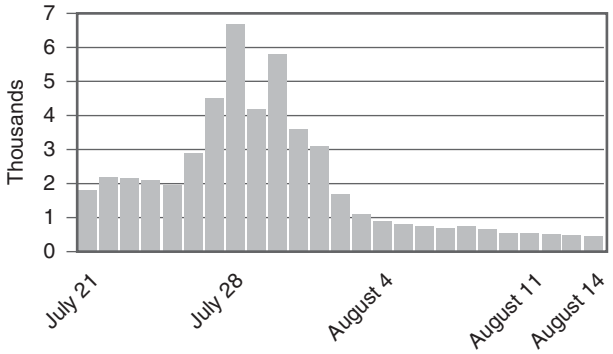

FIGURE 12-4 Number of deaths per day, July 21 to August 14, 1994, Rwandan refugees, North Kivu Camps, Zaire.

Reproduced with permission from Goma Epidemiology Group. (1995). Public health impact of Rwandan refugee crisis: What happened in Goma, Zaire, in July 1994? *The Lancet,* 345, 339–344.

and high incidence rates of certain communicable diseases (Toole & Bhatia, 1992). Although initial death rates among Rwandan refugees in eastern Zaire were extremely high, they declined dramatically within 1 to 2 months (**FIGURE 12-4**). Surveys in Darfur, Sudan, in 2004 showed that mortality was higher in the predisplacement period and generally declined once people reached refugee or IDP camps (Depoortere et al., 2004).

Most deaths have occurred among children younger than 5 years of age; for example, 65% of deaths among Kurdish refugees on the Turkish border occurred in the 17% of the population younger than 5 years (Yip & Sharp, 1993). However, in some refugee situations, such as Goma during the first month after the refugee exodus, mortality rates were comparable in all age groups because the major cause of death was cholera, which is equally lethal at any age. Among IDPs in countries affected by severe famine, high adult mortality has been reported. For example, in the Somali town of Baidoa, 59% of 15,105 deaths reported between August 1992 and February 1993 were among adults (Collins, 1993). In Ajiep, southern Sudan, the CMR among IDPs in August 1998 was equal to the under-5 mortality rate (Salama, Spiegel, & Brennan, 2001).

In most reports from refugee camps, mortality rates have not been stratified by sex. The surveillance system for Burmese refugees in Bangladesh did estimate sex-specific death rates, demonstrating considerably higher death rates in females. Gendered analyses that take into account differences in the sociocultural position of women have been rare in emergency settings.

In the 1980s and 1990s, the major reported causes of death among refugees and displaced populations were diarrheal diseases, measles, acute respiratory infections, and malaria, exacerbated by high rates of malnutrition. These diseases consistently accounted for between 60% and 95% of all reported causes of death in these populations. Measles epidemics caused high death rates among refugees during the 1980s. Epidemics of severe diarrheal disease have been increasingly common and contributed to high mortality. Cholera case-fatality ratios (CFRs) in refugee camps have ranged between 3% and 30%, and dysentery CFRs have been as high as 10% among young children and the elderly.

In eastern European conflicts, a high proportion of mortality among civilians was caused by trauma associated with the violence. Nevertheless, there was also increased mortality in these conflicts due to the collapse of the public health system. Chronic conditions, such as cardiovascular diseases, cancer, and renal conditions, were inadequately treated because the health system was focused on the management of war-related injuries. Preventive health services, including childhood immunization and antenatal care, ceased in many areas.

Over the past two decades, CEs have occurred without excess indirect mortality being reported among displaced populations. For example, mortality rates among Kosovar refugees in Albania and Macedonia remained less than 1 per 10,000 per day. Likewise, mortality rates among Syrian refugees who fled to Turkey, Jordan, and Lebanon have been below the emergency threshold.

Nutrition

Nutritional deficiencies are often the first public health effects of an evolving CE. Among refugees and IDPs, many factors might lead to high rates of nutritional deficiency disorders, including prolonged food scarcity prior to and during displacement, delays in the provision of complete rations, problems with registration and estimation of the size of an affected population, and inequitable distribution systems.

In the emergency phase, acute energy depletion is a life-threatening condition and leads to excess mortality. A critical factor is the synergy between malnutrition and infection; thus, malnutrition prevalence may be increased by high rates of infectious diseases, such as measles, diarrhea, dysentery, acute respiratory infections, malaria, and helminth infestation. Infections, by contrast, lead to decreased appetite and increased metabolic rate, which exacerbate acute malnutrition. These factors may differentially affect certain demographic groups within the population. The most vulnerable groups typically include children younger than 5 years of age, pregnant and lactating women, the elderly, unaccompanied children,

the disabled, the chronically ill (e.g., tuberculosis and human immunodeficiency virus [HIV]–infected patients), households lacking an adult male, and disadvantaged ethnic or religious groups. In industrialized countries, the elderly are often most vulnerable, especially those living alone on fixed incomes.

Malnutrition

In estimating the prevalence of acute malnutrition in a population, the prevalence among children between 6 months and 5 years of age is typically used as a surrogate. This approach is employed because the relationship between weight and height in this age group is generally similar in all ethnic groups, provided those children have access to adequate food. International reference tables developed by WHO (2009) are widely used to define various degrees of acute malnutrition.

The prevalence of moderate to severe acute malnutrition in a random sample of children between 6 months and 5 years of age (or 110 cm in height) is generally a reliable indicator of this condition in a population. Since weight is more sensitive to sudden changes in food availability than height, nutritional assessments during emergencies focus on measuring weight for height. Moderate to severe acute malnutrition is defined as a weight-for-height measurement more than 2 standard deviations below the mean of the WHO reference population (*Z*-score less than –2) (WHO, 2009). Severe acute malnutrition is defined as weight for height more than 3 standard deviations below the reference mean (*Z*-score less than –3). All children with bilateral pitting edema are classified as having severe acute malnutrition.

As a screening measurement, the middle upper arm circumference (MUAC) may also be used to assess acute malnutrition, although there is not complete agreement on which cutoff values should be used as indicators. Field studies indicate that a MUAC between 12.0 cm and 12.5 cm correlates with a weight-for-height *Z*-score of –2; the lower figure (12.0 cm) is more appropriate in children younger than 2 years of age (WHO, 2009).

Acute malnutrition without edema has been termed wasting or marasmus, and acute malnutrition with edema has been termed kwashiorkor; however, a combination of the two may occur in some children. Both are associated with anemia, though this condition is often more severe in children (or adults) with kwashiorkor. The anemia may be exacerbated by local conditions, such as malaria and hookworm infection.

In 2001, the United Nations Sub-Committee on Nutrition convened a meeting in Nairobi to review the assessment of nutritional status in adults and adolescents. The attendees recommended that assessment of adult malnutrition should be considered under the following circumstances:

- If the crude mortality rate increases in relation to the under-5 mortality rate
- If many adults are present at existing supplementary feeding centers
- Where there are high rates of under-5 malnutrition in the absence of an epidemic outbreak
- If there is reasonable doubt that the child malnutrition rates do not reflect the nutritional status of the general population
- If the populations are entirely reliant on food aid and if data are required as an advocacy tool to leverage resources

MUAC is commonly used as a screening tool in adult populations. A MUAC of less than 23 cm in men and less than 22 cm in women has been proposed as indicating moderate malnutrition (corresponding to body mass index [BMI] values of less than 17). MUAC values of less than 20 cm in men and less than 19 cm in women have been proposed as indicators of severe wasting, corresponding to BMIs less than 13 (Ferro-Luzzi & James, 1996). Nevertheless, one reliable clinical sign of severe malnutrition commonly observed in adults is inability to stand.

Prevalence of acute malnutrition among the internally displaced has tended to be extremely high. In southern Somalia during 1992, the prevalence of acute malnutrition among children younger than 5 years in displaced-persons camps in Marka and Qorioley was 75%, compared with 43% among town residents (Manoncourt et al., 1992). Among the estimated 1 million IDPs in Darfur, Sudan, acute malnutrition prevalence ranged between 12.6% and 21.5% in March–April 2004, increasing to 20.6% to 39% in May–June 2004. Following heightened international interest and assistance to this population, rates of malnutrition generally decreased to a range of 10.7% to 23.6% by September 2004. However, 5 years later, after many humanitarian aid agencies had been expelled from Sudan, malnutrition rates increased significantly. In northern Darfur, acute malnutrition prevalence ranged between 16.9% and 34.5% according to surveys conducted between May and July 2009. (**EXHIBIT 12-3** discusses malnutrition among Sudanese refugees.) The prevalence of acute malnutrition among children younger than 5 years of age in various displaced populations is presented in **TABLE 12-4**.

In South Sudan, where 1.9 million people have been internally displaced and 1.6 million have fled to other countries, the malnutrition prevalence has been critically high. An estimated 5.5 million people in

EXHIBIT 12-3 Sudanese Refugees in Chad, 2004–2010

As a result of the armed conflict in Darfur, Sudan, that began in early 2003, approximately 100,000 refugees fled to Chad during 2003. Initially, they lived in makeshift camps and received little international assistance. Early nutrition surveys indicated great variation in nutritional status of refugees between settlements; in November 2003, rates of acute malnutrition among children ranged from 7% to 27% (UN Standing Committee on Nutrition, 2004a). By May 2004, the camps were overcrowded, water and sanitation were inadequate, and an outbreak of the waterborne viral disease hepatitis E had occurred in some camps. In June, a joint agency survey found the overall acute malnutrition prevalence among children to be 35.6%, with 5.5% severely malnourished (UN Standing Committee on Nutrition, 2004c).

By the end of 2004, more than 200,000 Darfur refugees had fled to Chad. International media attention increasingly focused on both the conflict in Darfur and the plight of refugees and IDPs. International assistance increased, and by the end of 2004, most refugees were located in 11 camps run by UNHCR. Blanket supplementary feeding was introduced for all children younger than age 5 and for all pregnant and lactating women. According to food basket monitoring, the average energy content of the food ration reached 1,967 kilocalories per person per day by October 2004 (compared with an official ration of 2,063 kilocalories). A September survey in two camps found that the prevalence of acute malnutrition had dropped to 19.6%; although this represented an improvement, the rate remains high by international standards (UN Standing Committee on Nutrition, 2004d).

Five years later, the CMR in all refugee camps in Chad was less than 1 per 10,000 per day. The prevalence of acute malnutrition ranged between 4% and 10%. However, the prevalence of acute malnutrition in IDP camps across the border in Sudan remained high; between May and July 2009, it was between 17% and 34% in six camps in northern Darfur.

South Sudan (47% of the population) were projected to be severely food insecure at the height of the 2017 lean season between May and July 2017, and more than 1.1 million children were estimated to be acutely malnourished.

Micronutrient Deficiency Diseases

High incidence rates of several micronutrient deficiency diseases have been reported in many refugee camps, especially in Africa. Frequently, famine-affected and displaced populations have already experienced low levels of dietary vitamin A intake and, therefore, may have low vitamin A reserves. Furthermore, the typical rations provided in large-scale relief operations lack vitamin A, putting these populations at high risk of this micronutrient deficiency. In addition, those communicable diseases that are highly incident in refugee camps, such as measles and diarrhea, are known to rapidly deplete vitamin A stores. Consequently, young refugee and displaced children are at high risk of developing vitamin A deficiency.

In 1990, more than 18,000 cases of pellagra, caused by food rations deficient in niacin, were reported among Mozambican refugees in Malawi (CDC, 1991a). Despite the increased awareness of micronutrient deficiencies among relief agencies, niacin was not a component of the general food ration for IDPs in Angola in 2000. A large outbreak of pellagra was documented, with attack rates among IDPs more than twice those observed in the nondisplaced population (Salama et al., 2001).

Numerous outbreaks of scurvy (vitamin C deficiency) were documented in refugee camps in Somalia, Ethiopia, and Sudan between 1982 and 1991. Cross-sectional surveys performed in 1986–1987 reported prevalences as high as 45% among females and 36% among males; prevalence increased with age (Desenclos et al., 1989). The prevalence of scurvy was highly associated with the period of residence in camps, a reflection of the time exposed to rations lacking in vitamin C. Outbreaks of scurvy and beriberi were also reported among Bhutanese refugees in Nepal during 1993 (UN ACC/SCN, 1995).

Iron-deficiency anemia has been reported in many refugee populations, affecting particularly women of childbearing age and young children. For example, a survey among IDPs in Darfur, Sudan, in 2004 found that 55% of children younger than 5 years were anemic, as well as 26.2% of women of reproductive age (UN Standing Committee on Nutrition, 2004d).

Impact of Communicable Diseases

In most CEs in LMICs, the high rates of excess preventable mortality have been attributed primarily to communicable diseases. Acute respiratory infections, diarrhea, measles, and malaria have been most frequently cited as proximate causes. The substandard conditions found in refugee camps do not change the diseases that account for most of the morbidity and mortality in humanitarian emergency settings, but they do alter epidemiologic patterns in two important ways: The incidence, or attack, rates of commonly

TABLE 12-4 Prevalence of Acute Malnutrition Among Children Younger Than 5 Years in Internally Displaced and Conflict-Affected Populations, 1992–2004

Date	Country (Region)	Prevalence of Acute Malnutrition (%)
1992	Southern Somalia	47–75[a]
1994	Sudan (Bahr el Ghazal)	36.1[b]

occurring and potentially fatal diseases are increased, and the case-fatality ratios are higher than usual.

Individual communicable diseases commonly affecting emergency-affected populations are discussed in the section of this chapter dealing with the prevention and control of communicable diseases.

Reproductive Health

Unfortunately, reproductive health services for refugees and displaced persons have often been considered to be secondary priorities, although increased attention has been paid to reproductive health issues in the past 10 years. Although clearly the provision of food, water, sanitation facilities, and shelter are the highest priorities during a complex humanitarian emergency, steps should be taken to ensure that other critical health needs of women, men, and adolescents are met as quickly as possible. Women are a particularly vulnerable subset of the population because the gender-based discrimination that is all too common in stable societies is frequently exacerbated in times

of societal stress and meager resources. Uncontrolled violence and its aftermath are characterized by a number of specific features that negatively affect reproductive health—namely, the breakdown of family networks and the consequent loss of protection and safety, as well as the lack of channels by which to provide information to adolescents and women of reproductive age.

The Guttmacher Institute reviewed maternal deaths that occurred in 2008–2010 in 25 refugee camps in 10 countries (Hynes, Sakani, Spiegel, & Cornier, 2012). Reports were available on 108 deaths, including 68 deaths in Kenya. In every country but Bangladesh, maternal mortality ratios were lower among refugees than among the host population. The proportion of women who had had four or more antenatal care visits was lower among refugee women who had died (33%) than among the general refugee population (79%). Approximately 78% of the maternal deaths followed delivery or abortion, and 56% of those deaths occurred within 24 hours. Delays in seeking and receiving care were more prevalent than delays in reaching care. In Kenya, delays in seeking or accepting care and provider failure to recognize the severity of the woman's condition were the most common avoidable contributing factors.

A minimum initial package of essential reproductive health services (described later in this chapter) has been developed and is recommended by the major relevant international agencies. Interventions beyond this essential package require major investments of time and personnel who should not be diverted from the principal task of reducing excessive preventable mortality as rapidly as possible. In all cases, special care must be taken to ensure that women heads of household are being given equitable quantities of food and nonfood commodities for themselves and their families.

Noncommunicable Diseases

Prior to the last decade, responding to the health needs of refugees and IDPs traditionally emphasized the direct causes of ill health, such as firearms and other weaponry, as well as communicable diseases and nutritional deficiencies, which have been shown to pose a major problem in many CEs. More recently, and in light of the aging of the population generally and of the changing geographic distribution of conflicts to include areas previously well served by health care, such as Syria and Iraq, new problems have emerged.

Noncommunicable diseases are widespread in all populations of older adults worldwide. In those situations where medical care was at some stage available, the withdrawal or destruction of medical facilities and drug distribution mechanisms, and the withdrawal of health workers from areas of active conflict, all have an impact on the treatment and care available for NCDs. Examples of reductions in the quality and availability of care for NCDs come from Syria since the onset of civil war in 2011, from Iraq in the aftermath of the Gulf War and disruptions by ISIL, from Sarajevo during its siege in the Yugoslav civil war, and from the Kosovar Albanians, especially those internally displaced people who lost access to services and care.

Patients with conditions such as cardiovascular disease (including hypertension), diabetes, asthma, and cancer may deteriorate given the lack of access to medical care that typically occurs in conflict settings. A systematic review in 2014 found that, overall, the prevalence of NCDs was high among urban refugees in the Middle East, ranging from 9% to 50%; by comparison, the prevalence among urban refugees in Asia and Africa ranged from 1% to 30% (Amara & Aljunid, 2014). Prior to the conflict, 77% of deaths in Syria were due to NCDs. The prevalence of diabetes in Syria was 8.9% (adults age 20–79) prior to the conflict and the prevalence of hypertension was 28% (Amara & Aljunid, 2014). More than half of public hospitals in Syria are now either partially functional or completely out of service, constraining the treatment of patients with NCDs. Moreover, local production of medicines has declined by 70% associated with the increasing cost of medicines for treatment of NCDs.

Maintaining diagnostic and treatment services, drug supplies, and access to care is extremely difficult given the destruction of infrastructure, targeting of health services, disruption of logistics and supply systems, and absolute resource constraints present in many CEs. In some conflicts, the imposition of sanctions may play some role in reducing access to technologies and drugs necessary for the diagnosis, treatment, and care of NCDs.

Mental Health

War and political violence have direct and indirect mental health consequences for victims, relatives, neighbors, and communities. The severity and type of mental health problems reflect the nature, intensity, and form of the violence; the relationship of the assessed person to others affected—self, family, and community members; the cause of the conflict; and the affected person's relationship to participation, victimization, or causation of the conflict. Anxiety, uncertainty, and fear about the future and about

whether family members and homesteads remain alive and intact are significant sources of distress for affected individuals and communities. Among those who are forced to flee either as refugees or as internally displaced people, the lack of knowledge about relatives and property left behind creates stress and distress. Despite the ongoing challenges of maintaining lives and livelihoods, life as a refugee, especially in a camp situation, may be monotonous and conducive to stress, anxiety, and depression. Finally, it is clear, and little disputed, that some individuals who experience particularly horrific experiences as victims of torture or gross human rights abuses during conflicts may suffer from post-traumatic stress disorder.

Few national surveys of the mental health impact of conflicts are available, and even if such studies could be conducted, prior measurement of the distribution of mental health status within the population would be required to assess the CEs' impact. A number of small studies focused on particular subgroups of conflict-affected populations have been conducted, but their biomedical biases leave them open to challenge. Little is known about the etiology of the symptoms of multiple trauma, the mental health consequences suffered by those who victimize, and the role of coping mechanisms.

In emergencies, not everyone has or develops significant psychological problems. Many people show resilience—that is, the ability to cope relatively well in situations of adversity. Numerous social, psychological, and biological factors interact to influence whether people develop psychological problems or exhibit resilience in the face of adversity.

Depending on the emergency context, particular groups of people may be at increased risk of experiencing social and/or psychological problems. Although many key forms of support should be available to the emergency-affected population in general, good programming specifically includes the provision of relevant supports to the people at greatest risk, who need to be identified for each specific crisis.

All subgroups of a population can potentially be at risk of mental health disorders, depending on the nature of the crisis. The following are groups of people who frequently have been shown to be at increased risk of various problems in diverse emergencies (Inter-Agency Standing Committee, 2007):

- Women (e.g., pregnant women, mothers, single mothers, widows and, in some cultures, unmarried adult women and teenage girls)
- Men (e.g., ex-combatants; idle men who have lost the means to take care of their families; young men at risk of detention, abduction, or being targets of violence)
- Children (from newborn infants to youths 18 years of age), such as separated or unaccompanied children (including orphans), children recruited or used by armed forces or groups, trafficked children, children in conflict with the law, children engaged in dangerous labor, children who live or work on the streets, and undernourished and/or under-stimulated children
- Elderly people (especially when they have lost family members who were caregivers)
- People who have been exposed to extremely stressful events/trauma (e.g., people who have lost close family members or their entire livelihoods, rape and torture survivors, witnesses of atrocities)
- People in the community with preexisting, severe physical, neurologic, or mental disabilities or disorders
- People in institutions (e.g., orphans, elderly people, people with neurologic/mental disabilities or disorders)
- People experiencing severe social stigma (e.g., "untouchables," commercial sex workers, people with severe mental disorders, survivors of sexual violence)

Prevention and Mitigation of Complex Emergencies

The prevention of CEs is primarily the prevention of the conflicts that cause them; thus, the task is largely political. Since 1990, many CEs have had their roots in ethnic and religious conflicts within sovereign states. The United Nations Charter has been ill equipped to intervene in issues deemed to be "internal" by member states. Chapters 6 and 7 of the Charter do allow the Security Council to authorize appropriate action, including the use of force, in situations that threaten international peace and security. During the Cold War, these provisions were rarely used because such action was likely to be vetoed by one of the five permanent members of the Security Council. However, Security Council resolutions supported intervention by the international community to protect civilians in conflicts in Somalia, Bosnia and Herzegovina, Haiti, Iraq, Angola, and Timor-Leste during the 1990s. Since 2001, such international consensus has been rare. Armed interventions by the United States and its allies in Afghanistan and Iraq were not conducted under the auspices of the United Nations but rather through the North Atlantic Treaty Organization (NATO).

In general, the international community has had little success in resolving internal conflicts by using diplomacy. A major victory for these efforts occurred in 2005 when the government of Sudan and the Sudan People's Liberation Front signed a peace agreement in Nairobi. This led eventually to the establishment of the state of South Sudan. Similar peace agreements have been signed since 2001 in Sri Lanka, Angola, Liberia, Sierra Leone, and the DRC (although the last was still fragile in 2017).

The United Nations has a poor record in conflict resolution. The internal conflict in Somalia was allowed to evolve over five years into the total disintegration of the nation state. Only when famine reached appalling levels in 1992 did the Security Council authorize extraordinary action to ensure the protection and care of the civilian population. Within 6 months of their arrival, UN troops became embroiled in the conflict itself, taking sides with or against certain armed factions. This engagement led to heavy loss of life and the eventual withdrawal of the UN forces. Twenty-five years later, Somalia still lacks a functional government and the self-proclaimed Somaliland in the north of the country is essentially independent, though not internationally recognized.

In Bosnia and Herzegovina, between 1992 and 1995, the United Nations mobilized peacekeeping troops to safeguard the delivery of humanitarian supplies. However, these forces were not authorized to intervene to protect civilians from the violence intentionally directed at various ethnic groups; as a result, the international community's armed representatives were forced to silently witness gross abuses of human rights. This dilemma has been termed the "humanitarian trap."

When the genocide began in Rwanda in 1994, several Belgian peacekeepers already in the country with a UN contingent were killed by extreme Hutu nationalists. Instead of increasing the level of UN presence, the entire peacekeeping force was withdrawn, leaving civilians defenseless against these extremists. Eventually, more than half a million Rwandans were killed. It is likely that this string of UN failures led to NATO taking unilateral action in the form of a massive bombing campaign against Serbia to protect ethnic Albanians in 1999. Although well intentioned, this action seemed to accelerate the pace of atrocities and ethnic cleansing instigated by the Serbs against the Kosovar Albanians.

The basis of protection of civilians in time of conflict is the Geneva Conventions of 1949 and the Additional Protocols of 1977. In addition, the 1951 Convention on the Prevention and Punishment of the Crime of Genocide was intended to protect civilians from the type of slaughters that occurred in Cambodia in the 1970s and in Rwanda in 1994. General Assembly resolutions in 1971, 1985, and 1986 also elaborated on the protection of civilian populations. However, international human rights and humanitarian (armed conflict) laws are only as good as their enforcement. The Office of the UN High Commissioner for Human Rights in Geneva, Switzerland, is one of the primary official bodies that oversees this sometimes overwhelming task, relying on the documentation and testimony provided by accredited NGOs. Today, UNCHR passes influential resolutions on human rights abuses in member states and is the subject of intense lobbying by governments and NGOs. It is thanks to the efforts of a number of human rights advocacy groups that resolutions continue to be adopted by the commission condemning human rights violators. Such resolutions occasionally lead to action by the General Assembly and Security Council, which may dispatch peacekeeping forces to a troubled region.

Between 2004 and 2008, a number of UN Security Council resolutions demanded that the government of Sudan remove its support for the genocidal militia in Darfur. Finally, in 2008 the Security Council authorized a United Nations–African Union hybrid operation in Darfur (UNAMID). In December 2016, there were 19,248 uniformed personnel from 116 countries deployed in the region, though peace and well-being for the displaced population remain elusive.

Since 2008, the United Nations has been unable to resolve any armed conflicts within states. The international response to these conflicts has mainly been military, with various coalitions bombing different armed factions in Syria, Iraq, Yemen, and Somalia. The UN Security Council has been unable to reach a consensus on resolving the vicious civil war in Syria. While France intervened to bring about an uneasy peace in Mali in 2013, a vicious armed conflict continues to rage in nearby Central African Republic.

The UN Office for the Coordination of Humanitarian Affairs (OCHA), based in New York and Geneva, is responsible for coordinating efforts in early warning, prevention, mitigation, and response to disasters, including CEs. ReliefWeb's purpose is to strengthen the capacity of the humanitarian relief community through the timely dissemination of reliable information on prevention, preparedness, and disaster response. As with many other similar projects, this information is made available via the Internet (www.reliefweb.int).

Early Warning and Detection

Efforts to prevent and mitigate the impact of CEs on populations must rely on accurate and timely information to be effective. Given the enormous cost of military intervention and major relief and rehabilitation programs, it is surprising that so little has been invested in early warning, emergency detection, preparedness, and mitigation projects. In the late 1990s, a number of systems collected, aggregated, and disseminated information on a number of indicators relevant to CEs. Most of these systems relied on information collected by other agencies, such as governments, UN agencies, and NGOs. ReliefWeb, a project of OCHA, was mentioned earlier as an exemplar.

Unlike natural disaster early warning systems and preparedness programs, monitoring and detecting CEs is fraught with political obstacles. Indeed, the adage that "the first casualty in war is truth" applies to attempts to collect accurate data on the health outcomes of war. The existence of armed conflicts is no secret; the political response is still inadequate. What would be valuable as CEs evolve would be a more accurate picture of which health interventions will be the highest priorities and the most effective in preventing excess mortality and morbidity. Stopping the violence is a public health issue that can be addressed only by the world's leaders. In LMICs, the priorities are most likely to be nutrition and communicable disease control. Thus, key indicators to monitor in early warning systems include food availability, nutritional status, immunization coverage, incidence of vaccine-preventable diseases, and antenatal program coverage.

Responses to Complex Emergencies

Primary Prevention

Primary prevention is the basic strategy of public health, and epidemiology is one of its essential tools. In situations of armed conflict, however, epidemiology can be practiced safely and reliably in very few areas. Hence, the traditional documentation, monitoring, and evaluation elements of disease prevention may be ineffective in these settings. Because war and public health are essentially incompatible pursuits, the provision of adequate food, shelter, potable water, and sanitation, as well as vaccination and other primary healthcare services has proved problematic in countries disrupted by war. Primary prevention in such circumstances, therefore, means stopping the violence. More effective diplomatic and political mechanisms need to be developed that might resolve conflicts early in their evolution prior to the stage when food shortages occur, health services collapse, populations migrate, and significant adverse public health outcomes emerge.

Secondary Prevention

Secondary prevention involves the early detection of evolving conflict-related food scarcity and population movements, preparedness for interventions that mitigate their public health impact, and the development of appropriate public health skills to enable relief workers to work effectively in emergency settings. Preparedness planning needs to take place both at a coordinated international level and at the level of countries where CEs might occur. It might be argued that preparedness measures may be particularly important at the most peripheral levels—in communities and households. Relief agencies need resources not only to respond to emergencies when they occur, but also to implement early warning systems, maintain technical expertise, train personnel, build reserves of relief supplies, and develop their logistic capacity. At the country level, all health development programs should have an emergency preparedness component that includes the establishment of standard public health policies (e.g., rapid detection and management of epidemics, vaccination), treatment protocols, staff training, and the maintenance of reserves of essential drugs and vaccines for use in disasters.

Tertiary Prevention

Tertiary prevention involves prevention of excess mortality and morbidity once an emergency has occurred. The health problems that consistently cause the most deaths and severe morbidity as well as those demographic groups most at risk have been identified. Most deaths in refugee and displaced populations are preventable using currently available and affordable technology. Relief programs, therefore, must channel all available resources toward addressing measles and other vaccine-preventable diseases, diarrheal diseases (including cholera), malnutrition, acute respiratory infections, and, in some cases, malaria, especially among women and young children. Violence, especially sexual and gender-based violence, mental health problems and, as socioeconomic progress leads to longer life expectancy in many parts of the world, the ongoing control of noncommunicable diseases such as diabetes, cardiovascular conditions, and cancer, also need to be addressed. The challenge is to institutionalize this knowledge within the major relief organizations and to ensure that relief management and

logistical systems provide the necessary resources to implement key interventions in a timely manner.

Initially, many refugees and displaced persons may find themselves in crowded, unsanitary camps in remote regions where meeting their basic needs is extremely difficult. Recently, there has been a more noticeable settlement of displaced individuals and families in urban areas, where they are integrated with the local population. In either case, prolonged exposure to the violence of war and the deprivations of long journeys by refugees cause severe physical and psychological stress. Upon arrival at their destination, refugees—most of whom tend to be women and children—may suffer severe anxiety or depression, compounded by the loss of dignity associated with complete dependence on the generosity of others for their survival. If refugee camps are located near borders or close to areas of continuing armed conflict, the desire for security is an overriding concern. Therefore, the first priority of any relief operation is to ensure adequate protection; camps should be placed sufficiently distant from borders to reassure refugees that they are safe (Sphere Project, 2011).

To diminish their sense of helplessness and dependency, refugees should be given an active role in the planning and implementation of relief programs. Nevertheless, giving total control of the distribution of relief items to so-called refugee leaders may be dangerous. For example, leaders of the former Hutu-controlled Rwandan government took control of the distribution system in Zairian refugee camps in July 1994, resulting in relief supplies being diverted to young male members of the former Rwandan Army. Even when their intentions are good, the priorities of communities may differ from those of international relief agencies. Whereas the latter may offer preferential treatment of children because mortality rates have been shown to be highest in younger age groups, a community may feel that the elderly, for example, deserve special care because they carry with them the traditions and customs of the culture. In general, the targeting of food and other supplies to communities and to vulnerable groups within those communities should be the subject of discussion between relief authorities and the communities (Jaspars & Shoham, 1999).

In the absence of conflict resolution, those communities that are totally dependent on external aid for their survival either because they have been displaced from their homes or because they are living under a state of siege must be provided with the basic minimum resources necessary to maintain health and well-being. The provision of adequate food, clean water, shelter, sanitation, and warmth will prevent the most severe public health consequences of CEs. It would seem that the temporary location of refugees in small settlements or villages in the host country would have fewer adverse public health consequences than their placement in crowded, often unsanitary camps. Public health priorities include a rapid needs assessment, the establishment of a health information system, measles vaccination or other mass vaccination programs developed in accordance with WHO guidance (WHO, 2017e), the control of diarrheal and other communicable diseases, maternal and child health services, and nutritional rehabilitation. Critical to the success of the response is coordination of the many agencies involved in the relief effort.

Following the Goma crisis in 1994, the aid community recognized that aid agencies needed to demonstrate the effectiveness of their actions. This consensus led to the Sphere Project, which through a comprehensive, inclusive process developed the *Sphere Project Handbook: Humanitarian Charter and Minimum Standards in Disaster Response* in 2000. The *Handbook* includes minimum standards for shelter, water and sanitation, and a range of health and nutrition interventions and outcomes. A fourth edition of the *Handbook* was scheduled to appear in 2018.

Rapid Assessment

Displacement is the final, desperate act of a threatened population. Whenever possible, assessments of the public health needs of the population should be conducted prior to the act of migration or resettlement, whether it is within the country of origin or beyond its borders. Impending emergencies—even the development of CEs—can frequently be predicted. Knowing the size of the population and its age and gender distribution, having baseline data concerning its health status and the level of health services available to it, and being aware of the characteristics of the place or places to which refugees are most likely to move can be of immense help in knowing which relief supplies will be needed and which kinds of health programs should be implemented. Needless to say, such predisplacement assessments have been rare.

Early assessments can be made by a variety of means. Technology-dependent methods such as satellite surveillance can provide information regarding crop growth, population densities, and even troop movements, although such technology is often unavailable to those agencies that need it the most. Reviews of existing documents and other information provided by a variety of UN agencies, bilateral governments, NGOs, and national authorities familiar with the situation can be helpful. On-the-ground

economic evaluations, including a description of trends in market prices for food and essential commodities in food-basket analyses, can be helpful. More detailed information can frequently be obtained from visual inspection of the affected area, including mapping, key informant interviews, and observation of the affected population. Information-gathering projects and services, such as the Famine Early Warning System Network, ACAPS, and the UN-based ReliefWeb, have proved invaluable for early dissemination of information. For CEs, however, where political instability and increased violence are almost always compounding factors, more direct means of assessment prior to displacement are often impossible and the earliest assessment can be conducted only after the displaced persons have reached a relatively safe area of resettlement.

Early, rapid assessments have multiple purposes. They can provide important information about the evolution of the emergency, identify groups and areas at greatest risk, evaluate the existing local response capacity, determine the magnitude of external resources required, and indicate which health programs will be required in the short and medium terms. Every CE is characterized by a different set of causes and consequences, and each should be assessed for its impact on the health of the affected population.

For CEs, early assessment should include both a description of the conflict and its sequelae, in terms of the affected areas and populations, and a characterization of the health consequences of displacement. In some cases, affected populations may not have migrated but rather may be trapped in a siege-like setting, such as in Sarajevo (Bosnia), Aleppo (Syria), Mosul (Iraq), Juba (South Sudan), and Sanaa (Yemen). In regard to the conflict itself, variables of particular significance include the duration of the conflict, the progress of negotiations (and the likelihood of an early return for the displaced populations), the patterns of violence, the size and location of inaccessible areas and populations, and the state of remaining available health services.

The highest priorities for early assessment are the availability and adequacy of drinking water, food, and shelter. Minimum standards described later in this chapter must be met. Regarding the health status of the population, perhaps the most important and most sensitive indicator is the mortality rate. Early documentation of mortality will establish an indispensable baseline and allow for monitoring of trends that will attest to the overall effectiveness of the relief program. In an emergency, crude mortality rates are expressed as deaths per 10,000 per day. A CMR of greater than 1 has been used to define the existence of a public health emergency, and a CMR of greater than 2 indicates a critical situation. Of course, these thresholds are gross estimates. Whenever pre-crisis mortality rates are available, they should be taken into account (Guha-Sapir & van Panhuis, 2004). Age- and gender-specific mortality should be assessed to identify those population groups at the highest risk.

Rates of diseases commonly associated with high rates of preventable mortality should be assessed as early as possible. These include diarrheal illnesses, acute respiratory infections, and diseases with high epidemic potential, such as cholera, dysentery, measles, and meningitis. Where appropriate, the occurrence and risk of locally endemic diseases such as malaria and dengue should be analyzed as well. In middle-income countries, the prevalence of noncommunicable diseases should also be assessed, and attempts made to ensure ongoing care of those persons receiving long-term treatment for NCDs.

Complex emergencies are often accompanied by food shortages that can lead to malnutrition. Assessment of protein-energy malnutrition among children should be undertaken as soon as possible, using one of the variety of methods available for that purpose. Mass screening of all children is optimal, but an initial random sample of the population can establish the prevalence of malnutrition and indicate the need for targeted screening and feeding interventions. Vaccination coverage of children should also be assessed to determine the urgency of mounting vaccination campaigns. Notably, in the absence of any coverage data, measles vaccination should be considered a priority.

Rapid assessments require detailed planning and may fail because of the inadequacy of transport, maps, communications equipment, and fuel. In addition, attention needs to be given to the security situation in the affected area. An assessment is of limited value unless its results are communicated in a timely and effective manner to those who can act upon them. Presentation of the findings should be organized and clear, and the recommendations of the assessment team should indicate which actions are of highest priority, what a reasonable time frame for action would be, and which resources will be required. Without these data, essential information required for the survival of large populations of displaced individuals may not be acted upon in time to prevent high levels of excess preventable mortality.

The potential usefulness of rapid assessment should not be underestimated. Unfortunately, in the past there have often been too many assessments done by different agencies in an uncoordinated manner. It is essential that a designated lead agency coordinate rapid assessments, ensuring that sectoral assessments

(e.g., water and sanitation, medical services, and food) are integrated and that the findings are used to inform program policies and planning. For example, in the post-tsunami relief effort of January 2005, WHO organized teams from a number of UN and voluntary agencies, the Indonesian Ministry of Health, and the Indonesian military forces, and, using U.S. military assets for support, led a series of rapid assessments of stranded populations along the west coast of Aceh province on the island of Sumatra. These efforts proved quite helpful in identifying remote populations and their needs and in targeting appropriate relief. More recently, ACAPS (www.acaps.org), an NGO founded in 2009, has been providing assessment data to the emergency relief community. Of course, the collection and dissemination of useful information during the early days of an emergency, especially when security is a major concern, can be quite challenging.

In contrast to the post-tsunami assessments, the rapid assessments attempted following the Haiti earthquake of 2010 did not yield results that guided the relief effort in a timely manner. The extent of the destruction; the need to reserve means of transport, both ground and air, for the delivery of humanitarian goods; and the lack of a clear and creditable plan for exactly what to assess and where all resulted in the early days of the relief effort being a data-free period. Most important in that setting, perhaps, would have been to determine where hospital beds were available in the mostly destroyed capital city and throughout the country. Unfortunately, identification of these resources, and especially appropriate and effective sharing of the information with those who had the greatest need for it, was not rapidly forthcoming.

Health Information Systems

Epidemiologic surveillance is the ongoing and systematic collection, analysis, and interpretation of health data. This information is then used for planning, implementing, and evaluating public health interventions and programs. Surveillance data are used both to determine the need for public health action and to assess the effectiveness of programs. In CEs, after the response to an initial rapid assessment has been instituted, the development and implementation of ongoing health information systems immediately becomes a high-priority activity. Although data on many of the subjects included in the rapid assessment will continue to be collected on a regular basis, routine health information systems will allow for the monitoring of a significantly larger number of other potentially important health conditions and health programs.

Characteristics of Effective Health Information Systems

To be useful, surveillance systems must be relevant, especially in CEs, where time and resources are frequently in short supply. Data collection should be restricted to the most important of actual and potential public health problems. Equally important, data should be collected only if it will be useful in stimulating and guiding a response—if no intervention is feasible, there is little need to encumber the system with information on the problem.

The best health information systems are the simplest. In a number of CEs, difficulties have arisen in explaining the importance of the data to the local staff responsible for its collection, as well as to decision makers, who frequently do not appreciate the limitations of data of variable accuracy collected under the most difficult of circumstances. Case definitions must be clear, consistent, and suited to the local capacity to make accurate diagnoses. Where no microscopes or rapid diagnostic tests are readily available, for example, malaria may have to be represented by "fever and chills." The data generated from simple systems must be recognized for what it is worth and should not be over-interpreted. Nevertheless, good surveillance systems rely on laboratory confirmation of suspect or probable cases of diseases of public health importance. Efforts should be made to have available a basic public health laboratory, with appropriate supplies and technical expertise.

Representativeness is another essential element of health information systems that is related to the quality of the data. Careful interpretation of data collected from a surveillance system is required before extrapolations can be made to the general population. For example, in South Sudan during the 2000s, nutrition and mortality assessments were difficult to interpret because health information has been collected and reported from food distribution centers to which the displaced and most severely malnourished members of the population were drawn. Thus, the mortality and malnutrition rates derived from these sites were not necessarily representative of the entire population of the region.

The organization and implementation of health information systems should be made the responsibility of one individual or agency, which should also be responsible for ensuring widespread cooperation and coordination of data collection and use. If a host government is in place and guiding the response, it should establish appropriate policies and guidelines that can be implemented with help from appropriate technical partners. It is important for the interpretation

and response to the data that the health information system establishes standardized case definitions, data collection methods, and conditions of reporting. This sort of across-the-board consistency can help avoid the problems described earlier in which different agencies used different data collection methods.

In emergencies, both reporting and the response to reports must be timely. When the goal is to prevent excess mortality, undue delays between any two links of the surveillance chain, from the peripheral data-collection level to the more central, policy-making level and back to the periphery where action needs to be taken, can result in an unnecessary loss of life. Depending on the nature of the data, especially when an epidemic illness is deemed likely or is occurring, daily reporting of selected information by telephone, text messaging, or messenger is not necessarily excessive. Today, widely available technologies such as cell phones and digital data transfer have become the methods of choice for data transmission from more peripheral to central levels. For other conditions, data are generally reported and analyzed on a weekly basis during the emergency period and monthly during the less acute phases of the crisis. Of course, data needs may change rapidly as an emergency evolves to a more steady state. For this reason, information systems must have a high degree of flexibility, and their response to new demands should be achieved with minimal disruption.

Methods of Data Collection

As long as they possess the qualities mentioned previously, surveillance systems may combine active and passive reporting mechanisms. Active reporting can include randomized population-based surveys aimed at gathering data on one or a selected few parameters, such as vaccination coverage or nutritional status. Alternatively, it can involve the hiring of personnel for the specific purpose of monitoring important health events that might occur outside the bounds of the healthcare system itself, such as hiring gravediggers to report on burials so as to determine mortality.

Passive reporting generally refers to the routine collection and relaying of health statistics within the system itself, whether it is from community-based health posts, from primary care clinics, or from hospitals. In some cases, access to the healthcare system may be limited and utilization may be low owing to a variety of factors, such as fear or mistrust of the healthcare providers, unfamiliarity with the system, physical destruction of facilities, and other reasons that are frequently unrecognized by relief agencies. Thus, it is especially important that emergency health information systems be regularly evaluated for the characteristics described earlier.

Sometimes a combination of active and passive reporting can be used. In Haiti, for example, the system that had been established in 25 Pepfar-funded hospitals that had been treating patients for acquired immunodeficiency syndrome (AIDS) was adapted for use during the earthquake emergency, and those reporting sites began to report on a number of conditions for which information was required on a daily basis.

Content of Health Information Systems in Complex Emergencies

Trends in crude mortality remain an important feature of surveillance throughout the emergency phase and beyond. In many cultures, death is a family and religious matter, such that deaths are not normally brought to the attention of the healthcare system. In fact, severely ill patients in hospitals are frequently taken home to die. For this reason, active surveillance is best for estimating mortality. Grave watchers—often those who dig the graves—can be hired on a 24-hour basis to report new burials and, if possible, to ascertain the age and gender of the deceased. In some cultures, the free distribution of burial shrouds or other materials used for burial or funerals can provide a useful incentive for reporting. At times, mortality can be determined by means of a population-based survey, but the data derived from these surveys are subject to different sorts of bias and are frequently dated.

Sometimes large numbers of corpses are left unburied by families, as happened in Goma in 1994 because the ground was composed of volcanic rock that made it impossible to dig graves. Likewise, following extensive natural disasters such as the Indian Ocean tsunami of December 2004, bodies may be buried under rubble or swept away. In contrast, in epidemics such as the Ebola outbreak in West Africa that make safe burial procedures imperative, it may be possible to ask those responsible for body collection and mass burial to keep count of the number of dead they see. In other cases, as in Haiti in 2010, dead bodies cannot be found or are so quickly disposed of by the authorities that only gross estimates of the number of deaths can be given.

Health information systems should collect morbidity data on commonly occurring diseases and on diseases of epidemic potential. Diseases that have been prominent in all CEs include watery diarrhea, acute respiratory infections, malaria and other important endemic conditions, and malnutrition. Measles, meningitis, cholera, and shigellosis (dysentery or bloody diarrhea) have all been responsible for major

epidemics in emergency settings, and guidelines for the establishment of sensitive thresholds for the detection of each need to be followed where they already exist, or need to be developed. The detection of an epidemic should trigger an immediate and aggressive response.

In addition, at least two health programs—treatment of malnutrition and vaccination—need to be regularly monitored. Indicators of the numbers of patients in intensive or supplementary feeding programs need to be tracked. Vaccination coverage rates also need to be estimated, and, when deemed appropriate, measles vaccination should be offered to all children age 6 months to 15 years regardless of prior vaccination status as soon as resources permit. Vaccination with the antigens of the national routine immunization program should be established when feasible. Other vaccines may be offered after careful consideration by public health authorities of the epidemiology of the diseases, the characteristics of the available vaccine, and the context in which the CE is occurring.

Two areas that have been relatively neglected in CEs are reproductive health and psychosocial health (Spiegel et al., 2010). Ample evidence shows that in emergencies, women of reproductive age, and especially pregnant women, need special attention, and their health conditions, including pregnancy, should be carefully monitored by surveillance mechanisms. Gender-based violence is also a major concern, and recent evidence suggests that domestic or intimate-partner violence is an important factor in many populations that have been subjected to undue stress (Stark & Ager, 2011). Forced migration is itself a traumatic event. When its stresses are compounded by the ethnic strife and violence that frequently accompany CEs, close attention should be paid not only to individuals who might be seriously affected by post-traumatic stress disorders but also to the reestablishment of community structures. Finally, when the emergency has subsided (e.g., when crude mortality rates drop to less than 1 per 10,000 per day), increased attention can be paid to dealing with more chronic or less fatal diseases, such as tuberculosis, sexually transmitted infections (STIs, including HIV), diabetes, hypertension, and elective surgical conditions.

The establishment of a useful health information system, with all of the characteristics described here, is an essential function of the health service. Without one, programs will be developed by guesswork and the effectiveness of program implementation will remain a matter of conjecture. For a recent comprehensive review of health information needs and their use in complex emergencies, see Checchi et al. (2017). Information and surveillance systems are also covered in the *Public Health Infrastructure* chapter of this text.

Shelter and Environment

As mentioned earlier, the placement of refugees and IDPs in small settlements or integration into local villages is preferable to the establishment of large camps. Health outcomes are probably better in these small settlements because environmental conditions are more favorable and there is less crowding. However, the provision of relief assistance to a large number of scattered settlements may pose difficult management and logistical challenges and may provoke resentment in the surrounding communities. In Guinea in the early 1990s, food aid and other relief items were provided to communities for distribution to both Liberian refugees and local inhabitants. This system may have worked well because the refugees and the local population were of the same ethnic origin and many were related. In contrast, measles vaccination coverage of Mozambican refugees in Malawi who were absorbed into communities and were dependent on the national immunization program was considerably lower than that in refugee camps, where services were provided by the United Nations and international voluntary agencies.

An interesting case in point involves the crisis in Syria, which began in 2011. In addition to a large number of internally displaced persons, an estimated 5 million refugees have fled, mostly to neighboring countries. In Jordan, many of the refugees have been settled in camps. In contrast, in Lebanon, no camps have been built and refugees must settle in small clusters or try to integrate with the indigenous population. This leads to competition for jobs, housing, and other necessities and can result in an increase in xenophobic tensions. In Turkey, the situation is mixed: Approximately 3 million Syrian refugees have moved to that country, but only 260,000 are housed in camps, most camps ranging in size between 5,000 and 10,000 people.

When camps are unavoidable, three key determinants of location should be safety and protection of residents, access to essential supports such as adequate quantities of clean water for drinking and fuel for cooking, and all-weather access. In many instances, local politics determines the site, and the location is often less than desirable. For example, in 1988, the Ethiopian government placed Somali refugees in a large camp of 180,000 persons on a site that had no local supply of drinking water. The nearest source with an adequate quantity of water was situated in a

town 100 km from the camp. For many years, water was delivered daily in convoys of trucks at enormous cost to the relief agencies. The Ethiopian government refused to move the refugees closer to town for fear of exacerbating political problems that it was experiencing with local ethnic Somalis.

Sites should be chosen with ease of water drainage in mind, though sometimes drainage systems have to be created at the time of camp construction. This is critical to ensure access by vehicles, limit disease vector breeding, and facilitate refugees' access to services, such as health clinics and food distribution. When hundreds of thousands of refugees fled ethnic cleansing in Kosovo in 1999, spontaneous camps were established near the border of Macedonia, where as many as 45,000 refugees camped on a muddy, snowy field sheltered only by their vehicles and makeshift tents. An added hazard was a large quantity of land mines laid by Serb forces along the border. Other inappropriate locations have included the swampy, malarious areas on the Thai border where Cambodian refugees were housed, the inhospitable mountainous area on the border between Iraq and Turkey to which the Kurdish population of Iraq fled in the wake of the 1991 Gulf War, and the volcanic, rocky ground in eastern Zaire where Rwandan refugee camps were settled, precluding both latrine construction and burial of the dead.

The issue of shelter for refugees is a thorny one for Western European authorities as well. A case in point is the "Calais jungle" that was established in 2015–2016 during the ongoing European refugee crisis. Approximately 6,000 refugees settled around Calais, France, hoping to reach the United Kingdom. French authorities were reluctant to provide decent living conditions for fear of attracting additional refugees. Healthcare and other essential services were provided by NGOs that are usually involved in refugee crises in LMICs.

Ideally, the size of camps should be limited to 20,000 residents for reasons of security and ease of administration. Such camps should be further divided into sections of 5,000 persons for the purpose of services delivery. Shelter is an urgent priority. On average, the covered area provided per person should be 3.5 to 4.5 m^2 (Sphere Project, 2011). In warm, humid climates, shelters should have optimal ventilation and protection from direct sunlight. In cold climates, shelter material should provide adequate insulation combined with sufficient clothing, blankets, bedding, space heating, and caloric intake. Ideally, houses should be built using a traditional design and local materials. This may pose local environmental problems such as the destruction of trees, so building materials should be trucked in from areas remote from the camp. Waterproofing is essential and may be achieved with plastic sheeting or tarpaulins. Tents may provide temporary shelter; however, they deteriorate in rain and wind and should be replaced with local materials as soon as possible.

To limit further environmental damage through deforestation, cooking fuel, such as charcoal, wood, oil, or kerosene, should be brought to the site from remote areas and fuel-efficient stoves provided or constructed. Camps may easily become fire hazards, and fire prevention should be an objective of proper camp design.

While many proposals for shelter continue to be made, many focus solely on the design and materials used for housing structures themselves. Such a narrow focus does not take into account that the issue of providing adequate shelter to refugees and internally displaced persons is a process, much more than it is a product.

Water and Sanitation

When refugee camps are unavoidable, proximity to safe water sources needs to be recognized as the most important criterion for site selection. The Sphere Project's key indicator for minimum water supply is 15 liters of clean water per person per day for all domestic needs—cooking, drinking, and bathing. Other indicators include at least one water collection point per 250 people and a maximum distance from shelter to the nearest water point of 500 meters. Ideally, both the quantity and the quality of water provided to refugees and displaced persons should meet international standards; however, in many cases this is not possible. In general, ensuring access to adequate quantities of relatively clean water is probably more effective in preventing diarrheal disease, especially bacterial dysentery, than providing smaller quantities of microbe-free water.

The usual options for supplying water to refugees and IDPs include surface water (e.g., lakes, rivers, streams), shallow wells, springs, bore wells, and trucked water from remote sources. Although surface water is often abundant, it needs to be treated, usually through a system of sedimentation and chlorination, and sometimes with filtration. A system of piped distribution to bladders or other means of storage, as well as outlet taps needs to be developed to avoid crowding and drainage problems. Shallow wells and springs need to be protected and, unless gravity-fed, provided with a mechanism for drawing water, such as pumps. Deep-bore wells provide clean water at the source, but it may take some time to bring in the necessary equipment to establish them.

In addition, measures to prevent post-source contamination need to be implemented, including treatment at the source (e.g., "bucket chlorination"). Sufficient collection and storage containers (at least three 20-liter containers per family), especially containers with narrow openings that prevent post-collection contamination, should be made available. A study in a Malawian refugee camp in 1993 demonstrated a significant reduction in fecal contamination of water stored in such buckets compared with standard buckets. In addition, the incidence of diarrhea among children younger than 5 years of age in the households with the improved buckets was considerably lower than in control households (Roberts et al., 2001). Recently, newer methods of disinfecting water in the home, including simple chlorination and/or flocculation systems, such as the Safe Water System (CDC, 2008), have been moderately successful in CEs.

Adequate sanitation is an essential element of diarrheal disease prevention efforts and a critical component of any relief program. While the eventual goal of sanitation programs should be the construction of one latrine per family, interim measures may include the designation of separate defecation areas and the temporary provision of neighborhood latrines. The Sphere Project minimum indicator of acceptable household-level sanitation is a maximum of 20 persons per latrine. Toilets should be segregated by sex and be no more than 50 meters from dwellings for security reasons. To achieve maximal impact, these measures should be complemented by community hygiene education and regular distribution of at least 250 g of soap per person per month. Hygiene education has been shown to significantly increase the impact of sanitation programs. An analysis of data gathered in the Malawi study cited earlier demonstrated that the presence of soap in households significantly reduced the risk of diarrhea (Peterson, Roberts, Toole, & Peterson, 1998).

Achieving the goals associated with these indicators can be difficult. In Goma, where the ground was volcanic rock and digging was difficult, sanitation remained inadequate and undoubtedly contributed to the virulence of the cholera outbreak. In Haiti after the 2010 earthquake, in an almost totally destroyed urban area, reconstituting even rudimentary plumbing was out of the question during the emergency period. Moreover, the construction of latrines was painfully slow and greatly hampered by the prevailing conditions, even when the importance of improved sanitation was clearly recognized. The objective of post-emergency sanitation measures should be to restore the pre-disaster levels of environmental services rather than attempting to improve on the original levels, although longer-term reconstruction efforts can certainly aim to "build it back better"—that is, to improve upon the status quo ante.

The provision of water and sanitation in emergency-affected populations in urban and rural areas of Eastern Europe has posed different challenges. In general, the goal is to repair existing systems. Even so, interim measures may be required, such as rehabilitating old wells, providing generators to pump water from distant sources such as rivers, and providing containers and security for residents to collect water at available sources. In the "Calais jungle" mentioned earlier, sanitation was notoriously poor and the difference between the living conditions of the refugees and the surrounding population was stark.

Food Rations and Distribution

The quantity and quality of food rations is one of the most critical determinants of health outcomes in emergency-affected populations. During the early evolution of CEs, measures should be taken to increase access to food without forcing people to leave their homes. The establishment of "feeding camps" may act as a magnet for hungry families and lead to the spontaneous establishment of settlements and camps, with the subsequent health problems described earlier in this chapter. In addition, in conflict zones, warring parties may target areas where populations regularly congregate. Subsidized food shops; food-for-work or cash-for-work programs; emergency support for home food production, such as the distribution of fast-growing seed varieties and agricultural tools; and other measures may be effective in ensuring food provision prior to the onset of armed conflict.

Once armed conflict has commenced, either forcing people to flee their homes or be trapped in siege-like conditions, it is usually necessary to distribute food. General food rations should contain at least 2,100 kilocalories (kcal) of energy per person per day as well as the other nutrients listed in **TABLE 12-5**. Rations should take into consideration the demographic composition of the population, the specific needs of vulnerable groups, cultural food preferences, and access by the population to alternative sources of food and income. In cold climates, the minimum energy value of the ration should be adjusted upward. Pregnant women require, on average, an extra 285 kcal per day, and lactating women an extra 500 kcal. These extra requirements should be provided through distribution of rations within the household; however, this may need to be monitored, perhaps indirectly via the prevalence of low-birth-weight babies.

TABLE 12-5 Minimum Nutritional Requirements for Emergency-Affected Populations, for Planning Purposes During the Initial Stages of an Emergency

Nutrient	Minimum population requirements
Energy	2,100 kcals
Protein	53 g (10% of total energy)
Fat	40 g (17% of total energy)
Vitamin A	550 µg RAE
Vitamin D	6.1 µg
Vitamin E	8.0 mg alpha-TE
Vitamin K	48.2 µg
Vitamin B1 (Thiamin)	1.1 mg
Vitamin B2 (Riboflavin)	1.1 mg
Vitamin B3 (Niacin)	13.8 mg
Vitamin B6 (Pyridoxine)	1.2 mg
Vitamin B12 (Cobalamin)	2.2 µg
Folate	363 µg DFE
Pantothenate	4.6 mg
Vitamin C	41.6 mg
Iron	32 mg
Iodine	138 µg
Zinc	12.4 mg
Copper	1.1 mg
Selenium	27.6 µg
Calcium	989 mg
Magnesium	201 mg

Second edition, were used for all vitamin and mineral requirement calculations except copper, as requirements for this mineral were not included in FAOA/VHO (2004). Requirements for copper are taken from WHO (1996), Trace Elements in Human Nutntion and Health.
Abbreviations: Alpha-TE = alpha-tocopherol equivalents; DFE = dietary folate equivalents; NE = niacin equivalents; RAE = retinol activity equivalents.

Food should be distributed regularly as dry items to family units, taking care that socially vulnerable groups, such as female-headed households, unaccompanied minors, and the elderly, receive their fair share. Achieving this aim requires an accurate registration system listing all residents in family groups. Because of the indignity of being counted and the fact that many refugees are afraid to have their identities known and precise locations reported, attempts at registration for the distribution of humanitarian aid should be carried out with the security and cultural concerns of the population taken into careful consideration (Harrell-Bond, Voutira, & Leopold, 1992). If a refugee or displaced population is organized in well-defined communities, food may be distributed to community leaders, who then divide it further to the heads of households in quantities based on the number of family members. Sometimes, as was the case during the Kurdish exodus to camps on the Iraq–Turkey border in 1991, this arrangement has been established in voluntary exchange for demographic information that allows health authorities to enumerate the births and deaths occurring. In other situations, food is distributed directly to heads of households, based on a ration card system.

In LMICs, food rations usually comprise a staple cereal, such as rice, wheat, or maize, or a mix such as corn–soy blend; a source of dense fat, such as vegetable oil; a source of protein, such as beans, lentils, groundnuts, or dried fish; and extra items such as salt, tea, and spices. Experience has shown that women are fairer than men in distributing each food item in the correct quantity. Standard serving containers based on a known weight or volume of food are essential for distribution centers.

There is a widespread belief that currently available refugee rations, especially those distributed in non-European populations, are inadequate to meet nutrient requirements, which may be higher than the traditional recommended daily allowances. The best way to combat depletion of essential nutrients is to take active steps to increase the variety of the diet. This is not possible with relief foods that have to be capable of bulk storage and shipment—cereal, pulses, sugar, oil, and salt. For this reason, recipients of international aid should be encouraged to barter food items for local produce. Market facilities should be established, supported, and controlled by camp leaders. Seeds for leafy vegetables should be distributed as part of all relief activities, even in the acute phase of the CE. Every effort should be made to provide spices and herbs, used traditionally by the population, with all food baskets. There is no need for a special food basket for children or pregnant and lactating women—only a sufficiently varied diet for the whole family (Golden, 1999).

Increasingly, especially in urban areas, cash vouchers or ATM cards are provided to refugees to purchase food. At the first World Humanitarian Summit, held in Istanbul in 2015, one of the major elements of the "Grand Bargain" reached by attendees was to vastly increase the use of cash programming. That is, it was agreed that populations in need would be provided cash and allowed to budget for themselves and their households in accordance with their own priorities. Buying food in local markets based on individual preferences represents an important use of this new way of providing humanitarian assistance, albeit one that has not yet been adequately implemented or evaluated.

In addition to food, adequate cooking fuel, utensils, and facilities to grind whole-grain cereals need to be made available to all families. Fuel-efficient stoves, often made of mud, may lead to more efficient use of scarce fuel. In children younger than 2 years, breastfeeding will provide considerable protection against communicable diseases, including diarrhea. Thus, attempts to introduce or distribute breast milk substitutes and infant feeding bottles should be strongly opposed in an emergency situation. The evidence that vitamin A deficiency is associated with increased childhood mortality and disabling blindness is now so convincing that supplements of vitamin A should be given routinely to all refugee children younger than 5 years of age at first contact and every 3 to 6 months thereafter (Nieburg et al., 1988).

In Eastern Europe, the same principles have been followed in providing food rations, though the types of food have varied and have included cheese, meat, powdered orange juice, and fruit. In some industrialized countries experiencing economic and political instability, ration vouchers have been distributed to vulnerable persons, such as elderly pensioners, which can be redeemed for food at designated stores. More recently, cash transfers to cell phones or to debit cards have been made.

One of the main problems in Africa, and in some parts of Asia, has been providing refugees and IDPs with foods containing adequate quantities of micronutrients, especially niacin, riboflavin, thiamin, iron, and vitamin C. Epidemics of pellagra, scurvy, and beriberi have been common in African refugee camps. For many years, this was a blind spot in emergency food and nutrition planning; more recently, the problem has been acknowledged, although solutions are still inadequate.

In southern Africa, niacin has been added to maize flour during the milling process. However, vitamin C is water-soluble and sensitive to heat, light, and bruising; thus, the transport, storage, and distribution of large quantities of foods such as citrus fruit have been problematic. One solution to this problem is to allow and encourage people to swap some of their ration items in local markets for vitamin C–containing foods, such as tomatoes, onions, potatoes, green chili peppers, and other fruits and vegetables. In addition, the provision of seeds to enable refugees to grow small amounts of vegetables in kitchen gardens is an effective measure. The provision of fortified blended cereals has also been proposed as a vehicle for ensuring adequate micronutrient intake. Studies in Ethiopia, Nepal, and Tanzania have shown that these cereals are generally acceptable, although overcooking and consequent depletion of the vitamin C content may be a problem in some communities (Mears & Young, 1998). WHO has published a series of guidelines on the prevention of scurvy (WHO, 1999a), thiamine deficiency (WHO, 1999b), and pellagra (WHO, 2000a).

A food ration monitoring system is important to ensure that families are receiving fair and adequate quantities of food. On a food ration distribution day, monitoring teams can take up positions at several points not far from the distribution center. They should be equipped with weighing scales and food composition tables. Families should be stopped randomly as they return to their homes and asked to participate. Each of the items in their ration should be weighed and converted to calories and other nutrients using the tables. The total weight of each food item (in grams) and the total nutrients provided should be divided by the number of family members and the number of days until the next distribution day. This calculation will provide the average quantity per person per day and may be compared with the official ration and with standard tables of recommended daily allowances of nutrients.

Nutritional Rehabilitation

In general, the goal of an emergency feeding program is to provide adequate quantities of nutrients through the general household distribution of food rations. However, due to the many factors described earlier, some population subgroups may be either already acutely malnourished or at high risk of becoming malnourished. In general, children are defined as acutely malnourished according to their weight-for-height index, although mid-upper arm circumference is also frequently used as a screening tool. Adolescents and adults may be defined as acutely malnourished according to their MUAC, body mass index, or clinical signs.

Currently malnourished and at-risk groups may require targeted feeding, or what is termed *selective feeding*. **FIGURE 12-5** demonstrates the various kinds of selective feeding. Notably, these programs should be seen as additions to, rather than substitutes for, the general feeding program. They need clear objectives and criteria for opening, admission, discharge, and closure that should be based on population-based anthropometry surveys and agreed-upon nutritional indices. Selective feeding programs should be complemented by measures to improve the food ration distribution system, provide adequate clean water and sanitation, and control measles and other communicable diseases. They should be integrated into community health programs that offer other prevention and care services.

During the first decade of the 21st century, a major change evolved in the way in which selective feeding programs are delivered. There was a trend away from reliance on fixed sites to prepare and administer supplementary and therapeutic food. Community management of acute malnutrition (CMAM) programs are now the norm *except* for the management of severely malnourished children with complications such as dehydration, acidosis, sepsis, and hypothermia. Instead of labor-intensive on-site preparation of food, ready-to-use therapeutic foods (RUTF) manufactured by commercial companies have become the most preferred product. The most common is Plumpy'nut, which is produced by the French company Nutriset. Plumpy'nut requires no water preparation or

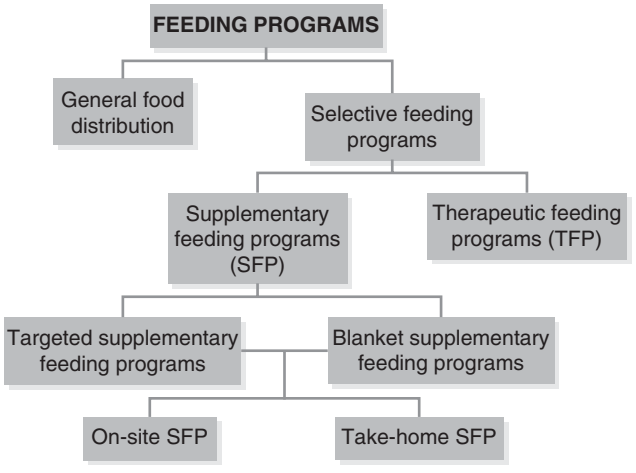

FIGURE 12-5 Overall feeding program.

refrigeration and has a 2-year shelf life, making it easy to deploy in difficult conditions to treat severe acute malnutrition. The ingredients of this product are peanut paste, vegetable oil, powdered milk, sugar, vitamins, and minerals, combined in a foil pouch. Each 92-g pack provides 500 kcal or 2.1 MJ.

RUTF has proved effective in the rehabilitation of malnourished children. In a study in Malawi, 219 children age 1 to 5 years with severe malnutrition and edema (but without other complications) were provided with RUTF for feeding at home. More than 83% of the children recovered, while 5% died, meaning that this intervention exceeded international minimum standards (Ciliberto, Manary, Ndekha, Briend, & Ashorn, 2006). Average weight gain was roughly 2.8 g/kg/day, which is less than international standards, but nonetheless resulted in good overall recovery. Research has further shown that effective RUTF can be manufactured in most settings worldwide at low cost using local foods and fairly common equipment.

Supplementary feeding programs (SFPs) provide nutritious foods in addition to the general ration, with the aim of rehabilitating moderately malnourished individuals and decreasing the population prevalence of acute malnutrition. There are two kinds of SFPs: targeted and blanket. Each type may provide food supplements as on-site, precooked ("wet"), or take-home ("dry") rations. Take-home rations are usually preferred because they require fewer resources, carry lower risks of cross-infection among recipients, and retain the family's primary responsibility for feeding. On-site feeding may be justified when the security situation is poor, when the general ration is inadequate such that food is likely to be shared within the household, or when cooking fuel is scarce.

A targeted SFP aims to prevent moderately malnourished individuals from becoming severely malnourished and to rehabilitate them. Such programs generally focus on children younger than 5 years and on pregnant and lactating women. Care should be taken not to apply strict guidelines for the opening of selective feeding programs. Like all decisions taken in an emergency, it should be based on a review of both current public health priorities and available resources.

Current guidelines suggest that a targeted SFP should be implemented when one or more of the following situations occur:

- The prevalence of acute malnutrition among children younger than 5 years is 10% to 14%.
- The prevalence of acute malnutrition among children is 5% to 9% in the presence of aggravating factors (e.g., inadequate general food ration, CMR greater than 1 per 10,000 per day, epidemics of measles or pertussis, and high incidence of acute respiratory infections and diarrheal diseases).

Criteria for admission should include the following:

- Children younger than 5 years with a weight-for-height *Z*-score between –3 and –2
- Older children, adolescents, and adults who are moderately malnourished according to their MUAC, BMI, or clinical condition
- Referrals of children graduating from therapeutic feeding programs
- Selected pregnant women and nursing mothers

Blanket SFPs are meant to provide extra nutritious food to all members of groups at risk of malnutrition. They are started under the following conditions:

- General food distribution systems not yet in place
- Problems in delivering and distributing the general ration
- Prevalence of acute malnutrition equal to or greater than 15%
- Prevalence of acute malnutrition of 10% to 14% in the presence of aggravating factors
- Anticipated increase in acute malnutrition rates due to seasonally induced epidemics
- In the case of micronutrient-deficiency disease outbreaks, to provide micronutrient-rich supplements to a target population

The primary recipients of blanket SFPs are all children younger than 5 years, pregnant women and nursing mothers (up to 6 months after delivery), and other groups such as the elderly or medically ill. As with RUTF, ready-to-use supplementary foods (RUSF) have been developed and are gaining popularity. Their judicious use has the potential to replace on-site supplementary feeding programs to a large extent.

Therapeutic feeding programs (TFPs) aim to rehabilitate severely malnourished persons, the majority of whom are children with severe wasting or nutritional edema—conditions commonly known as marasmus and kwashiorkor, respectively. A TFP should be initiated when the number of severely malnourished individuals cannot be treated adequately in other facilities. Although current guidelines for opening a TFP are based on population malnutrition prevalence, the decision should be based on an assessment of the public health needs and the resources available. In a large camp, the percentage of malnourished children may not be an appropriate basis for this decision. Perhaps a more practical guide would be the presence of, say, 50 potential beneficiaries in a settlement.

The following criteria are used for admission (UNHCR & World Food Programme, 2011):

- Children younger than 5 years with weight-for-height *Z*-scores less than –3 or with edema, with complications such as dehydration, sepsis, hypothermia, inability to take foods orally, or poor conscious state
- Severely malnourished children older than 5 years, adolescents, or adults assessed by other means and with complications
- Low-birth-weight babies (less than 2,500 g)
- Orphans younger than 1 year of age when traditional caring practices are inadequate
- Mothers of children younger than 1 year with breastfeeding failure where relactation counseling has failed

Rehabilitation of severely malnourished individuals is a medical procedure demanding careful attention to detail; therefore, well-trained staff are essential. TFPs usually have two phases:

1. The intensive care phase includes 24-hour care with medical treatment to control infection and dehydration and correct electrolyte imbalance, and nutritional treatment. Frequent feeds with therapeutic milk (F-75) are essential to prevent death from hypoglycemia and hypothermia. This phase usually lasts 1 week.
2. The rehabilitation phase provides at least 6 meals per day along with medical and psychological support, including for mothers of malnourished children. This phase usually lasts 5 weeks. This phase can take place at home using RUTF.

Details of the quantity and types of food recommended, discharge criteria, and reasons for stopping SFPs and TFPs are provided by UNHCR and the World Food Programme (2011). In addition, detailed information on the management of severe malnutrition is provided in WHO manuals (WHO, 1999c, 2000b). It should be noted that the increasing use of RUTF like Plumpy'nut has revolutionized the care of severe undernutrition; hospitalization with 24/7 supervision of the administration of detailed parenteral nutrition protocols is no longer regularly required and has, to a significant degree, been replaced by community therapeutic care.

Community Management of Acute Malnutrition

Collins et al. (2006) outline three levels of CMAM: (1) inpatient stabilization care for people with acute malnutrition and serious medical complications; (2) outpatient therapeutic programs for people with severe acute malnutrition but no complications; and (3) supplementary feeding for moderate acute malnutrition and no complications. Under this definition, inpatient care is provided according to WHO guidelines. It is worth noting that other studies have categorized CMAM programs differently. For example, a recent review of the effectiveness of CMAM separated programs into four categories: (1) residential nutrition centers; (2) day-care nutrition centers; (3) clinic-based care; and (4) domiciliary (home) care (Ashworth, 2006). Although the term CMAM is frequently used in reference to slightly different models, the three-level program structure outlined previously—inpatient care, outpatient care, and supplementary feeding program—is a useful one.

CMAM approaches are also becoming more effective as techniques and protocols develop. In an extensive literature review, comprising 33 community-based nutrition rehabilitation programs implemented between 1980 and 2005, only one-third (33%) were considered effective, using low mortality and acceptable weight gain as indicators of success (Ashworth, 2006). In contrast, among those programs implemented between 1995 and 2005, a much greater proportion (62%) was considered effective.

Health Services: Response to Complex Emergencies

Complex emergencies severely disrupt normal healthcare service activity (see Figure 12-3). In developing appropriate responses to this disruption, it is worth considering the impact on and response by at least three different sets of services:

- Service provision in the country affected by the CE
- Service provision in countries to which refugees have fled
- Service provision by multilateral agencies and NGOs

Service Provision in Countries Directly Affected by Complex Emergencies

The main challenge in these settings is to seek to minimize the direct and indirect adverse impacts of the conflict on the health services personnel and resources available. In many conflicts, as highlighted earlier, health services may be specifically targeted, as may health services providers. In such situations it may be extremely difficult to maintain services due to absent

or fleeing health personnel, lack of drugs and equipment, disruption of referral systems, and destruction of physical infrastructure, including hospitals and clinics. In recent years, the purposeful destruction of health facilities in Syria, Yemen, Afghanistan, and Iraq has represented clear violations of international law. In 2016, the United Nations Security Council adopted Resolution 2286, deploring the short- and long-term consequences of such attacks for the civilian populations and healthcare systems of the countries concerned. To date, no action has been taken on the basis of this resolution.

Even if the official health system is destroyed, however, the health workers who previously worked within it may still be present within the community (unless they have themselves fled to safer areas) and may still be able to offer services and advice. The extent to which services can be maintained is in part dependent on earlier disaster preparedness activities, in terms of both training and of prepositioning of drugs and other supplies in areas where logistic support was predicted to be vulnerable to disruption.

In some situations, it has been possible to ensure that areas where services are likely to be disrupted have received prior stocks of drugs and equipment so that they can maintain services despite disruption of the normal supply chains. Although this might be possible for certain forms of equipment and drugs, others, such as vaccination facilities (which are dependent upon maintaining an intact cold chain), and support activities, such as training and supervision, are invariably disrupted during CEs. Nevertheless, local-level responses are possible. In Afghanistan, despite the conflict in Kabul, the medical school was able to relocate to another city to continue its training activities. In relation to the availability of drugs for treatment, prior distribution of necessary drugs to responsible community members—such as community and other health workers, teachers, and in some cases patients with chronic conditions—may ensure their availability despite the population having to move suddenly. Patients with chronic conditions such as leprosy or tuberculosis could be issued with drug supplies for extended periods, assuming that the drugs can be procured and distributed and that patients with these conditions will be able to adhere to the treatment regimens prescribed for them. The potential to distribute insecticide-treated mosquito nets to populations on the move might be an option in areas of high malaria risk; some experience in this approach has been gained among the highly mobile Burmese refugees on the Thai border.

Service Provision in Countries to Which Refugees Have Fled

When refugees flee from their country and cross borders, their normal sources of health care are no longer available to them. Therefore, they may be dependent on what they can provide for themselves, which is often desperately little if they have been forced to flee suddenly, as was the case with the Kosovar Albanians in 1999 and with Syrians in 2011 and the ensuing years. Alternatively, they may depend on what can be provided in the host country to which they have fled, either through existing host country services or through additional services mobilized by NGOs and other organizations. Host government services may rapidly become overwhelmed if large numbers of refugees suddenly move into an area and seek to use the local health system. In addition to their absolute numbers, the health condition of refugees may be poor, especially if their journey has been traumatic and unplanned or if their prior state of health was poor.

In most cases, at least in the short term, these local host-country services will not receive additional resources and, therefore, will have to cope as best they can with the additional service load. In some instances, such as with significant flight from middle-income countries like Syria, services that require a moderate level of technical expertise and that may be expensive, such as renal dialysis or oncologic services, may no longer be able to cope with demand and need. This trend may disadvantage local community members who ordinarily utilize such services, because the supply of drugs and usual access to health workers may be compromised. Communities will typically be willing to accept these hardships for a time, but if the situation becomes protracted and leads to a lasting decline in services, tension may develop between the host and refugee communities. Another point of friction occurs when refugees are offered access to host services at no cost, while local community members may be required to pay user charges, both informal and formal, to obtain care.

Finally, different policies may be applied to refugee and local populations. For malaria treatment, for example, international organizations providing care to the emergency-affected population might opt for more effective drugs than those designated by existing national policies. Such was the case in Burundi in 2000–2001, where disagreements between MSF and the government of Burundi over malaria treatment policies took several months to resolve (MSF, 2001). Devoting attention to issues of equity and to ensuring that host and refugee communities gain similar access to services will be in the longer-term best interests of both groups.

Service Provision by Multilateral Organizations and Nongovernmental Organizations

The key challenges for these organizations are, in the short term, to reduce excess preventable loss of life and to reestablish an environment in which maintaining and promoting health is possible. Many of the subsequent sections deal with the nature of the health-related interventions that are necessary in these settings.

In camp settings, health services should be organized to ensure that the major causes of morbidity and mortality are addressed through fixed facilities and outreach programs. An essential drug list and standardized treatment protocols are necessary elements of a curative program. It is not necessary to develop totally new guidelines in each refugee situation; several excellent manuals already exist, from which guidelines can be adapted to suit the local conditions (MSF, 2017; WHO, 2003). Curative services should be decentralized by establishing a camp system consisting of community health workers, health posts, first-line outpatient clinics, and a small inpatient facility to treat severe emergency cases. Patients requiring surgery or prolonged hospitalization should be referred to a local district or provincial hospital; this facility will require provision of extra drugs and other medical supplies to cope with the greater patient load.

Organizations that typically espouse a development approach rather than relief-oriented approach have sought to place the issue of developmental relief onto the CE management agenda, arguing that early attention to the difficult issues of efficiency, effectiveness, sustainability, equity, and local ownership will be beneficial in the longer term. If the latter approach is adopted, greater effort will be devoted to activities such as training, building local capacity, and keeping costs down, rather than seeing these as desirable, but not practical, goals given the acute needs faced in relation to saving lives.

An additional concern facing the range of organizations offering services in response to humanitarian crises is the importance of coordination. Organizations need to work together if they are to reinforce each other's actions, maximize the use of available resources, minimize duplication and overlap, and enhance effectiveness, equity, and efficiency. The Code of Conduct for Humanitarian Organizations highlights the need for effective coordination, usually under the aegis of a lead organization from the United Nations system, such as OCHA, UNHCR, or, in some cases (especially for the health sector), WHO or UNICEF. Optimal levels of coordination have, unfortunately, been an elusive goal in many emergency settings.

Lastly, considerable concern has arisen in recent years regarding the quality of much of the service provision by NGOs operating in CEs. A key problem is the lack of transparency and accountability of such services, and the fact that despite meaning well, some organizations may do more harm than good. Recent initiatives, such as the Sphere Project (see Exhibit 12-4 later in this chapter), seek to establish standards and minimum indicators of acceptable performance for organizations operating in these environments. Although no enforcement mechanisms, or even effective incentives, have been developed to ensure compliance with these suggested standards, many voluntary organizations and even institutional and governmental donors have agreed to do what they can to comply. The increasing professionalization of the field of humanitarian assistance, briefly discussed toward the end of this chapter, similarly reflects these trends toward improved practice and accountability.

Refugee Health Workers

Community health workers (CHWs) are seen in many countries as the mainstay of primary healthcare promotion, although some critics have questioned their value to national primary healthcare programs (Chou et al., 2017; Walt, 1988). In refugee and displaced person settings, the selection and training of refugee health workers has been considered as one key mechanism by which health programs can work more closely with affected communities.

The principal advantages of refugee health workers may be related to their role as intermediaries between the affected community and the services provided by the humanitarian agencies, which are often led by expatriate staff. Refugee workers are more likely to understand the cultural, behavioral, and environmental influences on health status, to contribute to realizing the potential for self-care and refugee-provided services within the community, to share the health service provision workload, to build capacity and skills that will potentially be available after repatriation, and to enhance the dignity of both the community and the healthcare providers themselves. CHWs who are relatively unskilled and trained within the community may be the mainstay of service provision. However, it is important to recognize that the presence of trained health workers within the affected community—whether these be midwives, nurses, doctors, or others—represents an extremely valuable resource whose role should be promoted in whatever services are developed with expatriate agency support.

The role of CHWs in refugee settings will depend on the public health needs, the availability of host country– and NGO-provided services, the prior level of skill of the workers, and the extent and quality of training received. In many cases, refugee health workers have worked outside of health center settings and have performed a range of tasks, including the following:

- Identifying sick and malnourished community members and assisting them in obtaining assistance
- Collecting and reporting demographic data such as births and deaths
- Providing first aid and basic primary care such as oral rehydration for children with diarrhea
- Assisting in mass vaccination campaigns
- Encouraging participation in health campaigns and disease control programs
- Ensuring that the needs and perspectives of refugees are taken into account in the development of health programs

On a different level, in many conflict-affected countries, professional health workers, including, among others, radiologists, anesthesiologists, and surgeons, remain in their communities and, under extremely trying circumstances, attempt to provide at least essential services. The conflicts in Syria, Afghanistan, Yemen, and Iraq have all demonstrated the remarkable dedication and professionalism of health workers. As discussed earlier, these professionals have often been targeted by armed forces in an attempt to destabilize their communities.

One of the first refugee programs that systematically trained large numbers of CHWs as the basis of health services delivery was established in Somalia in the early 1980s. At that time, almost 1 million refugees from Ethiopia were housed in 35 camps scattered throughout three regions of the country. The Ministry of Health's Refugee Health Unit coordinated the training of approximately 2,000 CHWs and 1,000 traditional birth attendants with the help of NGOs working in the country. The training curriculum was standardized, as were treatment protocols, essential drugs, and salaries and conditions. As NGOs gradually withdrew from the country, health services were largely provided by CHWs and traditional birth attendants, supervised by Somali Ministry of Health trainers, nurses, and doctors.

Despite the many potential advantages of developing and working with a cadre of refugee health workers, this approach also faces numerous problems. It may be difficult to recruit health workers, especially in unstable settings or if potential workers have other pressing priorities, and they will require training and ongoing supervision. Their selection may be highly political, and identifying the affiliations of potential health workers may be difficult for agencies with limited knowledge of the area in which they are working. There is potential to stimulate rivalry and exacerbate perceptions of inequity if an inappropriate mix of workers from different areas and different backgrounds is selected. In the presence of adequately resourced host-country services, especially those that have sufficient numbers of trained staff, establishing a cadre of CHWs with more limited skills may not be seen as a priority.

Among the prerequisites for effective CHW training programs are a clear description of the tasks to be performed, an adequate level of logistic and supervisory support, a transparent system of selection and remuneration, and the consent and involvement of the affected and, where relevant, host communities.

Women's and Children's Healthcare Services

Children and women, especially pregnant women, have been repeatedly shown to be the most vulnerable members of refugee and displaced populations, especially during the emergency period. Among Rohingya refugees in Bangladesh (1992–1993), women and girls were seen less frequently at health facilities than men and boys, but had much higher mortality (**FIGURE 12-6**).

In Goma in 1994, households headed by women were found to have substantially less food and nonfood commodities that had been issued at general distribution points by international relief officials than those in which an adult male was present. For these reasons, health services oriented to the specific needs of children and women are essential in reducing morbidity and mortality within a population to a minimum level. Women's and children's health (WCH) care should begin within the community, at the household level, and not depend entirely on established health facilities. Often, as discussed earlier, community members, such as traditional birth attendants or others previously trained as CHWs, can be recruited from within the affected population itself to provide basic services.

For children, routine screening and preventive services are important. Growth monitoring, and referral of children whose growth is faltering to

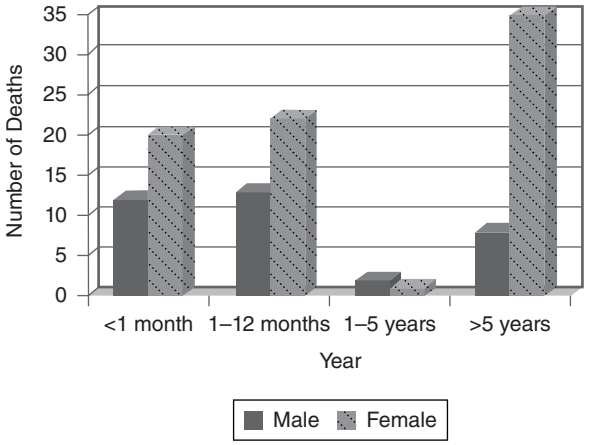

FIGURE 12-6 Number of deaths among Burmese refugees in the Gundhum II Camp, Bangladesh, May 6 to June 26, 1992 by age and sex.

Data from Centers for Disese Control and Prevention (CDC). (1992). Famine affected, refugee, and displaced populations: Recommendations for public health issues. *Morbidity and Mortality Weekly Report, 41*(RR-13).

supplementary feeding programs, is an essential function of WCH services. A WCH program will also ensure that all children are vaccinated on schedule and are receiving regular supplements of vitamin A. When curative care is required, as for diarrhea and acute respiratory infections, it can be offered at the household level by trained CHWs, or the child can be referred to peripheral, first-line health facilities.

Pregnant women (who typically constitute approximately 3% of the refugee population) should be regularly monitored. At least four prenatal examinations should be conducted to identify high-risk pregnancies. All women should be vaccinated with tetanus toxoid to prevent neonatal tetanus in their newborns. Iron and folic acid should be distributed (and their ingestion monitored, if possible). Insecticide-treated bed nets for the prevention of malaria should be distributed, and the presumptive treatment of malaria, if appropriate, should be undertaken in the second and third trimesters. In the postnatal period, counseling services addressing a variety of issues, from family planning to child care, and especially breastfeeding, should be offered.

Although many elements of women's and child health can be instituted in the post-emergency phase, a critical service that must be provided during the earliest stages of a relief effort is the establishment of emergency obstetric care. Cesarean section and transfusion facilities and the ability to give parenteral antibiotics are essential if maternal mortality is to be kept low. Provisions for emergency delivery are part of an overall minimum initial service package, discussed in the next section.

Reproductive Health

UNHCR, WHO, and the UN Population Fund (UNFPA) state that although food, water, and shelter remain priorities in an emergency assistance program, reproductive health care is among the crucial elements that give refugees the basic human welfare and dignity that is their right (UNHCR, 1995a). The response to reproductive health problems during emergencies consists of a constellation of assessment, services, and regular monitoring that addresses the implementation of the following programs:

- A minimum initial service package (MISP)
- Safe motherhood
- Prevention and treatment of sexual and gender-based violence
- Prevention and care for sexually transmitted diseases
- Family planning
- Reproductive health needs of adolescents

Minimum Initial Service Package

Although resources should not be diverted from attempts to control the diseases that have traditionally been the leading causes of death in CEs, five interventions related to reproductive health should be implemented even in the acute phase. In addition, a reproductive health coordinator should be designated to ensure that these measures are adequately addressed (http://www.who.int/reproductive-health/). Note that specific guidelines have been developed for the prevention and response to gender-based violence (UNHCR, 1995b).

Emergency Contraception

Forced migration is frequently accompanied by sexual violence. To prevent unwanted pregnancies resulting from rape, emergency postcoital contraceptive supplies should be available to women who request them. Although the extent of this problem has never been adequately documented, and although it is likely to vary from one situation to the next, the current recommendation is for sufficient supplies for 1% of women of reproductive age to be immediately available. Two methods of emergency contraception are currently available: (1) the combined oral contraceptive (two formulations are used), which must be taken within 3 days of unprotected sexual intercourse, and (2) the copper intrauterine device, which must be implanted within 5 days of unprotected intercourse.

Universal Precautions

To prevent the transmission of HIV, universal precautions must be respected from the outset of an emergency. Although chaotic conditions are frequently prevalent and although health services are implemented under stressful conditions during CEs, the threat of HIV infection can and must be minimized. Universal precautions include the following:

- Washing hands with soap and water after contact with body fluids or wounds
- Wearing gloves for procedures involving contact with blood or other body fluids
- Using protective clothing when exposure to large amounts of blood is likely
- Handling sharps safely
- Disposing of waste materials safely (burning and/or burial)
- Disinfecting or sterilizing medical equipment
- Wearing gloves when handling corpses, and washing with soap and water afterward

Delivery Services

All populations affected by CEs will include women in the later stages of pregnancy or who are at high risk for complicated deliveries. These women need services even during the acute phase of the emergency. In a population of 2,500 with a crude birth rate of approximately 3%, there will be 5 to 8 births per month. To deal with these deliveries, simple supplies must be made available. Both simple delivery kits and midwife kits are readily available from UNICEF and other suppliers of health supplies. Skilled attendants should be present at every delivery.

In addition, although it is not a formal part of the MISP, sites where complicated deliveries can be performed should be established as early as possible during an emergency. Cesarean section for obstructed delivery, transfusion for excessive hemorrhage, and parenteral antibiotics for the treatment of sepsis are the only ways to reduce maternal mortality, and these measures should be available and easily accessible from the onset of a relief operation.

Sexually Transmitted Infections

HIV and AIDS and other sexually transmitted infections (STIs) are major problems among emergency-affected populations from areas where there is a high prevalence of these conditions. Until recently, there was a paucity of data on the prevalence of HIV in refugee populations. It had been postulated that refugees and other conflict-affected populations might be at greater risk of acquiring HIV because of sexual exploitation, the breakdown of traditional societies and values, and the disruption of STI treatment and condom promotion programs. Nevertheless, some evidence indicates that conflict might actually inhibit the spread of HIV (Spiegel et al., 2007). For example, when the 20-year conflict in Angola ended in 2002, the country had a significantly lower HIV prevalence (5% to 10% in Luanda and 1% to 3% in rural areas) than that in all other southern African countries (15% to 40%).

Between 2002 and 2004, UNHCR surveys of pregnant women in 20 refugee camps in Kenya, Rwanda, Sudan, and Tanzania found lower HIV prevalence among refugees than in the surrounding population in three of the four countries (e.g., 5% versus 18% in Kenya), and in Sudan there was no significant difference (Spiegel, 2004). The UNHCR report notes that most refugees moved from low- to high-prevalence countries, that most refugees lived in remote rural areas with restricted freedom of movement, and that NGOs had mounted HIV prevention programs targeted at easily accessible, "captive" populations.

To minimize the transmission of STIs, including HIV, an adequate supply of condoms should be available on request to all members of the target population. Several guidelines have been developed for the prevention of HIV in refugee and post-emergency settings (Holmes, 2003; Inter-Agency Standing Committee Task Force on HIV/AIDS in Emergency Settings, 2003; Sphere Project, 2011).

Comprehensive Reproductive Health Services

The last element of the MISP is planning for the provision of comprehensive reproductive health services as rapidly as is feasible. To do this, reproductive health indicators should be included in health information systems to allow for the collection of baseline data on maternal, infant, and child mortality; prevalence of STIs; and population contraceptive prevalence rates. Suitable sites for the delivery of reproductive health services should be identified, though they need not be separate from other health facilities. These sites should be secure and allow for safe passage of women between their homes and the clinic. They should be easily accessible to all who wish to use them, guarantee privacy and confidentiality, and have access to clean water and latrines. In addition, an adequate referral system should be identified or established to provide care to women with obstetric complications or other health emergencies.

Post-Emergency Reproductive Health Programs

When adequate food, water, sanitation, and shelter have been provided, programs to address the initial emergency health priorities have been implemented (e.g., measles vaccination), and mortality rates have declined, the range of reproductive health services should gradually be expanded. In the post-emergency phase, health care would be quite incomplete unless the entire range of programs aimed at maintaining or improving reproductive health was included. The key to successful reproductive health programs is soliciting active participation of as many adolescents and women of reproductive age as possible. Although training female health workers (including traditional birth attendants) is usually the focus of such programs, male health workers should also be trained in the basic principles of reproductive health care. In addition, because adequate reproductive health services are frequently unavailable to the local, non-refugee population, it is a good idea to try to extend whatever programs are made available to refugees and displaced persons by expatriate relief workers to women and adolescents in the host population.

Communicable Disease Control

Concern for the potential impact of communicable diseases has dominated the public health response in many emergency settings. As discussed previously, this attention has frequently been warranted. Although many of the technical interventions and public health programs used in emergencies draw heavily from their counterparts in stable settings, a few important differences should be considered. Most important among them include addressing the needs of the local, nondisplaced, population; maintaining respect for national health policies when dealing with refugees (but not necessarily adhering to them); and promoting substantial community involvement as early as is feasible.

Measles

Measles was traditionally among the most feared of communicable diseases in emergency settings. During the 1970s and 1980s, measles epidemics were common, and it was not unusual for measles to be the major cause of mortality in large, displaced populations. Major outbreaks of measles have been uncommon in refugee camps since the late 1980s because of the high priority afforded to mass measles vaccination campaigns in the acute phase of humanitarian emergencies. However, major measles outbreaks, resulting in high mortality rates, were reported among IDPs in Ethiopia and the Democratic Republic of Congo during 2000 and 2001 because of delays in initiating vaccination campaigns (Salama et al., 2001).

Measles remains a significant problem in populations that cannot be reached for immunization because of armed conflict. In the case of Somalia, child immunization has been banned by the radical jihadist group Al Shabab. There have been major outbreaks of measles in Somalia with thousands of cases in 2014 and 2016, continuing into 2017 (WHO, 2017b).

Of the 1.8 million Syrian children born since the conflict in that country began, more than 50% are unvaccinated against measles. Measles has swept through Syria, including Aleppo and the northern regions, with more than 7,000 confirmed cases occurring between 2015 and 2016, and cases also reported in refugee camps in Jordan and Lebanon. Large outbreaks of measles have also occurred in war-torn South Sudan and Yemen (UNICEF, 2017; ReliefWeb, 2017b).

Because of the devastating impact that measles has had in many emergencies, it has become almost universally accepted that mass measles vaccination, regardless of vaccination history or place of provenance of the displaced, should be instituted as early during an emergency as possible. Leading reference publications (CDC, 1992; MSF, 1997; Sphere Project, 2011) accord measles vaccination the highest priority of all health-specific interventions and recommend that it be undertaken immediately after an initial rapid assessment regardless of the circumstances. If children cannot be vaccinated upon arrival or registration, a mass vaccination campaign should be undertaken. In general, this rule should be followed unless extenuating circumstances exist, such as the cholera epidemic in Goma in 1994 that required the full attention of health services workers.

Any mass vaccination program must be planned carefully if it is to be implemented successfully. Sufficient vaccine should be on hand (with a reserve in case of excess wastage) and stored in a functioning cold chain of adequate capacity. Only autodestruct syringes should be used, and safety boxes must be available for their storage and disposal.

The target population for measles vaccination in emergencies is usually children age 6 months to 15 years. WHO has recommended reducing the usual minimum age for measles vaccination from 9 months

to 6 months during CEs, because high attack rates and high CFRs have occurred in younger children, especially in large displaced populations living in relatively crowded conditions. Still, because vaccine efficacy in children age 6 to 9 months may be lower than optimal owing to the persistence of passively transferred maternal antibodies to measles virus, children in this age group should be vaccinated again at the age of 9 months. The upper age limit for mass vaccination is more flexible and depends, to a large extent, on the amount of measles vaccine, injection equipment, health personnel available, and the pressure of competing healthcare priorities. Because age and undernutrition are such important risk factors for complicated measles and for high CFRs, all children up to 15 years old who are eligible for selective feeding programs or who are hospitalized with other illnesses should be vaccinated against measles on a priority basis. Then, depending on the factors mentioned earlier, all children younger than 2 years should be considered for vaccination, followed by all children younger than 5 years. Finally, if the circumstances allow, the target population can be expanded. In any case, a mass vaccination campaign should seek to achieve at least 95% coverage of the target population.

Because a mass vaccination campaign can reach such a high proportion of the most vulnerable population, there are frequently demands to attach other services to it. Vitamin A, for example, can be offered to the same target group during the course of the campaign. Insecticide-treated bed nets and hygiene kits can be distributed to each household in which a child resides. There have been suggestions to provide polio vaccination along with measles vaccine, although the logistical burden of doing so must be carefully considered. In any case, a routine vaccination program for all children using the standard antigens recommended by WHO should be established during the post-emergency period. Other vaccines, such as yellow fever and meningitis, are effective in interrupting transmission of these infections during an epidemic, but should not be offered routinely at the time of measles vaccine. Cholera vaccination has also been recommended at the time of measles vaccination, as discussed in the following section.

The early detection of measles cases when they occur is an important feature of an effective community-based surveillance system. Measles treatment includes the administration of two doses of vitamin A and the appropriate treatment of common complications such as pneumonia, diarrhea, malnutrition, and meningoencephalitis. Children with measles should be closely monitored in regard to their nutritional status and, if indicated, should be enrolled in supplementary feeding programs during their convalescence.

Measles remains an important threat to the health of children in many emergency settings. However, as vaccination programs in many parts of the world have progressed and as vaccination coverage levels increase, measles vaccination should be considered alongside other priority interventions. In northern Iraq and in the Balkans, as in Goma, measles vaccination was delayed to address other, more urgent problems. In contrast, in Afghanistan (2002), in Darfur (2004), and in Aceh province, Indonesia, in the wake of the tsunami (2005), measles vaccination was among the first interventions organized and implemented. Nevertheless, despite the clear threat that measles poses to the health of populations in emergency settings, it is always appropriate to weigh the public health needs in light of the available resources and to order priorities accordingly. The guidelines titled *Vaccination in Emergencies: A Framework for Decision-Making*, which have been developed and disseminated by WHO (2017e), should be consulted at the start of any emergency health sector intervention.

Diarrheal Diseases

Unlike measles, which can be easily prevented with a vaccine, diarrheal diseases are often among the top three causes of mortality in humanitarian emergencies. Although diarrhea is mainly a condition of young children, cholera and dysentery—the major epidemic forms of diarrhea—affect people of all ages. Of all disease conditions, diarrhea is the most closely linked to poor sanitation, inadequate water quantity, and contaminated water.

The detection and reporting of diarrhea should be part of the routine surveillance system in all emergencies. Both acute watery diarrhea and bloody diarrhea should be reported separately by age (younger than 5 years and older than 5 years are minimum age groups—the elderly should be disaggregated if possible) and by gender.

All health personnel should be sensitized to the potential impact of diarrhea and should be skilled in most aspects of prevention and in treatment. The key to prevention lies in providing adequate sanitation facilities and at least the minimum recommended quantity of water of acceptable quality (see the "Water and Sanitation" section earlier in this chapter).

The mainstay of diarrhea case management is oral rehydration therapy (ORT). Although any fluids can be used to prevent the development of dehydration, low-osmolar oral rehydration salts (ORS) can be used

in all cases and are the treatment of choice for all levels of dehydration (see the *Infectious Diseases* chapter). In fact, the first large field trial of ORS took place in a refugee camp in West Bengal, India, where it was shown that cholera patients treated with the standard treatment at the time were 3.8 times as likely to die from dehydration as those treated with ORS (Mahalanabis et al., 1973). Zinc should be administered to all children with diarrhea for 10 days, if possible, to reduce the severity and duration of each episode, and to lengthen the time between episodes (Baqui et al., 2002).

Rehydration facilities should be available in all health facilities, including health posts and outreach sites within the community. Keys to the success of ORT in emergencies, where the caseload can be substantial, include careful organization of ORT centers and the presence of concerned and skilled staff. Mothers or other caretakers are important contributors to ORT and must be instructed as to the quantity of fluid that their children require. Assertive administration of ORT, especially for children who are tired and reluctant to drink, is essential. Breastfeeding should be continued, and the nutritional status of children recovering from diarrhea must be carefully monitored. Rehydration of unaccompanied children should be carefully overseen and appropriate follow-up ensured (see the *Understanding and Acting on Social Determinants of Health and Health Equity* chapter).

Cholera

Cholera epidemics have occurred frequently in emergency settings. Although deaths due to non-cholera watery diarrhea have been far more numerous, cholera, in addition to being able to cause death rapidly from dehydration, incites fear and even panic in many populations. Its ability to affect other relief activities and to divert health personnel and supplies from other activities may even contribute to higher death tolls due to other diseases. Outbreaks of cholera have occurred in all parts of the world; large outbreaks were recorded in India (1971), Thailand (1979), Sudan (1985), Somalia (1985), Ethiopia (1984), Malawi (1988–1991), northern Iraq (1991), Goma (1994), and Rwanda (1996).

In October 2010, nine months after the January 2010 earthquake, an outbreak of cholera started in Haiti, which quickly spread across the country. As of January 2014, 697,256 cholera cases and 8,534 deaths had been reported by the Haitian Ministry of Health (2014). One of the largest cholera epidemics in history, it occurred in a country where there had not been a cholera case for more than a century. Six years later, the United Nations acknowledged that cholera had been introduced to Haiti by UN peacekeepers from Nepal.

Most recently, outbreaks have occurred in Tanzania, Ethiopia, and Iraq in 2015, and in South Sudan, Somalia, and Yemen in 2016 and 2017. WHO has described the cholera outbreak in war-torn Yemen as the worst ever in the world (WHO, 2017c). By mid-September 2017, WHO was reporting 750,000 cumulative cases. In the first three months of 2017, WHO reported a cumulative number of 17,211 cases and 388 deaths from cholera in Somalia, with a case-fatality rate of 2.25%. Cholera is also widespread in South Sudan: As of May 2017, a total of 7,735 cholera cases including 246 deaths (CFR 3.23%) had been reported in South Sudan, involving 19 counties in 11 states, since the initial case was reported on June 18, 2016 (WHO, 2017d).

Investigations of cholera outbreaks have documented numerous modes of transmission and risk factors, including contaminated water, shared water containers, inadequately heated leftover food, insufficient soap, and funeral gatherings for cholera victims. One of the most lethal cholera epidemics ever recorded occurred among refugees in Goma, Zaire, in 1994, when it was estimated that 45,000 people (approximately 9% of the total population) died in a 3-week period. The source of contamination is believed to have been Lake Kivu, the principal source of water on which the population depended.

Early detection of possible cases of cholera is key to the effective management of an epidemic. Although non-cholera diarrhea is a far more common cause of morbidity and mortality in children, the death of an adult from dehydration should raise suspicions of cholera. Attack rates can be higher in refugee camps than in non-camp situations, but in all situations case-fatality rates can be kept as low as 1%. Laboratory confirmation should be obtained as quickly as possible at the start of a suspected epidemic, but need not be continued—even though most cases in a cholera epidemic, especially in areas with a high background rate of watery diarrhea, may not actually be due to cholera. Whenever cholera is suspected, aggressive attempts to educate the community should be made so as to limit the panic that frequently accompanies this disease. During the course of an epidemic, cases and deaths should be reported on a daily basis through the institution of an active surveillance mechanism.

In populations located in areas where cholera is a risk (e.g., if fecal culture-confirmed cholera diarrhea has occurred in three of the previous five years), WHO now recommends mass immunization with killed oral

cholera vaccines.[1] Although all age groups are vulnerable to cholera, immunization in resource-limited areas should be targeted to high-risk children age 1 year or older (Shanchol or Euvichol) or age 2 years or older (Dukoral) (WHO, 2017f). Although the availability of oral cholera vaccines has increased rapidly in recent years, mass immunization campaigns should not disrupt or delay other critical prevention programs, such as clean water and sanitation.

Cholera vaccine is now used both prophylactically and reactively in many emergency settings. Large shipments of vaccine from the well-established global vaccine stockpile have been sent to CE situations as diverse as those in Sierra Leone (in anticipation of cholera after a series of floods and mudslides devastated parts of Freetown in 2017), northern Nigeria (to prevent outbreaks in the Boko Haram–menaced areas of Borno State), and war-torn Yemen, where initial shipments of vaccine were refused by the Yemeni government.

The need to establish rehydration facilities at multiple sites within the community has been dramatically highlighted by the occurrence of epidemics of cholera. In an outbreak in Somalia in 1985, a new camp with only a centralized treatment facility and no trained CHWs reported a case fatality rate of 23.3%. In contrast, in seven camps in which peripheral ORT corners with trained CHWs had been established in the framework of a primary healthcare system, the CFR was limited to 2.4%. Even more dramatically, during the devastating outbreak in Goma in 1994, more than 90% of the approximately 45,000 deaths that occurred during a 3-week period occurred beyond the reach of the health system. Active case finding and rehydration therapy within the community, rather than reliance on overwhelmed and understaffed health facilities, may have averted a significant fraction of these deaths.

Although as many as 90% of patients during a cholera epidemic can be treated orally, intravenous rehydration will be required for the most severe cases. A referral system for such care must be in place, and cholera treatment sites should be identified and prepared with adequate bed capacity, human resources, water, drugs and other supplies, and disposal facilities. The treatment of cholera is the same as is described in the *Infectious Diseases* chapter. In emergency settings, however, selective chemoprophylaxis is usually not indicated. Resources can be used more efficiently and effectively in other ways, such as by establishing adequate water and sanitation and ensuring that all patients are identified and treated quickly and appropriately.

Dysentery Due to *Shigella dysenteriae* Type 1

The management of epidemics of dysentery in emergency settings is difficult. As is true of other diarrheal diseases, ensuring adequate water and sanitation facilities is essential, but because of the highly communicable nature of *Shigella dysenteriae* type 1, this measure's role in reducing transmission may be limited, especially in the crowded conditions of refugee camps. Nevertheless, the use of narrow-neck containers for water storage to reduce contamination and the distribution and use of soap for hand washing have been shown to be useful. Early case detection and prompt treatment are the keys to limiting spread. An epidemic of *S. dysenteriae* type 1 should be suspected whenever a case of diarrhea with blood in the stool is reported. Laboratory confirmation and sensitivity to antibiotics should be obtained immediately, with careful attention paid to the transport of stool specimens.

The key to dysentery case management is antibiotic therapy, but severe limitations may prevent effective case management on a large scale. These include the large caseloads that may require treatment, the resistance of organisms to first-line and even second-line antibiotics, and the difficulty of ensuring patient compliance with 3- to 5-day courses of treatment.

In general, during epidemics of *S. dysenteriae* type 1, an effective antibiotic such as ciprofloxacin should be given to all patients, under close supervision of health staff. If supplies of an effective antibiotic are limited, patients who are severely ill or most vulnerable (e.g., children, pregnant women, the elderly) should be given antibiotics, and others given only supportive treatment—that is, nutritional support, rehydration when necessary, and other specific measures. Oddly, no outbreaks of *S. dysenteriae* type 1 have been reported from emergency settings in recent years.

Acute Respiratory Infection

Acute lower respiratory infection (ALRI), or pneumonia, has been an important cause of morbidity and mortality in emergency settings. Risk factors have included crowded conditions, inadequate shelter, vitamin A deficiency, and indoor air pollution, especially in societies that cook indoors (such as Nepal). ALRI is undoubtedly a major cause of morbidity and mortality in cold climates, such as northern Iraq, the Balkans, and the war-torn former Soviet republics. Such infection is the leading cause of death among

[1] Dukoral, Shanchol, or Euvichol.

children in LMICs, but has been less consistently reported and investigated than many other communicable diseases in emergency settings.

The management of ALRI is the same as in non-emergency settings, with prompt antibiotic treatment and supportive care. Community health workers need to be trained to diagnose ALRI in children, based on signs such as chest indrawing and a rapid respiratory rate.

Malaria

In endemic areas, including Southeast Asia, the Indian subcontinent, and most of Africa, malaria is consistently among the leading causes of morbidity and mortality. It has been responsible for incidence rates as high as 1,037 per 1,000 per year (Burmese refugees in Thailand, 1984) and for as many as 30% of all deaths in displaced populations (Rwanda, 1994). It has been well established that populations that are displaced to areas of higher malaria endemicity than their place of origin have higher incidence rates and higher mortality from malaria.

A study of refugee sites in Burundi, Chad, Cameroon, Ethiopia, Kenya, Sudan, Tanzania, Thailand, and Uganda to describe trends in malaria incidence and mortality was published in 2011 (Anderson, Doocy, Haskew, Spiegel, & Moss, 2011). An average of 1.18 million refugees resided in 60 refugee sites, with at least 50 cases of malaria occurring per 1,000 refugees during the study period 2008–2009. The highest incidence of malaria was in refugee sites in Tanzania, where the annual incidence of malaria was 399 confirmed cases per 1,000 refugees and 728 confirmed cases per 1,000 refugee children younger than 5 years. Annual malaria mortality rates were highest in sites in Sudan (0.9 death per 1,000 refugees), Uganda and Tanzania (0.7 death per 1,000 refugees each). Malaria was the cause of 16% of deaths in refugee children younger than 5 years of age across all study sites.

Major risk factors for malaria in refugee situations include the lack of adequate housing, poor siting of camps (especially when they are placed in marshy areas), overcrowding, proximity to livestock (which may be the primary targets of mosquito vectors), and a general lack of competently trained health personnel. Malaria control in emergencies depends to some extent on knowledge of the local vectors. In any case, site planning and selection should be done with the possibility of malaria in mind, and areas with swamps, marshes, and other characteristics that favor vector breeding should be avoided. Where mosquito density is high and immunity of the population is low, periodic residual spraying of interior walls can be undertaken, although it is less effective where temporary and shoddy shelters are in use and where mosquitoes bite and rest outdoors. Aerial spraying should usually be avoided except in special circumstances, to avoid further traumatizing the population. In all circumstances, long-lasting insecticide-treated bed nets should be distributed (Bloland & Williams, 2003). In emergencies where people are displaced with their livestock, periodic permethrin sponging of the animals has been shown to reduce vector density and malaria transmission.

The presumptive treatment of pregnant women with pyrimethamine/sulfadoxine in a single dose during the second and third trimesters (especially during women's first and second pregnancies) is also a commonly recommended strategy. The presumptive treatment of children attending feeding centers can also be considered, and presumptive treatment of children for malaria at the time of mass measles vaccination or vaccination during routine programs may have a role in malaria control after further investigation. Whenever feasible, it is highly recommended that the diagnosis of malaria should be confirmed, either microscopically or, even better, with one of several available rapid diagnostic tests. If facilities are not available to do so, malaria should be treated on the basis of a presumptive diagnosis, although other causes of fever should be suspected as well.

In determining who should be treated, with which drugs, and according to what dosage schedule, it is important to consider the national guidelines of the host country, although malaria control policies may also be updated in accordance with the latest information regarding antimalarial drug sensitivities. In most parts of the world, artemisinin combination therapy is currently the most effective, and most recommended, treatment. Note, however, that artemisinin-resistant malaria has recently been reported from Cambodia, Laos, and Myanmar (WHO, 2017g). Strategies for uncomplicated malaria, for severe malaria, and for treatment failures should be developed and explained to all health service personnel.

Meningitis

Although not a consistent problem in emergencies, the threat of meningococcal (group A) meningitis is a formidable one. Overcrowding, especially during the drier seasons of the year, can be an important risk factor for this disease, which is transmitted via the respiratory route. Epidemics have occurred in Thailand (1980), Sudan (1989), Ethiopia (1993), Guinea (1993), and Goma; in the last case, attack rates ranged from 94 to 137 per 100,000 population over a period of

2 months. Outbreaks of meningitis tend to be protracted, lasting from 1 to 2 months. Unless they are detected and controlled at an early stage, they can be directly responsible for high mortality; in addition, patients can require resource-intensive care, which diverts attention from other high-priority health programs. In early 2005, an outbreak of the emerging W135 strain of meningococcus led to the vaccination of more than 150,000 Sudanese refugees in Chad.

The detection of outbreaks of meningococcal meningitis at an early stage is essential. During emergencies, a high level of suspicion should be maintained. All clinically suspicious cases should be diagnosed by either visual inspection of cerebrospinal fluid or, where available, by the appropriate microscopic, serologic, and bacteriologic analyses. Background rates of meningococcal disease vary considerably from one area to another, and the occurrence of disease is highly seasonal. For these reasons, the detection of an epidemic requires a sensitive surveillance system. It has become customary to institute epidemic control measures when a threshold incidence rate of 15 cases per 100,000 population per week has been exceeded for 2 consecutive weeks. In small populations, or where the population has not been accurately determined, a weekly doubling of the number of cases over a 3-week period can signal the early stages of an epidemic. WHO has established both alert and response thresholds that should be reviewed and adhered to when emergencies occur in meningitis-prone areas.

Vulnerability to meningococcal meningitis has decreased markedly since the development and widespread distribution of an effective, affordable vaccine. In December 2010, a new inexpensive and effective meningococcal A conjugate vaccine (MenAfriVac) was introduced, first in Burkina Faso and selected regions of Mali and Niger. By 2016, all 26 countries in the African meningitis belt had introduced this vaccine. High coverage of the target age group of 1–29 years is expected to eliminate meningococcal A epidemics from this region of Africa.

In non-immune populations, mass vaccination campaigns are the intervention of choice in areas in which an epidemic is occurring. Vaccination campaigns usually target the entire population age 1 year and older, although resource constraints may require limiting the age group to be vaccinated. Neither mass chemoprophylaxis nor prophylaxis of household contacts has proved to be an effective intervention during outbreaks, and neither should be instituted.

When epidemics occur in Africa, ceftriaxone is the drug of choice for its treatment. Penicillin, ampicillin, and chloramphenicol are also effective.

Hepatitis E

Like meningitis, outbreaks of hepatitis E have not been frequent occurrences in emergencies but have had major consequences when they arose. An enterically transmitted disease, usually linked to contaminated drinking water, especially when water quantity is compromised, hepatitis E is associated with a particularly high CFR in pregnant women. Clinical attack rates appear to be higher in adults, with children being relatively spared.

A severe epidemic occurred in 2004 among both IDPs in Darfur, Sudan, and refugees from Darfur in Chad. Starting in West Darfur in May of that year, a total of 2,431 cases and 41 deaths (CFR 1.7%) of suspected hepatitis E were reported from health clinics in the Greater Darfur region. A survey conducted in November 2004 found a CFR of 8.2% among pregnant women with hepatitis (Boccia, Klovstad, & Guthmann, 2004). Between June and September 2004, a total of 1,442 cases of suspected hepatitis E and 46 deaths (CFR 3.2%) were reported from two refugee camps and neighboring villages in Chad. Investigation of the epidemic was aided by the use of a newly licensed rapid diagnostic kit.

The most recent outbreak of hepatitis E in Africa occurred in the Lake Chad Basin region, including hundreds of cases in Chad and Niger. The security of this area has been considered unstable for many years due to the presence of Boko Haram forces (jihadists based in northeast Nigeria).

There is no treatment for hepatitis E. Thus, the response to an outbreak is prevention through ensuring access to adequate quantities of clean drinking water and hygiene promotion in communities.

Tuberculosis

Tuberculosis (TB) is one of the most important communicable diseases to control in the post-emergency phase. Its re-emergence as a public health problem in many parts of the world has been characterized by its close association with immune deficiency disorders, especially HIV infection, and with the identification of multiple drug-resistant strains.

Prior to the large movements of refugees in the Middle East, more than 85% of refugees originated from, or remained within, countries with high burdens of TB, such as Pakistan, DRC, Ethiopia, Myanmar, Kenya, Afghanistan, and South Sudan (WHO & UNHCR, 2007). In populations displaced by conflict in the Middle East, TB has been a lesser problem. For example, TB screening of 69,000 Syrian refugees in Jordan from January to June 2014 found only three smear-positive cases and a total of 33 culture-confirmed cases (Cookson et al., 2015).

Tuberculosis control should be instituted only after mortality rates have fallen below 1 per 10,000 per day or when an emergency situation has stabilized and it is apparent that the displaced population will remain in its current location for at least 6 months. However, for individuals being treated for tuberculosis at the time of onset of the emergency, arrangements should be made to allow them to continue their treatment in an uninterrupted manner.

From a public health standpoint, the objectives of TB control are to treat patients so that they cannot infect others, and to restore health to infected individuals. For this reason, only sputum smear–positive individuals are usually included in TB control programs initially, although individuals who are severely ill with noninfectious, extrapulmonary forms of TB should also be treated if they are identified. WHO guidelines for treatment stress directly observed therapy with a short course (6 to 8 months) of a combination of antituberculosis drugs (WHO & UNHCR, 2007). Because both infection with HIV and malnutrition are associated with TB, the presence of these conditions should be determined and dealt with appropriately.

Programs geared toward treating and preventing TB are complicated, and the decision to implement one should not be made unless there are clear written guidelines that will be followed. Laboratory facilities must be available and the regular provision of supplies ensured. Drugs must be stocked and their resupply guaranteed. Finally, a system for tracing those persons who are unable to adhere to treatment regimens must be in place so that they can be identified and assistance provided to ensure treatment completion. Ultimately, successful implementation of a TB control program requires a high level of community awareness, education, and involvement. Every element of such a control program needs to be carefully and meticulously developed and nurtured over time. Agencies that intend to implement TB control programs in post-emergency settings should have a clear commitment to continue for at least 12 to 15 months, have an adequate budget, and have the personnel and material resources necessary to run a successful program.

Other Communicable Diseases

Other communicable diseases that have occurred in emergency or post-emergency settings have had a relatively minor impact on refugees. In the individual setting in which they occur, however, they command an important allocation of resources and may be important contributors to morbidity and mortality. Yellow fever, typhoid fever, relapsing fever, Japanese B encephalitis, dengue hemorrhagic fever, typhus, and leptospirosis are all real threats. Outbreaks of cutaneous leishmaniasis have occurred in war-torn Syria. The last reservoirs of wild poliovirus are found in conflict-affected populations in Afghanistan, Pakistan, and Nigeria. Nevertheless, morbidity and mortality in CEs has been shown time and again to be due to the same conditions that are responsible for the bulk of the disease burden in LMICs in nonemergency settings.

Noncommunicable Diseases

As noted earlier in this chapter, NCDs such as diabetes and hypertension have been the main cause of morbidity and mortality among Syrian, and many Iraqi, refugees and IDPs. Research and evidence are lacking on how to best address care for NCDs in emergencies. To make interventions more effective and sustainable, further NCD-oriented research is needed (Perone et al., 2017). Given the lack of sophisticated medical resources in most emergency settings, it is suggested that NCDs be addressed through a primary healthcare setting combining health education messages with clinical monitoring of patients.

Another important element of a humanitarian response is to address mental health issues. A growing body of evidence has been used to inform effective mental health programs in emergencies, and interagency guidelines have been developed (Inter-Agency Standing Committee, 2007).

Role of International, National, and Nongovernmental Organizations

The vast and complex array of organizations involved in the various stages of humanitarian emergency preparedness and response reflect the complexity of the international community itself. It is difficult to imagine any other situation that attracts such a range of players: heads of state; diplomats; celebrities; bilateral foreign assistance agencies; UN political, social, economic, and technical organizations; military forces; and a broad variety of nongovernmental organizations, including an increasing number of commercial interests.

The UN Security Council plays a critical role in determining how and when the world will respond to the conflicts that lead to CEs and how emergency humanitarian assistance programs will be protected from the forces that fuel the conflicts themselves.

Security Council decisions are, in turn, determined by the leaders of its member states—in particular, the permanent members (the United States, Russia, France, the United Kingdom, and China). The UN Office for the Coordination of Humanitarian Affairs (OCHA) coordinates emergency preparedness and response within the UN system and is steered by an Inter-Agency Standing Committee of relevant UN agencies, including UNHCR, WHO, UNICEF, the World Food Programme (WFP), and UNFPA, as well as NGOs. OCHA launches joint appeals for funds to support coordinated UN agency response programs; however, these may sometimes compete with appeals launched by individual agencies.

The UN Refugee Agency, UNHCR, is responsible for the protection and care of all refugees who cross international borders. In some emergency situations, such as the crises in the former Yugoslavia, the UN secretary-general has designated UNHCR as the lead relief agency; UNHCR has referred to those who do not qualify for assistance as refugees as "persons of interest." Nowadays, UNHCR is the primary agency responsible for the care of most IDP populations.

In general, UNHCR and other lead relief agencies need to be invited to provide assistance by the government of the affected country. In situations of internal conflict, the Security Council may authorize involvement by a UN agency without the approval of the host government, as was the case concerning the displaced Kurdish population in northern Iraq in 1991. The lead UN agency is mandated to coordinate the activities of other relief agencies, including NGOs, in cooperation with the host government where that type of collaboration is appropriate. However, in certain chaotic emergency settings, individual NGOs have sometimes negotiated involvement directly with government authorities and ignored efforts by the lead agency to coordinate activities.

United Nations Reforms

Between 2005 and 2010, the United Nations instituted a set of humanitarian reforms. The three major points of the reforms, which are intended to improve the coordination of humanitarian relief efforts and to streamline the chaotic funding streams, are discussed here.

First, the reforms call for the appointment of a humanitarian coordinator in every situation from which an appeal for emergency funds will emanate. Every UN agency, and NGOs that wish to participate, can submit an estimate of its financial needs to the humanitarian coordinator, who aggregates these requests into a single consolidated appeal. Ideally, this should reduce the level of competition between the individual UN agencies, and between the UN agencies and the NGO community, and provide donors with a clear and agreed upon approximation of financial needs for the relief effort.

Second, the United Nations established the United Nations Central Emergency Response Fund (CERF). CERF was created by the United Nations General Assembly in 2005. CERF is, essentially, a bank account into which donors deposit funds that the Emergency Relief Coordinator (ERC) of the UN, who is also an Under-Secretary-General of the United Nations and the director of OCHA, can draw upon to provide funds to UN agencies in a timely and efficient manner when humanitarian relief needs arise. Since its inception, CERF has provided, on average, more than $400 million per year for humanitarian relief in all kinds of emergencies—natural disasters and conflict, acute and protracted. In addition, CERF funds can be used, at the discretion of the ERC, to address "chronically underfunded" or "silent" emergencies, such as those that have plagued central Africa for most of the past decade.

Third, a system of technical "clusters" has been developed to bring a systematic approach to a previously cluttered humanitarian scene. For a range of technical areas, a UN agency has been assigned to function as the "lead agency" to bring together donors, NGOs, other UN agencies, and other interveners to develop and review policy, to formulate plans for coordinated responses, and to review and evaluate past performance. The current global clusters include, but are not restricted to, health (WHO lead), logistics (WFP), shelter (UNHCR), water and sanitation (UNICEF), nutrition (UNICEF), and food security (WFP). In the field, each cluster is co-chaired by an NGO that, together with the appropriate UN agency, works in cooperation with and under the guidance of the host country's government. The performance of the clusters has been variable to date, and external evaluation will, it is hoped, bring about improvements to what is a promising system, but one that is difficult to implement.

Host Country Role

In many emergencies, especially those involving large refugee populations, the host government has granted temporary asylum to the refugees and has become actively engaged in the relief effort. Many countries have coordinating bodies, such as relief commissions, that take a lead role in mobilizing, organizing,

and delivering relief services. For example, in Somalia in the early 1980s, the Ministry of Health formed the Refugee Health Unit (RHU), which coordinated public health and nutrition assistance to the 800,000 Ethiopian refugees scattered in 35 camps throughout the country. NGOs wishing to provide assistance to refugees had to agree to follow the technical guidelines developed by the RHU and sign a tripartite agreement with the RHU and UNHCR. During the tsunami relief effort of 2004–2005, the picture was more mixed. In India and Thailand, most of the relief effort was run entirely by national authorities. In contrast, in Indonesia and Sri Lanka, a combination of national and international organizations collaborated on policy development and on the day-to-day implementation of relief services.

The International Committee of the Red Cross (ICRC), based in Geneva, Switzerland, is mandated to carry out the protection and care of civilian populations during armed conflict, as outlined in the Geneva Conventions. The ICRC relies on low-key and confidential negotiations with all parties to a conflict to allow it to provide humanitarian assistance. The ICRC is committed to carrying out its mission with independence, impartiality, and neutrality. Although it was once the only organization to operate within areas affected by conflict, in recent years many other NGOs have joined the ICRC in taking on this challenge. Some of these NGOs, while providing relief impartially to all those in need, believe that they should also speak out in the face of gross human rights abuses and have become advocates for more effective international responses. This action may sometimes jeopardize their ability to remain in the affected area, so it is not taken lightly. One of the most hotly debated issues within NGOs is whether to provide humanitarian relief and remain silent about human rights abuses and the diversion of relief resources or to speak out and risk having to leave the area.

Many NGOs are engaged in providing humanitarian assistance in emergencies; they include national Red Cross and Red Crescent societies, international secular and religious agencies, and local churches and community-based organizations in the affected country. Specialized public health agencies such as the U.S. Centers for Disease Control and Prevention, a government agency, and the Paris-based Epicentre, the epidemiology arm of Médecins sans Frontières, provide technical advice to a range of bilateral, UN, and nongovernmental operational agencies. The level of technical skills, experience, management, and logistics capacity within NGOs varies enormously. In an effort to promote coordination and the implementation of best practices among NGOs, a number of initiatives have been introduced, including the Code of Conduct for the International Red Cross and Red Crescent Movement and NGOs in Disaster Response and the Humanitarian Charter and Minimum Standards in Disaster Response (Sphere Project, 2011). In addition to relief NGOs, an increasing number of human rights advocacy NGOs have been active in recent years, including Amnesty International, Human Rights Watch, and Physicians for Human Rights.

Funding for international humanitarian assistance programs generally comes from the governments of high-income countries, such as the United States, Japan, members of the European Union, and other OECD states. The generosity of such governments varies enormously. Although the principle of "humanity"—the provision of assistance to those in need—should govern their commitments, in reality the size and sustainability of foreign aid often depends more on the perceived geopolitical importance of the conflict than on the actual needs of the affected populations. High-profile media, such as CNN, *The New York Times*, Al Jazeera, and the BBC, often play an influential role in determining the size of the response to an emergency. For example, the blanket media coverage of emergencies in the Middle East ensures that relief programs targeting this region are relatively well funded. By comparison, the conflict in Central African Republic has largely been ignored. What is certain is that until there is a consistent response to conflict-related emergencies around the world, the quality and timeliness of humanitarian responses will be unpredictable.

Rehabilitation, Repatriation, and Recovery

In countries emerging from conflict, the costs of reconstruction may be staggering. In the immediate aftermath of the first Gulf War, it was estimated that Iraq would require $110 billion to $200 billion and Kuwait $60 billion to $95 billion to repair the war damage from the actions of the United States–led coalition (Lee & Haines, 1991). Initial estimates for the reconstruction of Afghanistan were on the order of $1 billion to 2 billion per year for at least a decade. As these conflicts have dragged on toward the end of the second decade of this century, those projections have fallen by the wayside, and there is no end in sight.

A particularly important issue for those engaged in dealing with the aftermath of conflicts is to determine the extent to which the prior health system will be simply reestablished along the lines of its previous existence, or whether it will be reformed in an effort to improve its efficiency, effectiveness, and equity. The usual response is to seek to reconstruct what has been destroyed in the conflict, although the mantra for the reconstruction

of Haiti and subsequent natural disasters has been to "build it back better." This apparently logical response may be deeply flawed, however. One key impediment is that the resource base available for reconstructing and operating the health system may be vastly inferior to what it was previously. In Uganda, the post-conflict resource base was less than 10% of that available prior to the civil war, making simple reestablishment of prior services totally unfeasible. Furthermore, much changes during the period of ongoing conflict: the range of providers operating, the role of the state, the attitudes and demands of the community that uses services, and the approach of the international community and key donor organizations. Members of the last group, for example, may seek to promote a radically different state—one that functions as a steward of the health system, running the civil service, setting policies, establishing evaluation frameworks, and so on, but not providing services, and that adopts cost-effectiveness and value for money as its core concerns. This has been the case in Afghanistan since 2003: All health services, except those in Kabul, have been contracted out to NGOs that promise to provide a standard basic package of health services. During the post-conflict phase, international financial institutions and donor governments may greatly influence policy direction, and frequently do so in favor of reducing state expenditures and enhancing the role of the private sector.

In the period between the onset of conflict and its resolution, which may last decades, approaches to the nature of health services and who purchases and provides them may change dramatically. In many conflicts, other providers enter the scene to fill the gap left by retreating and undermined state-provided health services—these include for-profit and not-for-profit providers, as well as the indigenous and traditional sector. There has been little documentation of how and why the private sector emerges to play an important role in these settings. Nor is there any clarity about how best to control and regulate such activities in the interests of ensuring that minimum standards are adhered to and that the medical treatment offered by different providers does not compromise public health goals and objectives. The emergence and changing role of the nonprofit, nongovernmental sector is easier to appreciate: It fills gaps resulting from withering state services and is often supported by donor country funds that ensure that humanitarian relief services are provided in acute emergencies and that development-oriented services are offered where suitable funding and partner organizations, including the government, can be identified.

A major weakness of NGO-provided services is that they are often poorly coordinated, act in parallel with the state systems, have a different vision of the system they are seeking to bolster or reestablish, and compete for partners, resources, and publicity. During CEs, failure to support the indigenous capacity may increase the risk of little being left behind when humanitarian agencies withdraw from the area; increasingly, there is debate regarding how best such services could interface with host government services and policy and could reinforce the limited capacity often present. A particularly important and difficult challenge is to establish the policy framework within which health services and the health system will operate.

Key issues to be debated in the aftermath of periods of conflict include the financing of health services, the extent to which those services can and should be decentralized, the role of the private sector, and the priority to be accorded to issues of equity. These concerns need to be addressed within the broader context of promoting and consolidating the peace, reestablishing the economy, facilitating the demobilization of troops and their absorption into the economy, and facilitating the return of refugees and internally displaced people. Ensuring that, to as great an extent as possible, existing inequities in distribution and access to health services are resolved in the aftermath of conflict may assist in lowering tensions between groups. Promoting the development of a more equitable health and social system may provide an important opportunity for bringing together different groups within affected populations, and may provide early opportunities to stimulate debate, exchange of ideas, and the rekindling of trust.

Gender inequalities permeate many societies; in the post-conflict environment, it may be possible to address these inequities given that the conflict itself may have changed gender relations and modified the traditional roles of men and women. Conflict often leads to women taking on a more important role in relation to making household decisions and controlling household resources, given that even in patriarchal societies, men will often be absent during periods of conflict and women will absorb a multitude of usually male-dominated roles.

An initiative to focus on the health system challenges facing countries emerging from conflict has identified a number of key priorities for intervention in this setting (Zwi, Ugalde, & Richards, 1999):

- Maximizing the contribution of both government and donors to the formulation and development of health policy
- Developing a clear conceptual framework, informed by multidisciplinary approaches, to guide health system development

- Establishing inclusive processes that involve a range of stakeholders in a participatory and transparent process of identifying needs and priorities and agreeing on models and approaches to health system development
- Appreciating the limitations and constraints operating upon the range of stakeholders (government at central and local levels, UN agencies, NGOs, traditional public- and private-sector providers) involved in financing, providing, and overseeing health services
- Promoting evidence-based policy and planning to ensure that more good than harm results from interventions and that resources are used as equitably and efficiently as possible

The Role of the Military and Other Humanitarian Actors

Traditionally the domain of international agencies and not-for-profit nongovernmental humanitarian organizations, CEs have evolved into major geopolitical theaters in which many diverse and disparate actors have sought to carve out new roles for themselves. Because an increasing number of CEs have been precipitated by armed conflict within and between nations, third-party military forces, especially those of Western nations, have been prominently involved in recent relief operations. In addition, during the 21st century, interstate warfare has become less common and the rise of nonstate militias bent on using nonconventional warfare methods has introduced new complications to the provision of humanitarian services to beleaguered populations.

Following the Gulf War of 1991, an extensive international humanitarian effort for the Kurdish population of northern Iraq was coordinated by the U.S. military, which operated under the auspices, but not the command, of the United Nations. For almost the first time, NGOs were to a large degree dependent on Western military forces (including those from Germany, the United Kingdom, France, and the Netherlands, in addition to the United States) for security, transportation, and logistics. The establishment of a secure operational area and the delegation of the delivery of relief services to the humanitarian community were important elements in bringing about a rapid response to the plight of the internally displaced Kurds. However, many NGOs, including the ICRC, were uncomfortable working so closely with the military and were forced to confront and reassess their notions of political neutrality. In addition, although their presence was positive in a number of ways, the military authorities proved to be novices when it came to humanitarian relief. They were ignorant of its basic principles, unfamiliar with appropriate relief services, and unable to promptly deliver essential supplies, such as measles vaccine, to meet the public health needs of a civilian population where maternal and child health problems were the main priority.

The military intervention in Somalia by the allied armed forces, including the U.S. military, in 1992 was launched for humanitarian reasons, with the assent of the UN Security Council. In a chaotic situation characterized by general lawlessness, severe factional combat, and the total collapse of governance, compounded by crop failure and ensuing famine, the only way to secure the delivery of essential relief was with the protection of armed forces. From a military standpoint, the intervention was perceived as a fiasco. However, many humanitarian organizations believed that the military operation contributed to decreasing the high mortality rate, at least initially. Prior to this episode, military forces had steadfastly maintained that their role should be limited to providing security for humanitarian supplies; following the Somali experience, they began to review in earnest the broader role of the military in humanitarian relief.

Following the invasion of Iraq by the United States in 2003 and the overthrow of the Saddam Hussein regime, private contractors hired by the U.S. Department of Defense assumed much of the relief and reconstruction burden. For the first time, NGOs were for the most part sidelined. This event has been the subject of intense debate in the humanitarian community, and it is not clear whether this episode is an exceptional one or whether the entire nature of humanitarian relief is in the process of tumultuous change.

Important lessons for current and future peace and stability operations can be found in the experiences of Provincial Reconstruction Teams (PRTs) in Afghanistan. PRTs are small, joint civilian–military organizations whose mission is to promote governance, security, and reconstruction throughout the country. They are managed by the United States and other members of the International Security Assistance Force (e.g., the United Kingdom, Italy, Germany, France, Australia, the Netherlands). The U.S. PRTs have stressed governance, force protection, and quick impact development projects to "win hearts and minds." Their contribution to long-term health development is dubious.

In 2017, the World Health Organization, in an attempt to provide better access for health services providers, especially emergency trauma teams, to civilian populations trapped in fighting that was taking place in Mosul, Iraq, embedded health professionals from both for-profit and nonprofit organizations

with Iraqi security forces. This allowed for the early evacuation of wounded civilians to trauma services, but also rendered relief personnel indistinguishable from one of the fighting parties. Again, this represents a clear lack of respect for the existing humanitarian principles of neutrality, impartiality, and independence, even while it may have resulted in reducing the loss of life. The ICRC and Médecins sans Frontières have argued against this clear collaboration between a UN agency and bilateral armed forces, while others have suggested that the nature of war has changed to the point that the classical humanitarian principles, as enunciated in the Geneva Conventions and other documents from which international humanitarian law is derived, may be outdated and in need of revision.

In addition to the military and other participants listed earlier in this chapter, other important agencies in addressing humanitarian issues have emerged in recent years. Organizations that specialize in monitoring, detecting, and publicizing human rights abuses and prosecuting their perpetrators have become increasingly active during CEs. These include the Office of the UN High Commissioner for Human Rights; regional organizations such as the Office for Security and Cooperation in Europe; private organizations such as Amnesty International, Human Rights Watch, and Physicians for Human Rights; and national committees supporting the international war crimes tribunals. In some situations, spanning from the Rwanda genocide in 1994 through the ongoing fighting in Syria, where human rights abuses were extremely common, these organizations have tried to ensure that public health assistance programs addressed the sequelae of these abuses.

Finally, there has been increasing criticism of existing relief organizations because of their perceived inability to implement relief programs on the scale that is frequently necessary. Some have suggested that the rapid construction, maintenance, and management of large refugee camps, global logistical support, organization of healthcare services for delivery to large populations, and even the provision of security services might be done more effectively, rapidly, and efficiently by commercial companies contracted by governments or the United Nations. This challenge to the existing relief mechanisms, based as they are on the humanitarian motive, has yet to be resolved. In many ways it could lead to the transformation of humanitarian relief into a business enterprise—one that might inevitably become more closely linked to the donor agencies and used by them as agents of foreign policy. This has been the experience of bilateral development programs.

Professionalization

Partly to stave off this challenge, and partly to correct perceptions of incompetence and amateurism, efforts have been made to establish certain minimum standards of performance for relief workers (**EXHIBIT 12-4**). Due to the transient nature of NGO relief programs and the high personnel turnover both in the field and at headquarters, experiences are not easily institutionalized and lessons need to be learned repeatedly. Limited field experience, a poor understanding of the public health priorities of emergencies, and inadequate skills to carry out the most essential tasks, such as organizing large-scale vaccination and ORT programs, have been frequently observed problems. After what is widely regarded as an initially ineffective relief effort in Goma in 1994, major efforts were undertaken to improve the technical abilities of relief workers in the public health sector.

A number of short-term training courses have been developed and implemented by schools of public health, government disaster relief agencies, and the

EXHIBIT 12-4 The Sphere Project

Perhaps the largest single effort to establish minimum standards of care in emergency settings has been the Sphere Project (www.sphereproject.org). Launched in 1997 by a group of private humanitarian agencies, Sphere recognized that humanitarian relief would be increasingly required for many years and that the existing capacity to respond with high-quality interventions was, for the most part, lacking. To address this situation, a large consortium, including more than 228 private humanitarian organizations from around the world, participated in the development of the Sphere Humanitarian Charter and Minimum Standards in Disaster Response. First published in 1999, and undergoing a third revision in 2018, these standards are intended to govern the overall conduct of relief NGOs and to provide benchmark levels of performance in the areas of water supply and sanitation, food security, nutrition, food aid, shelter and site management, and health services, including mental health and sexual and reproductive health. The Sphere Project does not intend to establish new standards, but rather seeks to consolidate and reach agreement based on existing information. Standards will continue to be developed and existing standards will be modified in accordance with new findings, both from research and from experience gained in the field.

NGOs themselves. Master of public health programs in humanitarian assistance and public health in CEs have been established in schools of public health in the United States and Europe. Although emergency public health workers are not yet required to have accredited qualifications, the quality of health care may improve as more of these training courses become available and as more people complete them.

Research

The acquisition of new knowledge relevant to public health practice in displaced populations has been scant. Although most emergency public health programs rely on the safe and effective interventions that already exist (e.g., vaccines, ORS, water purification, essential drugs, and the like), the implementation of these interventions in emergency settings may be affected by the size of the populations and the urgency of the circumstances. Little is known about the impact of rapid, forced migration on human behavior, disease transmission, and the delivery of effective services in emergency settings. For many years, it had been considered unethical to conduct research of any kind among emergency-affected populations, who could be characterized as the most vulnerable members of the world's population. More recently, however, it has been acknowledged that without applied research studies designed specifically to address operational issues in the context of emergencies, it will be difficult to reduce morbidity and mortality levels from their current, excessively high levels.

Existing standards are largely based on field experience; few are based on rigorously designed and evaluated observational field trials. Although policies in some areas, such as measles vaccination and aspects of food and nutrition, are based on field research, this is not the case in other important public health areas, such as reproductive health and the control of sexually transmitted infections. Similarly, little reliable information is available on which to base policies and programs to promote psychosocial health, despite its rapid emergence as a consistent major public health problem. Of course, research is truly useful only where there is genuine concern for improved performance.

Unfortunately, much of what is learned in humanitarian response is rapidly lost from the short-lived knowledge base. Of the many people who have worked in the field, few forge careers in humanitarian assistance. Data that are collected and reported by field workers are often either discarded or filed in internal agency reports and never seen again. There is no professional society for humanitarian public health workers, and few peer-reviewed journals in which the results of high-quality studies can be published. Although the number of people affected by CEs continues to grow, a solid body of research on which to base policy and practice is still sadly lacking. Without such a database, relief policies will remain relatively uninformed, and mistakes will continue to be made. The relatively new Research for Health in Humanitarian Crises (R2HC) initiative, funded by the U.K. Department for International Development, the U.K. Department of Health and Social Care, and the Wellcome Trust, is a potentially important contributor to the generation of new knowledge regarding what works in humanitarian relief (http://www.elrha.org/r2hc/home/).

Conclusion

Significant progress has been made during the past two decades toward the provision of effective, focused, needs-based humanitarian assistance to conflict-affected populations. Greater emphasis is now placed on the impact, including health outcomes, of international aid. The quantity of aid delivered is no longer considered a valid indicator of effectiveness; instead, its relevance, quality, coverage, and equitable distribution are accepted as more pertinent factors. As public health in emergency settings has developed as a specialized technical field, a number of relief agencies, especially NGOs, have developed technical manuals, field guidelines, and targeted training courses geared toward improving performance in this area. Ability to meet the standard performance indicators developed recently by the Sphere Project and adherence to the international NGO code of ethics are arguably valid criteria by which to assess the quality of specific agencies.

Although a considerable body of knowledge has accumulated specifically relating to the health needs of emergency-affected populations, many areas require further development. Donor agencies should acknowledge the need to support applied health research in emergency settings if more effective interventions are to be developed against both old problems, such as cholera, and emerging issues, such as noncommunicable diseases, TB, mental health, and reproductive health.

In planning for responses to future humanitarian emergencies, there is a need to recognize that improving the technical and management capacity of operational agencies will not be sufficient. Recent experience has dramatically demonstrated that populations in

need will not benefit unless the international community ensures that there are mechanisms to permit secure access by those agencies. The means by which this access is provided is critical and most likely to be the central focus of international policy dialogue. The varied nature of the responses to emergencies in Iraq, Somalia, Bosnia, Rwanda, Kosovo, Sierra Leone, East Timor, Darfur, Syria, Central African Republic, Yemen, and many others demonstrates the lack of consistency and predictability of CE-related humanitarian relief.

Finally, there remains the issue of primary prevention. The perceived differences between communities are generally tolerated in prosperous societies; conflict and all its consequences tend to arise in times of economic distress and political instability. Although programs in good governance proliferate, the reality is that governments everywhere today are perceived to have failed to provide for the basic needs of their peoples. Unless these root causes of conflict are seriously addressed, all that will be accomplished is the perpetuation of a perennial relief industry that inevitably will experience only patchy success.

Discussion Questions

1. What are the major objectives in the initial management of a refugee emergency?
2. What does the word *complex* as used in the term *complex emergency* imply?
3. What is the best indicator of the general health of a refugee population during an emergency?
4. Why are female-headed households in refugee camps at special risk of food scarcity?
5. What are the minimum standards in emergency relief operations for the provision of water and latrines?
6. What roles do general rations, supplementary feeding programs, and therapeutic feeding programs play in maintaining population nutrition?
7. At what age should children in emergency-affected populations be vaccinated against measles?
8. What are the immediate measures that can be taken in an emergency-affected population to prevent HIV/AIDS?
9. How adequate are the existing international legal statutes in protecting internally displaced persons?
10. What roles may community health workers play in an emergency public health program?
11. What are the immediate interventions that should be in place to address the reproductive health needs of both women and men?
12. Which population-based interventions have been developed to address the mental health needs of emergency-affected populations?
13. If there is conflict between adhering to humanitarian principles and saving lives, what are possible options to resolve the dilemma?

CHAPTER 13

The Design of Health Systems

Anne J. Mills, Melisa Martinez-Álvarez, and M. Kent Ranson

Health systems are the means whereby many of the programs and interventions discussed in other chapters in this text are planned and delivered. They are a crucial influence on the extent to which countries are able to address their disease burden and improve overall levels of health and the health of particular groups in the population.

A health system comprises all organizations, institutions, and resources that produce actions whose primary purpose is to improve health (World Health Organization [WHO], 2000). The healthcare system consists of those organizations, institutions, and resources that deliver health care to individuals. Health systems are examples of "complex" systems, wherein the overall system contains numerous subsystems, each with its own characteristics, meaning that the outcome of various interacting subsystems is unpredictable (Adam & De Savigny, 2012).

Health systems vary greatly from country to country. Unlike in the study of disease, there is only limited standardized terminology or methodology for studying and understanding health systems. Each country's health system is the product of a complex range of factors, especially its historical patterns of development and the power of different interest groups (Balabanova et al., 2013). Nonetheless, it is possible to identify common features, and knowledge is increasing regarding which design features are associated with which outcomes, thereby facilitating cross-country learning.

It is extremely important to study and understand how health systems function and how they can be changed, given their importance in global and national economies. Health tends to consume a growing share of a country's gross domestic product (GDP) as income increases. On a worldwide basis, total expenditures on health care grew from 3% of world GDP in 1948 to 8.7% in 2006 (WHO, 2009). More recent trends for the period 2010 to 2015 show the same indicator increasing for high-income countries from 6.5% to 7.83%, and for low- and middle-income countries (LMICs) from 5.4% to 6.4% (WHO, 2017). Nevertheless, countries at similar income levels differ greatly in how effectively they look after the health of their populations. The health-related differences between countries of similar income can be enormous. For example, Bangladesh, with a 2016 GDP per capita of $1,030, has an under-5 mortality rate of 34 deaths per 1,000 live births, whereas Cote d'Ivoire has a 2016 GDP per capita of $1,553 and under-5 mortality rate of 92 deaths per 1,000 live births (World Bank Data, 2018a, 2018b). By comparison, in two somewhat richer countries, Thailand, with a GDP per capita of $5,902, has an under-5 mortality rate of 12 deaths, whereas South Africa, with only a slightly lower GDP per capita of $7,489, has a mortality rate of 43 deaths. It is challenging to disentangle the contributions of the health system to health outcomes relative to other determinants such as income, education, and diet (see the *Understanding and Acting on Social Determinants of Health and Health Equity* chapter), but it is clear that the health system is an important determinant of health.

The global attention given to achieving the health-related Millennium Development Goals (MDGs) by

2015 focused attention on the state of the health systems of many LMICs. Disease- and program-specific initiatives such as the GAVI Alliance (supporting immunization) and the Global Fund to Fight AIDs, TB and Malaria realized that the achievement and maintenance of their disease-focused goals was not possible in countries with weak and fragile health systems. Research pointed to the multiple problems affecting the health systems of low-income countries and many middle-income countries, and analyzed the multiple constraints they face in scaling up needed interventions to high levels of coverage (Mills & Hanson, 2003). There has recently been increasing recognition of the need for health systems resilience, so that such countries can prepare for and respond to crises effectively (Gilson et al., 2017; Kruk, Myers, Varpilah, & Dahn, 2015).

In the current age of the Sustainable Development Goals (SDGs), health systems remain a key theme, but are now strongly linked to the target of universal health coverage (UHC). Based on a review of evidence, McIntyre, Meheus, and Rottingen (2017) estimated that countries progressing toward UHC should aim at a target of government spending on health that amounts to at least 5% of GDP, and a per capita target of $86, to promote universal access to primary care in low-income countries.

Understanding health systems and how they can be changed is an endeavor that can benefit from the insights of a number of disciplines—most notably, economics, sociology, anthropology, history, political science, and management science. In the recent past, and not least because concerns regarding resource scarcity, cost inflation, and efficiency have been uppermost in policy makers' minds, the discipline of economics has dominated the study of health systems. However, with the emergence of health policy and systems research as an important area of inquiry (Gilson & WHO, 2013), other disciplines have been making growing contributions to effort, especially political science (contributing to understanding of the political and policy process) and the behavioral sciences (insights into the behavior of people and organizations). The importance of embracing other perspectives on health systems is also apparent in the report of the health systems knowledge network of the Commission on Social Determinants of Health (Gilson, Doherty, Loewenson, & Francis, 2007). This chapter draws strongly on economics to review key features of the design of health systems, but brings in learnings from other disciplines where they add critical insights.

The section that follows provides an overview of the health system and its key elements, and presents criteria for evaluating health systems. A brief review of the historical development of health systems is followed by a section addressing the fundamental and controversial question of the role of the state. Subsequent sections then consider each of the key functions of health systems in turn and recent reform trends: regulation, financing, resource allocation, and provision. Current topical issues in health systems are then reviewed. Throughout, the discussion is illustrated by country examples, with a core set of illustrations drawn from Tanzania, Sierra Leone, India, Mexico, and Thailand being chosen to illuminate key differences in health systems across the world.

It should be noted that the *Public Health Infrastructure* chapter focuses on the public health branch of a health system, including both its structure and its capabilities. This chapter addresses generic issues concerning the financing and organization of the system as a whole, as well as the more specific issues relevant to what is often called the healthcare system, referring to that part of the health system concerned largely with personal health services, which consume the great majority of health system funding.

Understanding the Health System

Since the seminal study of Kohn and White (1976), an expanding body of literature has been attempting to systematize the discussion of the various elements of health systems, categorize health systems into a limited number of types, develop performance indicators, and look at health systems less as economic entities and more as social institutions. These four issues are discussed in turn in this section.

Elements of Health Systems

Roemer (1991) identified five major categories that facilitate a comprehensive description of a country's health system:

- Production of resources (trained staff, commodities such as drugs, facilities, and knowledge)
- Organization of programs (by government ministries, private providers, and voluntary agencies)
- Economic support mechanisms (sources of funds, such as tax, insurance, and user fees)
- Management methods (planning, administration, regulation, and legislation)
- Delivery of services (preventive and curative personal health services; primary, secondary, and tertiary services; public health services; and services for specific population groups, such as children, or for specific conditions, such as mental illness)

More recently, WHO (2007) has developed a system for describing and categorizing health systems based on six "building blocks":

- Service delivery
- Health workforce
- Information
- Medical products, vaccines and technologies
- Financing
- Leadership and governance (stewardship)

These types of categorization are helpful for describing health systems; indeed, Roemer (1991, 1993) applied his approach to a large number of countries. However, such categorizations are less helpful for understanding how well health systems perform. Making this determination requires much more detailed subcategories and greater elaboration of the relationships, not just within each category but particularly between categories (e.g., between economic support mechanisms and organization of programs).

Typologies of Health Systems

To make comparisons based on how different types of health systems perform, it is necessary to group countries and their health systems into distinct types. There have been various attempts to do this. Countries can be classified according to the following criteria:

- The dominant method of financing (e.g., tax, social insurance, private insurance, out-of-pocket payments)
- The underlying political philosophy (e.g., capitalist, socialist)
- The nature of state intervention (e.g., to cover the whole population or only the poor)
- The level of gross national product (GNP) (e.g., low, middle, high)
- Historical or cultural attributes (e.g., industrialized, nonindustrialized, transitional)

A key difficulty, however, is that countries do not fit neatly into these categories. In particular, the health systems of LMICs tend to be fragmented, with different arrangements for different population groups (McPake & Machray, 1997). As an illustration of these differences, **EXHIBIT 13-1** summarizes the structure of the health systems in five countries.

The Organization for Economic Cooperation and Development (OECD) has developed a typology that is helpful for categorizing not only the economic

EXHIBIT 13-1 Illustrations of the Structure of Health Systems

Sierra Leone (GNI per capita $490; low-income country)

The public sector plays a leading role in Sierra Leone's health system, along with a large informal sector as well as high-tech Western-style private hospitals, faith-based and nongovernmental providers, independent private biomedical providers, drug sellers, and traditional healers (F. Martineau, personal communication, July 31, 2017). The primary health sector is managed at the district level by district health management teams, with decentralized funding provided through district or city councils. This organization was implemented as part of a broader push toward decentralization following the civil war (which ended in 2002) and has had mixed results. In particular, although health funding is supposed to be ring-fenced, in practice it can be extremely difficult for district medical officers or hospital superintendents to access funds. Secondary care is managed by hospital superintendents, who report directly to the country's Ministry of Health. There are four tertiary facilities focusing on different specialties, all located in the capital. The most important recent health system reform was the national rollout of free health care for children younger than 5 years, pregnant women, and lactating women. People living with disabilities, as well as Ebola survivors, are also legally entitled to free government care. To complement the free health initiative, performance-based financing was introduced for those sectors that deal most commonly with children and with pregnant and lactating women, including extra salary for staff members and discretionary funds to improve facilities.

Tanzania (GNI per capita $900; low-income country)

The public sector plays a leading role in Tanzania's health system, owning approximately 64% of all health facilities and covering all levels of care from primary to tertiary (Mtei et al., 2007). Relative to neighboring countries, the public system is quite decentralized, with public services managed at the district level. Mission (church) services are an important source of care outside the main towns, providing the same number of hospitals as the government, and are subsidized by the state. Private doctors practice in the main cities, and there is a large informal sector of traditional practitioners and drug sellers. The majority of health expenditures flow through the government; most of the remainder consists of out-of-pocket expenditures. The two largest health insurance arrangements are the National Health Insurance Fund (NHIF),

(continues)

EXHIBIT 13-1 Illustrations of the Structure of Health Systems *(continued)*

a mandatory scheme offering comprehensive benefits to the formal sector, and the Community Health Fund (CHF), now managed by the NHIF, which is a voluntary scheme for the informal sector in rural areas, offering limited benefits in lower-level public facilities. In 2016, total coverage of insurance schemes (including a small private insurance sector) was 25.8% of the total population (Health Policy Project, 2016).

India (GNI per capita $1,680; lower-middle-income country)

India's public sector is large in absolute terms, providing all levels of care. Health care is in general a state-level function, with central government involved mainly in overall policy and specific disease-control programs. There is a large formal private sector, providing both ambulatory and inpatient care, and an even larger informal sector consisting of unlicensed and unqualified practitioners and drug sellers. There is a limited formal interaction between public and private sectors. A compulsory state insurance system covers lower-paid, formal-sector workers, while another scheme covers senior government officers. An additional health insurance scheme was launched by the government of India in 2008, targeted at the 300 million people who live below the poverty line. As of 2017, this scheme covered some 41 million informal-sector workers and their families (RSBY, 2017). In addition to these measures, many states have introduced financial protection schemes for specific types of tertiary care such as cardiac surgery, cancer therapy, and neurosurgery.

Thailand (GNI per capita $5,640; upper-middle-income country)

Both the public and private health sectors are quite large in Thailand, providing all levels of care. There is widespread use of private-sector resources, especially for outpatient care. Compulsory social insurance covers those employees with formal private employment and finances care provided by public and private health facilities (chosen by the insured). Civil servants have their own medical benefit scheme, which pays for care mostly at public hospitals. Since 2001, the remainder of the population—who formerly could get a low-income card exempting them from fees if they were poor, purchase a voluntary health insurance card, or pay out of pocket for care—has been covered by a universal coverage arrangement in which individuals register at a local facility and can then access a wide range of free healthcare benefits (Towse, Mills, & Tangcharoensathien, 2004).

Mexico (GNI per capita $9,040; upper-middle-income country)

Both the public and private sectors play an important role in financing and provision of healthcare services in Mexico. Formal-sector employees are covered by various social insurance institutions. The poor receive care through government facilities or private providers (allopathic and traditional). There is little interaction between the public and private sectors, in the form of either regulation or contracting for service delivery. Concern about duplication and waste of resources within the three subsystems (i.e., social security, other government, and private) and lack of protection against the burden of healthcare costs, especially for the poor, have led to reforms based on decentralization, managed market principles, and a voluntary insurance scheme called *Seguro Popular*. Between *Seguro Popular* and its social security institutions, Mexico is reaching universal health coverage (i.e. 100% of the population covered by health insurance) (Knaul et al., 2012), although some estimate that more than 20% of the Mexican population remains unaffiliated with an insurance plan (CONEVAL, 2012).

Note: GNI (gross national income), calculated using the World Bank Atlas method, is in 2016 prices.

dimensions of health systems in OECD countries, but also the directions in which reforms are taking them (OECD, 1992). The key categories are as follows:

- Whether the prime funding source consists of payments that are made voluntarily (as in private insurance or payment of user fees) or are compulsory (as in taxation or social insurance)
- Whether services are provided by direct ownership (termed the integrated pattern, in which a ministry of health or social insurance agency provides services itself), by contractual arrangements (in which a ministry of health or social insurance agency contracts with providers to deliver services), or simply by private providers (paid by direct out-of-pocket payments)
- How services are paid for (prospectively, where financial risk is transferred to providers, or retrospectively, where the cost of care is reimbursed)
- The basic insurance package (population covered, services included, and degree of cost sharing)
- The degree of reliance on centralized "command-and-control" systems to steer demand and supply of health services, versus market mechanisms, which rely on private provision financed on a fee-for-service basis, competition among private providers driven by user choice, and private insurance
- The existence of a gatekeeper and user choice

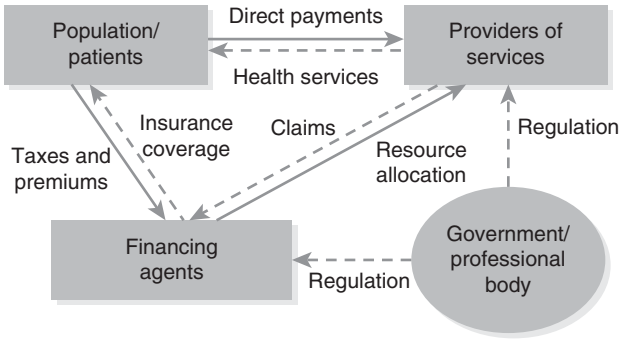

FIGURE 13-1 A map of the health system.

Modified from World Health Organization (WHO). (1993). *Evaluation of recent changes in the financing of health services*. Geneva, Switzerland: Author. Retrieved from http://apps.who.int/iris/bitstream/10665/41528/1/WHO_TRS_829.pdf. Copyright ©1993.

More recent OECD analysis has organized the various dimensions into six different types of health system (OECD, 2011). This categorization is most relevant to countries at a relatively advanced stage of development, where the coverage of the health system is universal or consists of a limited number of arrangements, as opposed to poorer countries, where the health system is fragmented.

Given the lack of an agreed typology for LMICs, the content of this chapter is based on a simple framework (shown in **FIGURE 13-1**) that identifies four key actors and four key functions required in any health system. The actors are as follows:

- The government and professional bodies that govern, structure, and regulate the system
- The population, including patients, who as individuals and households ultimately pay for the health system and receive services
- Financing agents, who collect funds and allocate them to providers or purchase services at national or lower levels
- The providers of health services, who themselves can be categorized in various ways, such as by level (primary, secondary, tertiary), service type (curative, preventive), ownership (public; private, for-profit; private, not-for-profit), degree of organization (formal, informal), or medical system (allopathic, ayurvedic)

The functions are as follows:

- Governance and regulation
- Financing (through taxes, premiums, and direct payments)
- Resource allocation
- Providing services

Evaluation of Health Systems

WHO (2000) has argued that the health system has three main objectives, which are intrinsically valuable:

- Good health (both its absolute level and its distribution across the population)
- Fairness in financial contribution
- Responsiveness to peoples' expectations (both level and distribution)

In assessing the actual performance of health systems, criteria of efficiency and equity are frequently applied, so it is important to understand their various meanings. Efficiency has a number of different dimensions:

- Macroeconomic efficiency refers to the total costs of the health system in relation to overall health status; countries differ in how efficiently their health systems convert resources used into health gains.
- Microeconomic efficiency refers to the scope for achieving greater efficiency from existing resources. It is of two types:
  - Allocative efficiency: Devoting resources to the mix of activities that will have the greatest impact on health (i.e., is most cost-effective).
  - Technical efficiency: Using only the minimum necessary resources to finance, purchase, and deliver a particular activity or set of activities (i.e., avoiding waste).

Equity refers to the fair distribution of the costs of health services and the benefits obtained from their use among different groups in the population. It is inherently a question of values, with views differing as to what constitutes fairness of financing or access to health care. However, indicators of who pays for health services and who receives benefits provide evidence that serves as the basis for judgments about the degree of equity achieved by particular health systems. Equity is commonly expressed in two different ways.

- *Horizontal equity* refers to the equal treatment of equals. With respect to financing and resource allocation, this type of equity implies that the charge levied by all agents or providers for a particular good or service should be the same for households with equal ability to pay (regardless of gender, marital status, and so on). Horizontal equity is therefore assessed by the extent to which contribution levels are similar between those with similar ability to pay. With respect to provision of services, horizontal equity means that individuals with the same health condition should have equal access to health services.
- *Vertical equity* is based on the principle that individuals who are unequal in society should be treated differently. Vertical equity in the financing and purchasing of health services means that consumers should be charged for the same good or service according to their ability to pay.

TABLE 13-1 demonstrates how equity and efficiency criteria can be used to guide the financing, allocation of resources, and provision of health services and to evaluate performance. In the literature, Mills et al. (2012) provide an example of financing and benefit incidence analysis to evaluate the equity of health systems in Ghana, South Africa, and Tanzania.

In WHO's (2000) Health Systems: Improving Performance study, a conceptual framework, based on the goals and functions listed earlier, was applied to country data to assess and understand country health system performance. Countries were ranked in relation to their attainment of the individual goals, in relation to overall goal attainment, and in terms of performance on level of health and the functioning of the overall health system. Although the conceptual framework and new databases have proved useful, the ranking was extremely controversial (e.g., see Almeida et al., 2001; Coyne & Hilsenrath, 2002) and has not been continued in subsequent World Health Reports.

Health Systems as Social Institutions

A number of health systems frameworks have been put forward since 1945 that build on the notion of health systems as social institutions, especially frameworks drawing on political theories. A review by van Olmen et al. (2012) found that the evolution of thinking about health systems over time is not a result of accumulation of knowledge, but rather a function of the policy context and dominant actors. In the 1950s, WHO and UNICEF were the dominant actors, and the scope of global health was increased from a medical focus to one of Health for All at the Alma Ata declaration. In the decades that followed, the World Bank

TABLE 13-1 Equity and Efficiency Criteria Applied to Financing, Resource Allocation, and Provision of Health Care

	Efficiency		Equity	
Functions	**Allocative**	**Technical**	**Horizontal**	**Vertical**
Financing		Maximize the proportion of resources raised that are actually available for purchasing health care (e.g., reduce the overhead costs of collecting taxes)	Equal payment by those with equal ability to pay (e.g., same insurance premium for same income group)	Payment in relation to ability to pay (e.g., progressive income tax rates)
Allocating resources	Purchase the mix of interventions that provides the greatest health gains	Maximize the proportion of resources spent by agents that are actually available for providing health care	Services purchased for similar groups (e.g., the elderly) should be the same in different geographic areas	Services purchased should reflect the different needs of different groups (e.g., the elderly versus children)
Providing services	Provide those interventions that return the greatest value for money (e.g., in a poor country, antenatal care should be provided before radiotherapy for cancer)	Make the best use of resources in providing interventions deemed worthwhile (e.g., have nurses as opposed to doctors provide most antenatal care)	Equal access for equal need (e.g., equal waiting time for treatment for patients with similar conditions)	Unequal treatment for unequal need (e.g., unequal treatment of those with trivial versus serious conditions)

Data from Donaldson, C., & Gerard, K. (1993). *Economics of health care financing: The visible hand.* London, UK: Macmillan Press.

became a more active player in health, and the scope of frameworks was narrowed to a special package of essential services that was deemed more realistic. Since 2000, health systems thinking has been shaped by a change in the number and type of global health actors (with the introduction of global health initiatives and private philanthropies), WHO's attention to performance of health systems, and the recognition of the complexity of health systems made up of dynamic relationships.

Gilson (2003) has called for health systems to be conceptualized beyond "delivery points for biomedical interventions"—that is, as complex geopolitical institutions, underlined by different sets of relationships, including relationships between patient and provider, between employer and employee, and between different providers. A key influence in these relationships is the concept of trust, whose formation and maintenance require adequate managerial and organizational practices and political processes, and a focus on equity and justice.

Building on the view of health systems as social institutions, a number of recent studies have conceptualized health systems as a demonstration of social solidarity. For instance, Kruk et al. (2010) view investment in health systems as a state-building activity in post-conflict settings; they suggest that such investment can promote social cohesion, restore accountability, strengthen the social contract, and strengthen government capacity. Social solidarity has also been argued to underpin European models of health system financing.

Backman et al. (2008) developed a set of indicators to assess the health systems of 194 countries from a human rights perspective. These indicators included recognition of the right to health, the availability of a national health plan, the degree of participation, discrimination, health information, access to health services, and distribution of human resources, among others. Building on this work, Gruskin et al. (2012) identified four priority areas for incorporating human rights in health systems frameworks: (1) including client interaction at all stages of health system design and implementation, (2) promoting equality and nondiscrimination, (3) systematically addressing laws and policies negatively affecting health and health service utilization, and (4) strengthening accountability.

A historical perspective on the development of health systems, provided in the next section, adds to the understanding of health systems as complex institutions that have developed over time in particular ways in response to local and external influences.

Historical Development of Health Systems

As indicated by archaeological evidence, medicine has had a role in all cultures and civilizations (e.g., in ancient Mesopotamia and Egypt). It has also been a concern of the state throughout the ages. For example, the law code of Hammurabi (1792–1750 BC) specified the fees for an operation to be paid to a healer on a sliding scale, depending on the status of the patient, and also specified penalties for failure. The Romans built hospitals for domestic slaves and soldiers in permanent forts in occupied territories such as England. Despite these efforts, the origins of the modern hospital lie primarily in the spread of Christianity and of ideas of Christian charity and caring for all who might be in need after the conversion of Constantine (died 337 AD) made Christianity an official imperial religion (Porter, 1996a). Hospitals were founded in the main cities of the Christian world, often associated with churches or monasteries. The Islamic world also developed hospitals, and by the 11th century there were large hospitals in every major Muslim town. Such hospitals were intended for sick individuals who lacked families or servants to care for them—for example, the poor, travelers, and those working away from home.

In Europe by the Middle Ages, a multiplicity of institutions and organizations had developed with pretensions to authority over medicine: the church, guilds, medical colleges, town councils, and powerful individuals. In Brussels, for example, a board of clergy, doctors, and midwives licensed midwives in the 15th century. The arrival of the plague—the Black Death—which in its first wave killed approximately 25% of Europe's population, stimulated growing state involvement in protection of health through measures such as imposing quarantines and isolating the sick.

From the early 19th century onward, the scientific basis of Western medicine was increasingly established, with scientific training becoming essential for the practice of medicine (Porter, 1996b). The 18th and 19th centuries saw a vast expansion of hospitals in Europe and the United States, supported both by philanthropy and by public funds, especially hospitals for persons with infectious diseases and the mentally ill (Porter, 1996a). The charitable and voluntary basis for the funding of hospitals in many countries faced a crisis, however, as medicine became more elaborate and expensive. The enormous increase in the number of surgical procedures performed and

the development of technology led to both much larger numbers of patients and much higher costs per patient. In the face of these trends, voluntary hospitals ran into financial difficulties. In the United States, hospitals developed business strategies based on insurance that could attract more affluent patients. In the United Kingdom, where insurance was much less well developed, hospitals were eventually brought into public ownership. In Scandinavia, local authorities had had responsibility for providing hospital services since the late 19th century, so these facilities developed largely as a public service.

The development of the discipline of public health in the 19th century was a response to the disease hazards of the urban environment. In England and Germany, public health measures focused on safe water supply and drains.

Over the 18th and 19th centuries, modern forms of medical regulation developed. Trends in countries in which medicine was dominated by free markets (such as the United States) converged with trends in countries in Europe with strong state control (such as Germany) to produce the closely regulated medical markets that exist today. However, the degree of state involvement in the provision of health services varied enormously between countries, as remains true today.

A key development was the increase in collective arrangements for funding health services. State services developed in all Western countries to provide health services for those persons who could not afford to purchase them themselves. In addition, mutual insurance schemes emerged in Europe and the United States as means to protect workers against financial losses, with these plans often including medical care. Such mutual insurance schemes were encouraged by the German states and ultimately developed into a national program of health insurance. In the United Kingdom, in contrast, they were nationalized as part of the expansion of state welfare. Other European countries also saw the development and expansion of compulsory financial arrangements for health services, whether through the extension of insurance arrangements for medical care (the Bismarck model, named after the German chancellor who introduced the first compulsory insurance scheme) or through general taxation (the Beveridge model, named after the British minister of health who is regarded as the founder of the U.K. National Health Service). Since World War II, all high-income countries—except the United States, where progress has been slower (Gaffney & McCormack, 2017)—have extended mechanisms for protection against the financial risks of ill health, to the point where they can be said to have achieved universal coverage.

Another key development in the creation of the modern health system was the development of organized systems of medical care, as opposed to fragmented and competing individual doctors and hospitals. World War I marked a turning point in Europe, when the need to organize medical care on a massive scale highlighted the advantages of a large, coordinated system. In the United Kingdom, the Dawson report in 1920 designed a system of district health services based on general practitioners and health centers, with referral upward to hospitals (WHO, 1999). The later development of the philosophy of national economic plans and of a strong government role in many sectors of the economy also supported the development of organized health systems. Even in those countries with less of a tradition of a strong state role in health services, cost escalation in recent decades has forced greater state involvement in this realm.

In the late 19th century Western medicine spread around the world, often as part of the process of colonial expansion (Zwi & Mills, 1995). Medicine acted in part as an agency of Western imperialism, with organized health services being a notable component of British, French, German, and Belgian colonization. These services were initially intended for the military, settler, and civil service communities, but it rapidly became apparent that protecting the health of expatriates required addressing health needs among the colonized peoples. In addition, health services were introduced by commercial interests if they believed that these services would improve their economic returns, and by the church as part of missionary activities. To a much greater extent than was the case in the home countries of the colonizers, the provision of health services in the colonies became associated with the state. This was accentuated in the postcolonial era by the prevalent ideologies of state-led growth and state responsibility for the welfare of all inhabitants. In the most extreme form of these ideologies, socialist countries such as Tanzania, China, and Vietnam banned private practice. More generally in Africa and Asia, the attention of policy makers focused on extending publicly financed and provided services to the whole population, while neglecting the often large private sector and the even larger traditional medicine sector.

Developments in Latin America were somewhat different. As in Africa, the earliest Western health services were developed by the colonists, especially for the armed forces and the police. Major employers provided health services, particularly where enterprises were remote from urban centers. Some religious

hospitals were built to care for the poor. These hospitals were later supplemented by government hospitals and clinics, especially in areas lacking charitable hospitals. A key difference between Latin America and most of Africa and Asia was the early development of compulsory insurance arrangements for workers in the formal sector. Because medical care infrastructure in this region was lacking, the insurance agencies often built and ran their own services, thereby contributing to the evolution of the parallel health systems still seen today in many Latin American countries.

The historical development of health services in many countries resulted in a health infrastructure that was biased toward hospitals. Attempts to reorient services culminated in 1978 in the Declaration of Alma Ata, which emphasized the importance of primary health care, involving the delivery of curative and preventive services at the community level. This perspective encouraged strong emphasis on the building up of integrated health services, involving community-based health workers. Nonetheless, a rival approach argued in favor of selective primary health care, to include those interventions that addressed the greatest disease burden and were most cost-effective (Walsh & Warren, 1979). Services for children were a key priority in this approach, and, together with the emphasis on family planning that resulted from the preoccupation of many donors with world population growth, meant that peripheral health services in many low-income countries were targeted primarily at women and children. Only recently has there been greater emphasis on achieving a more integrated approach to the delivery of health services at peripheral levels, and on addressing the health needs of adolescents and adults. The need to develop services to support human immunodeficiency virus (HIV) treatment, and then to deal with the growing incidence of noncommunicable diseases, has further highlighted the importance of continuity of care (Beaglehole et al., 2008).

A marked development in the 1980s and 1990s was greater questioning of the government's role in health systems. The most radical changes occurred in countries formerly under strict communist rule, where a market economy was introduced and market forces were allowed to influence health services (see Saltman & Figueras, 1997, for a discussion of such developments in eastern and central Europe). Social insurance arrangements were introduced for those in formal employment, health professionals permitted to have private practices, the development of private markets in pharmaceuticals was encouraged, and much greater costs fell directly on household budgets. In China, for example, approximately 71% of the population—including 48% of the rural population—had some insurance protection in 1981; by 1993, the overall insurance coverage in that country had dropped to 21%, with only 7% coverage of the rural population (WHO, 1999). Although changes were less dramatic in other parts of the world, governments were forced by economic crises in the 1980s and 1990s to consider how they could best prioritize what they do and ration services to those most in need; many introduced revenue generation schemes, such as user fees. This reconsideration was also forced by rapidly growing private markets in medical care.

Most recently, in the 21st century, there has been a marked increase in development assistance for health, in part associated with the movement surrounding the MDGs but also driven by the international response to the HIV pandemic and the entry of new sources of funding such as the Bill and Melinda Gates Foundation and new funding mechanisms such as the Global Fund for HIV, TB and Malaria. Funding streams became increasingly stratified by disease or health programs, in marked contrast to the primary healthcare ethos of earlier decades. By 2009, this shift in perspective was producing a strong reaction, with analyses highlighting how the success of disease-specific programs was hampered by overall weak health systems (Travis et al., 2004), and calling for much greater investment in health system strengthening. This trend culminated with the inclusion of universal health coverage as a target in the SDGs.

The Role of the State

The preceding historical review indicates that one of the key issues in the design of health systems is the role assigned to the state. This section examines the economic arguments commonly put forward to specify the state's role in health and then considers other explanations for the roles observed in practice. Health economics textbooks set out the arguments in more detail; see, for example, Chapter 7 in McPake, Normand, and Smith (2013), and Chapter 3 in Donaldson and Gerard (2005).

The first main economic justification lies in explanations of market failure. The efficient outcomes of private markets depend on a number of conditions being met. Because of the particular characteristics of health and health services, this may not be the case in the health sector.

First, the presence of externalities means that the optimal amount of health services may not be produced or consumed. Externalities are costs or benefits that are not taken into account in the transactions of producers or consumers. For example, an individual's decision on whether to be immunized will be related to the value of the protection to that individual, rather than the value of such protection that may be accorded to others and that reduces the pool of susceptible individuals.

Second, for goods that are public goods, the market may fail to produce them at all. Such goods are those where consumption is nonrival (i.e., consumption by one person does not reduce the consumption of another) and nonexcludable (i.e., a consumer cannot be prevented from benefiting from the good—for example, through requiring payment). Control of mosquito breeding sites to reduce malaria transmission is an obvious example: All people living in the area will benefit from such interventions regardless of whether they have paid for them. Information can also be seen to be a public good because it is nonrival; it is not nonexcludable, but the cost of providing information to extra people is often low. This applies to knowledge gained through research, for example.

Third, monopoly power can lead to market failure, because it enables the provider to charge more than if the market were competitive. Monopoly power may be held by a hospital in a particular geographic area, by a pharmaceutical firm, or even by a profession as a whole (such as the medical profession).

These arguments provide a rather weak justification for state intervention in the entire health system, since the range of services they apply to is quite limited. The arguments are most relevant to public health services and preventive care, and less relevant to the bulk of curative services. Moreover, problems such as monopoly are not unique to health and are commonly dealt with by regulation rather than by state provision of services. A more powerful argument for a large state role in health systems relates to the asymmetry of information between provider and consumer. Medical consultations are often sought precisely because patients do not know what is wrong with them: They are therefore ill informed, in contrast to the normal assumption in economics of perfectly informed consumers. Hence, in medical care, providers are in an unusually strong position. Although they may act as perfect agents for the consumer, it is also possible, especially when the consumer's income level is related to the care provided, that the personal interests of the providers may enter into decisions made on treatment. The poor and less educated are particularly vulnerable to unscrupulous profit seeking by private providers.

Another characteristic of health care is its uncertain nature, and the potential for high costs. This makes health care an obvious candidate for insurance, but it is generally accepted that private insurance markets do not work well in this realm (McPake et al., 2013). Individuals who purchase insurance may indulge in activities that put their health more at risk than if they were not insured, or once ill may consume more health care. This phenomenon, which is known as moral hazard, tends to raise the cost of insurance, making it unaffordable for some. Another problem is that those persons who are at greatest risk of needing care will be more likely to seek insurance, but due to asymmetries of information between insurer and insured, it is often difficult for the insurer to tailor the premium charged to the nature of the risk. This process, known as adverse selection, means that the insurer ends up with a more costly risk pool, premiums rise, and the healthier individuals opt out. In addition, insurance becomes more expensive, so that people who cannot afford the increased premiums are excluded from the market. Although the result is clearly inequitable, it is also inefficient because there will be people unprotected who would be willing and able to purchase insurance if the market worked well.

Other arguments in favor of state involvement are distinct from the arguments related to market failure. For example, one might argue that some types of health services are merit goods—that is, goods that society believes should be provided, but that individuals, if left to themselves, might underconsume because they are not the best judge of what is in their own or the public's interest. This argument is strongest for health services for children and the mentally ill.

Another argument is founded on equity principles: Namely, even with perfectly operating private markets for health services and health insurance, there will inevitably be individuals who are too poor to afford to access them. Although it could be argued that this problem could be addressed by income redistribution policies, equitable access to health services remains a concern; hence, it can be argued that providing benefits in kind is appropriate.

Although these are the standard arguments used to explore the appropriate role of the state in health services, the judgment of their significance differs greatly among economists, leading to radically different policy prescriptions. Even though much of this debate has focused on the relative merits of the U.S.

health system versus the Canadian or British health systems, it has also influenced the nature of the debate concerning the reform of health systems in LMICs, as noted later. Underlying this debate are alternative views on the ethical basis of a health system. One view sees access to health services as similar to access to other goods and services, and dependent on an individual's success in gaining or inheriting income. The other perspective sees access to health services as a right of citizenship that should not depend on individual income or wealth. According to the first view, the state's role in health should be confined to regulation of the market, public health measures, and public welfare for the poor to provide a minimum acceptable level of services, but nothing like the level of services available to those who are financially better off. According to the second view, the role of the state should be to ensure equal access to health services, meaning that access does not differ depending on economic or social status.

Although economic arguments provide justification for state involvement, they provide little guidance on the precise nature of intervention. In particular, they do not necessarily imply that the state should itself provide health services (as opposed to purchasing services from others). A key change in recent decades in thinking about public management has been the recognition that the state need not provide services itself directly, but instead could play an enabling role (Walsh, 1995).

An important influence on this position is a recognition that in many countries the state has failed in its policies to provide good-quality public services, including health services, for everyone. These arguments derive from a number of strands of economic thinking, especially public choice theory and property rights theories. The former is concerned with the nature of decision making in government. That is, public choice theorists argue that government officials are no different from anyone else in pursuing their own interests. Thus, politicians will be concerned with maximizing their chances of being reelected, and bureaucrats will serve their own interests (e.g., maximizing their budgets because their own rewards [salary, status] are related to that). The result is that the public sector is wasteful because politicians and bureaucrats have no incentive to promote allocative or technical efficiency.

In contrast, property rights theorists argue that the source of inefficiency in the public sector is the weakening of property rights. In the private sector, it can be argued, entrepreneurs or shareholders have a strong interest in the efficient use of resources. In contrast, in the public sector, there is little obvious threat to an enterprise if staff perform poorly; hence, incentives for efficient performance are weak.

These theories underlie what has been termed the "new public management," which seeks to expose public services to market pressures, without necessarily privatizing them (Walsh, 1995). Such approaches change the nature of state involvement, with policies of opening up services to competitive bids or putting services out to contract on a competitive basis; introducing internal markets where public providers have to compete for contracts from public purchasers; devolving financial control to organizations such as individual hospitals; spinning off parts of government into separate public agencies, such as an agency to manage government health services; and increasing the choice and influence of consumers by giving them resources in cash or kind, such as vouchers for treating sexually transmitted disease). This last approach, termed demand-side financing, enables consumers to purchase healthcare services from their chosen (usually accredited) provider.

Although theories justifying particular roles of the state feature prominently in writings on health systems, it is clear in practice that the actual role of the state in any particular country is shaped by a wide variety of influences. Most notable are the history of state involvement in health services and the rationale for its involvement over time, the extent to which private providers and insurers developed early in the history of the health system and thus were able to play a prominent role, and the attitude of the medical profession toward an increased state role (Mills et al., 2001). One key issue has been the extent to which the state took on itself the responsibility for providing services to the whole population, or instead concerned itself only with the poor and indigent.

EXHIBIT 13-2 summarizes the role of the state in five countries' health systems. In these countries, the government's financial contribution to health can be assessed against the commonly suggested benchmark of contributing 5% of GDP (McIntyre et al., 2017), and for Africa, the pledge of the African Union member states to set a target of allocating at least 15% of their annual budgets to improve the healthcare sector (WHO, 2011). In Tanzania, India, and Sierra Leone, the state's aims have historically been to provide services free at the point of use to the whole population. In contrast, both Mexico and Thailand have established specific schemes that cater to the poor and indigent, although in 2001 Thailand extended financial protection to the whole population through its "universal coverage" policy (Towse et al., 2004).

EXHIBIT 13-2 Illustrations of the Role of the State

Sierra Leone

The public health sector consumes 1.9% of GDP in Sierra Leone, and general government expenditures on health amount to 10.8% of total government expenditures and 7% of total health expenditures. The private sector in Sierra Leone is underdeveloped, with private facilities operating on a fee-for-service basis. Data on the private sector are scant.

Tanzania

Health services for the whole population have traditionally been seen as the responsibility of the state in Tanzania. Government expenditures on health accounts for 2.6% of GDP (and general government expenditures on health are 12.3% of total government expenditures), and 47% of total health expenditures are contributed by the government. More than 95% of hospital beds are owned either by government or by churches, while fewer than 5% are owned by the private sector (United Republic of Tanzania, Ministry of Health and Social Welfare, 2015). Independence brought in a government that was anti-private sector; even so, for at least the last 10 years, private-sector engagement has been an integral part of the country's health policy. Public-sector reforms have decentralized public management and introduced fees for public services. The poor are reliant mainly on public and church services and the informal private sector.

India

The historical emphasis in India was on a strong state role in health services, but resources were never provided to make this a reality. Public expenditures account for 1.4% of GDP in India, and general government expenditures on health amount to 5.0% of total government expenditures and 30% of total health expenditures. Approximately 65% of total hospital beds are public. Public services are often of poor quality and are adversely affected by the private practices of government doctors. People in general distrust the state. The policies related to charging for public facilities vary by state, but income from fees is small. There is widespread use of the private healthcare services sector by all sections of the population, including the poor.

Thailand

The public health sector amounts to 3.2% of GDP in Thailand, and general government expenditures on health represent 13.3% of total government expenditures and 77.8% of total health expenditures. In 2015, 79% of total hospital beds were found in public-sector facilities (Asia Pacific Observatory on Health Systems and Policies, 2015). Thailand has had a tradition of strong central government and laissez-faire economic policies. Historically, government policies have encouraged the private sector to grow through tax exemptions and public funding for private care for specific groups. With the introduction of the recent universal coverage policy, the government strengthened its commitment to inclusive social policies. Public services are of generally good quality; their main problem is considered to be lack of a consumer orientation.

Mexico

In Mexico, the public health sector makes up 3.3% of GDP, and general government expenditures on health account for 11.6% of total government expenditures and 51.8% of total health expenditures. Approximately 66% of hospital beds are found in public facilities (OECD, 2016). The government's primary role is that of owner of social security institutions, which account for some 55% of general government expenditures on health. The federal and state health ministries provide health care to those not covered by social security institutions, with state health ministries operating *Seguro Popular*, a program that provides free access to almost 300 healthcare interventions. There is dissatisfaction with the quality of public services in general, with those who can afford it preferring to use private services.

Note: Where not otherwise cited, expenditure data are from http://www.who.int/nha/country/en/.

Governance and Regulation

The governance function for health systems encompasses a set of rules guiding the roles and responsibilities of political, economic, and institutional processes with the aim of achieving health-sector objectives (Brinkerhoff & Bossert, 2008). Health governance involves three sets of actors: state actors (health and nonhealth, including health ministry, health insurance and pharmaceutical procurement and distribution agents, ministry of finance, the judiciary, regulatory bodies), health service providers (public-, private-, and voluntary-sector hospitals, laboratories, pharmaceutical companies, equipment suppliers, and education institutions), and beneficiaries (service users and the general public). Governance rules should ensure the accountability of key actors to the general public for

access to health services that achieve good health outcomes, satisfaction for patients and the general public, and equity. Accountability mechanisms can include judiciary and regulatory processes, advisory committees, and transparency of information. Governance also involves a policy process wherein actors with competing priorities have a "level playing field," with the aim of reducing unfair lobbying practices and corruption and increasing the voice of underserved populations.

States need to have sufficient capacity, power, and legitimacy to ensure effective governance. Yet ministries of health often lack the capacity to ensure a fair health policy process, which in turn undermines their legitimacy. This problem is particularly acute in fragile states (Brinkerhoff, 2007). A study in Nepal, Burma, and Afghanistan, for example, showed the link between service delivery and state fragility (Berry & Igboemeka, 2004). Civil society also needs to have sufficient capacity and power to engage in the health policy process, in its role as a representative of the broader public and as a watchdog of health services provision. In addition, an uneven distribution of power and external factors (either global or domestic) can hinder effective governance.

Within the broader concept of governance, regulation is traditionally defined as the imposition of rules by government, backed by the use of penalties, that are intended to modify the behavior of individuals and firms in the private sector. With the creation of autonomous entities within the public sector (e.g., self-managing hospitals), regulation commonly now extends to those organizations. Regulation is a role that all governments must carry out, regardless of their degree of involvement in health services provision. The traditional rationale for regulation relates to the arguments of market failure outlined previously as well as to the desire of governments to meet other social objectives, such as equity. Market failure creates the need either to regulate to make the market work better (e.g., to limit the control any one pharmaceutical firm may have over the market) or to prevent harmful effects (e.g., to ensure minimum quality standards for private clinics).

Although regulation is often thought of as action involving control, sanctions, and penalties, it can also take the form of incentives to encourage appropriate behavior. In health services, where outcomes are difficult to observe (i.e., it can be difficult to relate a treatment to a change in health), it can be argued that incentives are particularly appropriate, although they can be complicated to design and predicting response can be difficult (Baldwin & Cave, 1999). In LMICs where capacity and resources for enforcement are often weak, it has been argued that the concept of regulation should be extended to encompass incentives in combination with other tools such as consumer information, contracting, and accreditation, and working through other actors such as consumer groups or nongovernmental organizations (NGOs) can offer policy makers a wider and softer approach to enforcement (Ensor & Weinzierl, 2007). Indeed, the prime motivation for examining regulation in LMIC health systems has usually been determining how best to engage with the private healthcare sector. In this context, "prohibit, constrain, encourage, or purchase" (Montagu & Goodman, 2016) have all been strategies considered. The first two of these approaches are considered here, and the remaining two in subsequent sections.

Regulatory action seeks primarily to influence the following factors:

- Market entry and exit
- Remuneration of providers
- Quality and distribution of services
- Standards and quality

Key mechanisms used in the health system to regulate the provision of health services are summarized in **TABLE 13-2**. Controls over market entry and exit are not shown separately because they also serve to influence quantities and quality.

Licensing of professionals to provide services is one of the key forms of regulation, with professional councils usually being empowered to carry out this function. As new professions arise or become more important, eventually they are brought within the scope of laws. Although such laws dictate entry into the market, their prime rationale from a government perspective is to maintain quality and protect the consumer. However, actual experience demonstrates that licensing on its own is not adequate to ensure quality, since other factors affect professional behavior.

A second key type of regulation is licensing or registration of facilities, which is required before they can open. Legislation often specifies the requirements that particular categories of facility should meet, covering such aspects as trained staff, availability of equipment and supplies, and buildings. Because of the costliness of high technology, some countries have an approval process for the purchase of major items of equipment. Entry to medical school may also be controlled with the same aim: Controlling costs by limiting supply. In a normal market, such action might be expected to raise costs, but it is considered justified in health because of the power physicians have to generate their own income or to prevail on the government to employ greater numbers of physicians than the country can really afford.

Often countries are concerned about the geographic distribution of providers, and controls and

TABLE 13-2 Examples of Regulatory Mechanisms for Healthcare Provision

Variable	Mechanism	Examples from LMICs
Quantities/ distribution	■ Bans on provision	■ Abortion services (many countries)
	■ Licensing of providers	■ Universal for main professional groups
	■ Licensing of facilities	■ Increasingly common for hospitals and clinics
	■ Controls on number and size of medical schools	■ Common (e.g., Latin America)
	■ Controls on location of facilities and technology	■ South Africa: private hospitals; Tanzania pharmacies
	■ Incentives to practice in underserved areas and specialties	■ Many countries for doctors, often in the form of compulsory rural service
	■ Requiring capitation or case-based payment to control the supply of services	■ Social insurance in Korea (case payment) and Thailand (capitation)
Prices	■ Negotiation of salary scales	■ Zimbabwe: nursing salaries; Argentina: doctors
	■ Fixing of charges (e.g., for lab tests; drugs markup)	■ South Africa: drugs markup for medical schemes' reimbursement; Niger: wholesale and retail drugs markups
	■ Negotiation of reimbursement rates	■ Many social insurance schemes (e.g., Chile)
Quality	■ Licensing of practitioners	■ Universal for main professions
	■ Registration of facilities	■ Increasingly common; specifies structural standards
	■ Control on who provides which services	■ Restrictions on drug sales by unqualified staff (many countries); on drug dispensing by general practitioners (e.g., Zimbabwe); on a range of procedures (clinical officers, Kenya)
	■ Accessibility	■ Hospitals legally obliged to provide emergency care irrespective of patient financial status (Thailand, Malaysia)
	■ Required complaints procedures	■ Consumer laws applicable (India)
	■ Required provision of information for monitoring quality	■ Many countries
	■ Control of training curricula	■ Many countries
	■ Requirements for continuing education of physicians	■ Increasingly being introduced
	■ Accreditation	■ Increasingly being introduced (e.g., schemes in Taiwan, Kenya, and Thailand)

Data from Bennett, S., & Ngalande-Bamda, E. (1994). *Public and private roles in health: A review and analysis of experience in sub-Saharan Africa.* Geneva, Switzerland: World Health Organization. Retrieved from http://apps.who.int/iris/bitstream/handle/10665/62173/WHO_ARA_CC_97.6.pdf?sequence=1&isAllowed=y

incentives are used to influence where new providers can set up. For example, South African provinces have the authority to license the creation and expansion of private hospitals, depending on "necessity" (Doherty, 2015). Certificate-of-need legislation has been used for many years to control the construction of new buildings and investment in new equipment in the United States (Certificate of Need State Laws, 2017).

Control of prices and reimbursement levels may have several purposes: To restrict incomes in the private sector so that remuneration differences between public and private professionals do not get too great; to ensure that health services remain affordable for the not-so-wealthy; and to restrict the financial burden placed on risk-pooling arrangements, such as social insurance or employer medical benefit schemes. However, given the power of the medical profession, there is a risk that price control will operate more in the interests of the profession than in the interest of the public; in addition, this practice can be difficult to enforce or monitor.

Control of quality is one of the prime concerns of regulation. Licensing and registration have this aim, as well as control of quantity. Doherty (2015) provides a mapping of these regulations affecting providers in seven sub-Saharan African countries. In Kenya, for

example, a private clinic must be kept in good order and state of repair, and must have a spacious consultation room, a sheltered waiting room, a treatment room, access to toilets, and transport.

Regulations often seek to control the nature of services provided, both to ensure that services are within the competence of a particular type of provider and to limit the scope for excessive service provision. Regulations usually specify which type of health professional can prescribe which type of drug, limiting, for example, the range of drugs that can be given by low-level health workers. It is quite common for private practitioners to be allowed to dispense medicines only if there is no pharmacy nearby. Where this rule does not exist, drug dispensing is often a major source of private physicians' income, leading to predictable concerns about overprescribing.

Control of training curricula is fundamental to ensuring quality, and is often one of the functions given by law to professional bodies. A trend in high-income countries, which is also becoming apparent elsewhere, is the requirement for professionals to receive regular refresher training to merit continued licensing. Such a provision is demanding on regulatory bodies, because it requires the introduction of monitoring procedures, training programs, and relicensing arrangements.

Accreditation is a process of certifying that a facility meets a certain standard. It is usually applied as a self-regulating procedure that is voluntary and managed by an independent body. In practice, it may act more as a regulatory device than as a peer review process, especially when accreditation is required for hospitals to be eligible for reimbursement from a social insurance scheme, as in Taiwan (Lu & Chiang, 2011).

Governments also regulate other markets with considerable relevance to health services, including the health insurance and pharmaceutical markets. Regulation of both of these markets has unique features. In the case of insurance, regulations may impose a particular approach to risk pooling (e.g., requiring schemes to give lifetime coverage or to use community risk rather than risk rating). In the case of pharmaceuticals, regulations may establish which drugs can be imported and which can be sold over the counter or require a doctor's prescription; they may also specify quality control procedures for imported and locally made drugs.

Separate consideration may be given in regulatory structures to not-for-profit providers. On the one hand, they may be treated more strictly. For example, their fee structures may be regulated, they may be required to provide a certain amount of free care to the poor, and requirements to provide information may be stricter. On the other hand, they may benefit from their not-for-profit status. For example, tax exemptions are often available to these organizations.

In practice, regulation encounters a number of key problems (Doherty, 2015; Mills et al., 2001; Sheikh, Saligram, & Hort, 2013). **EXHIBIT 13-3** highlights these issues for the five exemplar countries. One problem is that laws are frequently outdated and are difficult to change. For example, many LMICs have laws they inherited from colonial regimes that have not kept pace with the development of the private sector, resulting in whole categories of facilities that may be completely unregulated. Private laboratories are often a case in point.

EXHIBIT 13-3 Key Regulatory Problems in Selected Countries

Sierra Leone (Frederick Martineau, personal communication, July 31, 2017)

- Informal payments for care that should be free remain common.
- Large numbers of volunteer health workers work in the government sector for many years before being officially recognized with a salary.
- Drug procurement and distribution are particularly problematic, with frequent stock-outs requiring patients to visit private pharmacies.
- Informal practitioners are largely unregulated and unknown to the state.

Tanzania (Mtei et al., 2007)

- The country relies on legal instruments rather than complementing them with other approaches to regulation.
- There is a limited capacity to enforce regulations, especially with respect to drug prescribing and sales.
- The regulations covering private providers permit the health minister to set maximum prices for medical treatment, but on a practical level private hospitals are free to charge what they like.
- The registrar of private hospitals has a mandate to inspect private facilities, but there is little evidence such inspections are done.

(continues)

EXHIBIT 13-3 Key Regulatory Problems in Selected Countries *(continued)*

India (Mills et al., 2001)

- Few states require any registration and inspection of private hospitals.
- Practice by unqualified personnel is widespread.
- Unethical practices (e.g., payments between hospitals and general practitioners to encourage referrals) are widespread.
- No database of private providers exists.
- There is little ability to enforce regulations.
- Regulatory bodies lack resources.

Thailand (Teerawattananon, Tangcharoensathien, Tantivess, & Mills, 2003)

- The regulatory framework is largely complete, but its application is weak.
- Regulatory bodies lack resources for enforcement.
- There is insufficient information on activity in the private sector.
- It is difficult to control unethical practices (e.g., turning away emergency cases).
- Professional council regulation is largely ineffective.

Mexico (David Lugo Palacios, personal communication, July 31, 2017)

- Private hospitals are not subject to a strict process of accreditation that verifies their capacity to provide an acceptable standard of care.
- Public facilities are used by physicians for treating their own private patients.
- The private sector resists providing epidemiologic and other information.
- Some people are covered by two, or even three, public health insurance schemes, which in principle is not allowed by the *Seguro Popular* regulation. For example, more than 14% of *Seguro Popular* beneficiaries are also covered by social security institutions (FUNSALUD, 2012).

Another problem is that regulation requires substantial knowledge on the part of the regulatory bodies. However, it is common in LMICs for even basic information, such as lists of providers and facilities, to be incomplete. Moreover, the poorer the country, the greater the proportion of providers that are small and informally organized, making it difficult to require any regular provision of information by those organizations.

A third problem is that of regulatory capture: The body meant to be doing the regulating in practice operates in the interests of those being regulated, rather than in the public interest. This is a common problem in the case of regulation of professional groups, which is often done by the profession itself, leading to slow processing of complaints and concerns related to professional negligence. Moreover, the overlap of public and private interests can make it extremely difficult to introduce new regulations or change existing laws. In India, as in a number of countries, it is common to find government-employed doctors with private practices—with or without legal sanction—and senior Ministry of Health officials, as well as politicians, having financial interests in private-sector health services (Mills et al., 2001). Thus, a clear distinction between the regulators and those being regulated is lacking. In India, the consumer rights law provides an alternative channel for pursuing complaints, but consumer forum officials interviewed by Sheikh et al. (2013) reported that it was difficult to rule against doctors because of the subjective nature of medical cases and a perception that doctors were doing "fundamentally noble work" (p. 51).

A fourth problem is the inadequacy of the resources provided to the regulatory bodies to apply the laws effectively. Quality monitoring, in particular, requires regular inspection to ensure laws are being followed. This places great demands on the limited staff capacity of regulatory agencies, especially in regard to monitoring of drugs and clinics, whose outlets are numerous and widely dispersed. A further problem may be that low-paid staff seek illicit payments instead of carrying out their jobs effectively. An extreme form of this failure to monitor was found in China: Because government subsidies to public health activities were severely cut, environmental health units were dependent on revenue generation for much of their income and, therefore, tended to inspect those firms that were more able to pay their fees (Liu & Mills, 2002). Those that were less profitable, and in turn likely to have worse safety and hygiene practices, went uninspected.

A final problem is a lack of institutional structures to back up the regulatory process. Strong consumer groups, media, professional associations, and insurance agencies all have important roles to play in ensuring regulations are respected and enforced (Brinkerhoff & Bossert, 2008). The consumer role is particularly important, because consumers can identify problems through complaints procedures and legal action and also levy pressure more broadly through consumer groups. However, the common imbalance in power and access to resources between consumers and professionals suggests that complementary pressures are also important. One source of this type of influence can be purchasing agencies, which are considered in depth later in this chapter.

As part of efforts to strengthen their health systems, many countries have amended out-of-date legislation and sought to ensure that new private activities are brought within the scope of the law. Countries that previously banned or strictly controlled the private healthcare sector, such as countries in eastern and central Europe, some countries in Africa, and Vietnam and China, now allow and in some cases even encourage private-sector services through tax subsidies. However, much of the expansion of the private sector has taken place without deliberate planning, and often with little regulation. The challenges of both designing and implementing regulations have encouraged an emphasis on interventions that incentivize private providers to improve the quality and coverage of their healthcare services (Montagu & Goodman, 2016), including social marketing and vouchers (found to be successful) and accreditation and contracting (less evidence of success).

Financing

This section lays out a conceptual model for the financing of health services, and describes and evaluates the major sources of health financing in LMICs.

Conceptual Model

Financing refers here to the raising or collection of revenue to pay for the operation of the health system. This definition is narrower than that used by WHO, for example; WHO considers the financing building block to encompass raising money, pooling funds, and paying providers. Financing agents are those entities that collect money to pay providers on behalf of consumers. Financing agents may be publicly or privately owned, and may provide health services directly (e.g., the ministry of health through public hospitals and health centers) or purchase health services from providers (e.g., a private insurer may purchase inpatient care from a variety of hospitals).

There is some variation in the literature as to the definition of "sources" of financing. Sources may be defined as the entities that provide funds to financing agents. In this sense, individuals and firms can be thought of as the primary sources of funds. Individuals generate income in the form of wages or salaries, while businesses may earn a profit on capital investments or rent on properties owned. Resources may pass through several levels of sources before reaching the agents. For example, the ministry of finance can be thought of as a secondary-level source insofar as it generates funds by taxing the incomes of households and businesses and then transfers these resources to other government agencies to purchase health services. A single entity may act both as a source and as an agent of financing. For example, households commonly pay for health services both indirectly (through taxation, contributions to social and private insurance, donations to charities, and so on) and directly (through out-of-pocket payments).

More often, however, the term "source" is applied to the method whereby an agent mobilizes or collects resources. For example, the sources of financing for the ministry of health include personal and business taxes, and donations, loans, and grants from domestic and foreign agencies. The sources of financing for private insurance agencies are premiums paid by the enrollees in these schemes. In this chapter, the term "source" is used with this definition in mind unless otherwise indicated.

Description and Evaluation of Predominant Sources

This section defines the most commonly used sources of financing and briefly discusses the efficiency, equity, and revenue-generating ability of each source. **TABLE 13-3** summarizes the relative merits of each source.

Efficiency with respect to a source of financing involves a number of elements, including administrative (or technical) efficiency, stability, and flexibility. Administrative efficiency relates to the cost of the system's management and is the difference between gross yield (all funds that are collected) and net yield (that portion of the gross yield that is actually available for the purposes of health services delivery). This difference results from the costs of revenue collection, allocation, and distribution; advertising and promotion; and funds lost to corruption and fraud as well as the

TABLE 13-3 Evaluation of Health Financing Sources

	Efficiency			Equity		
	Administrative Efficiency	Stability	Flexibility	Horizontal	Vertical	Revenue Generation
Public Sources						
General tax revenues	Highı	Low	Low	High	Progressive	High
Retail sales taxes	High	High	Low	High	Regressive	Low
Lotteries and betting	Low	High	Low	High	Regressive	Low
Deficit financing	Low	Low	Low	Depends	Depends	Depends
External grants	Low	Low	Low	High	Progressive	Low
Social insurance	Low	High	Low	High	Regressive	Depends on size of formal sector
Private Sources						
Households	Low	High	High	Low	Regressive	High
Employers	Low to medium	High	Variable	Low	Depends	Low
Private insurance	Low	High	High	Low	Regressive	Low
Voluntary organizations	High	Variable	Variable	High	Progressive	Medium

cost of fighting that corruption and fraud. The stability of an agent is determined by the degree to which revenue raising varies with changes in economic or political conditions. Finally, for a financing agent to be efficient, there must be flexibility in terms of the allocation of funds to different expenditure categories. The least flexible sources of financing are those pledged to a specific activity. Public-sector sources tend to be less flexible than private-sector sources due to the rules and regulations that are often applied to government spending, as well as the political constraints on reallocation.

The concepts of horizontal and vertical equity of financing were introduced earlier. With respect to vertical equity, a progressive system is one in which lower-income groups pay a smaller proportion of their income to fund services compared to higher-income groups. A regressive system is one in which lower-income groups pay a higher share of their income for this purpose than do higher-income groups. A proportional or neutral system is one in which all income groups pay the same percentage of their income for financing purposes.

Apart from problems of inefficiency and inequity, health systems in many LMICs face the difficulty of simply not being able to generate sufficient funds to ensure that the entire population has access to a minimal package of health services. Thus, a goal of the

financing function of health systems is to increase the availability of funds for the purchase and provision of health services. As countries become richer and the demand for high-technology, hospital-based interventions increases, the goal generally shifts from generating funds to constraining the financial flow through the health system (i.e., cost containment).

Public Sources of Financing

Direct taxes are paid directly by individuals or organizations to government and include personal income tax, property and land taxes, taxes on domestic business transactions and profits, duties on imports and exports, and property taxes. Some portion of these resources may then be allocated to the annual budget for health services. The most commonly quoted example of general tax financing for health services is the United Kingdom's National Health Service.

Direct tax revenues should have relatively high net yields, though this will depend on the overhead costs of the government bureaucracy needed to collect, allocate, and disburse them. They may not be a particularly reliable or stable source of financing, because the health sector must compete directly with other social and economic programs for a portion of the government's budget; as such, this source may fluctuate depending on the economic and political climate. Furthermore, this source of financing is likely to be inflexible because it is controlled by public-sector agents that are constrained by rules and regulations and the political feasibility of reallocations.

Direct taxation achieves horizontal equity insofar as taxes on individuals are usually not related to characteristics other than income. Income tax is generally a progressive form of revenue raising across the world, including in LMICs (Asante, Price, Hayen, Jan, & Wiseman, 2016), because income tax rates usually rise as a person's taxable income increases. Direct taxes are typically progressive, as in Bangladesh, the Philippines, Sri Lanka, and Thailand, where direct taxes are almost exclusively paid by the better-off members of society (O'Donnell et al., 2008). Notably, however, the ability of taxation to redistribute resources from the rich to the poor is hindered when the wealthy are able to evade the payment of taxes.

Ability to mobilize resources is another strength of direct taxation. Although most developing countries are restricted in their ability to collect income taxes and indirect taxes (due to limited infrastructure and small formal sectors), the government has many other options for generating tax revenue, including property, business, and import and export taxes. For example, taxes on international trade in 2016 accounted for 24% of central government revenues in Bangladesh, 13% in Russia, and 33% in Namibia (World Bank, 2017), but overall these proportions have been declining over time.

Indirect taxes pass through an intermediary en route to government coffers. Such taxes are incorporated into the selling price of a good or service; they include sales and value-added taxes (taxes on a broad variety of items) and excise duties (imposed on the sale of specific items, such as tobacco products, beer, and liquor). Revenues generated in this manner are often allocated to finance specific programs. Taxes that are pledged to a specific sector or activity are described as "hypothecated," and the practice is known as earmarking.

As with direct sales taxes, the net yield of indirect taxes will vary depending on the efficiency of the government agency responsible for collecting them. Indirect taxes are likely to be reliable when they are earmarked for the health sector, or even specific projects within the health sector. The flexibility of this source may be constrained by the government rules and regulations that guide revenue allocation.

Indirect taxation, and excise duties in particular, is generally considered to be regressive, because poorer households often spend a higher percentage of their income on the goods being taxed (e.g., alcohol and cigarettes). As in higher-income countries, this has been found to be the case in LMICs, especially for value-added taxes (VAT) (Asante et al., 2016). In an exception to this pattern, Mills et al. (2012) found that VAT was progressive in Ghana and Tanzania, reflecting the types of goods and services liable for VAT and the local consumption patterns in poorer groups.

Lotteries and betting may also serve as sources of earmarked income for health services, although these methods are not often used. They have low net yields because they are costly to administer. As with indirect taxes, the resulting revenues are likely to be reliable because they are earmarked, but inflexible because they are administered by public agents. Like retail sales taxes, lotteries and betting tend to take a particularly heavy toll on the earnings of the poor, because of their popularity among lower-income groups.

National authorities can augment general tax revenues through domestic and international deficit financing (loans) and through grants. Deficit financing means that funds are borrowed for a specific project or activity and have to be paid back to the source over some future period of time. Domestic deficit financing is usually achieved through the issuance of debt certificates, or bonds, with guaranteed interest rates. International borrowing typically takes the form of loans from bilateral and multilateral

organizations. External grants are transfers to governments made in cash, goods, or services by foreign governments or organizations; they do not have to be repaid.

In 2008, the World Bank noted that there were more than 100 international entities providing development assistance for health. Total official development assistance to health reached nearly $24 billion in 2013, up from $7.6 billion in 2003 (Grollman et al., 2017). According to the same source, only 9.6% of all development assistance for health was spent on health system strengthening and general health-sector support. Major sources of grants include bilateral donor agencies (such as Britain's Department for International Development [DFID] and the U.S. Agency for International Development [USAID]), the Bill and Melinda Gates Foundation, and the Global Fund to Fight AIDS, Tuberculosis and Malaria. One of the largest financiers of health services in LMICs is the World Bank, which provides two main types of loans. The first type is intended for developing countries that are able to pay near-market interest rates. The second type of loan goes to the poorest countries in the world, many of which are in Africa. These loans carry little or no interest, and are long term (generally 40 years, including 10 years' grace). Loans that bear an interest rate substantially below market interest rates are termed soft loans.

The costs of processing and administering donor assistance in the health sector can be quite high, particularly when the aid to a country is spread among a large number of donor projects. Fragmentation is common: According to a recent study, a typical recipient country received aid for reproductive, maternal, newborn, and child health from an average of 15 donors between 2008 and 2013, although some countries had as many as 30 donors. In addition, it results in officials spending a large amount of their time meeting donors' requirements (Martinez-Álvarez et al., 2017). The stability of this financing source is also limited, insofar as external funds are typically of short duration, with no guarantee of renewal.

The flexibility of loan and grant financing is variable. At one time, it was common for external funds to be made available for specific, free-standing health projects; decisions on expenditures were usually made prior to the funds' disbursement. Later, encouraged by high-level declarations on aid effectiveness in the early 2000s (Rome, Paris, and Busan), donors increasingly chose to disburse aid as program-based approaches. These have the characteristics of being led by the recipient country, with a single program and budget framework; they promote donor coordination and use of country public financial management systems (Martinez-Álvarez, 2014). Program-based approaches include aid delivered as general or sector budgetary support, sector-wide approaches, and basket funds (where donors pool their funds and jointly agree with governments on the priorities and management procedures). More recently, disillusioned with a lack of progress and under increasing pressure to show results, donors have favored vertical project-based funds over program-based approaches.

The equity of deficit financing will depend entirely on how the loan is ultimately paid back. If, for example, funds generated through direct taxation are used to pay back a loan, then their impact may be progressive. External grants should be equitable since they are provided by wealthy nations and should be used to establish and run projects in remote or underserved areas (though this is by no means always the case). However, the extent to which they actually achieve a progressive redistribution of resources will depend on the extent to which the government shifts its spending as the result of the grants.

The displacement effect that one source of finance may have on others is termed fungibility, and the introduction or expansion of one source of financing may have an impact on the efficiency, equity, or revenue-generating ability of other sources. This may be especially important when large external grants or loans are introduced into a health sector. For example, it might seem that a large external grant earmarked for the treatment of tuberculosis (TB) among the rural poor would be equitable. However, in response to such a grant, the ministry of health may shift resources that would have been spent on this activity toward high-technology, hospital-based services. Thus, the positive impact that the new source of funding has on equity might be counterbalanced by the negative equity impact of displacement.

Despite debates about the existence and impact of fungibility, in reality little is known about the actual extent to which this practice occurs (Martinez-Álvarez, 2014), partly due to data limitations. Current estimates of health-sector fungibility range from a decrease of $0.27– $1.65 to a $1.50 increase in response to a $1 increase in development assistance for health. A country case study in Tanzania found some evidence of substitution of development assistance for health from the health sector to the education sector, perhaps reflecting a budget allocation process operating under conditions of scarcity and rational behavior by the government (Martinez Álvarez, Borghi, Acharya, & Vassall, 2016). Fungibility is one of the rationales for program-based approaches.

Only limited resources are generated through external loans and grants except in the poorest countries: Low-income countries spend, on average, $37 per capita on health; of this amount, 28% comes from development assistance (WHO, 2017). In specific countries, however, external funding can represent a much higher share of total health expenditures—for example, 49% in Mozambique.

Social insurance premiums are mandatory insurance payments made by employers and employees in the formal sector, usually as a percentage of wages; hence, they are often called payroll taxes. Social insurance payments can have relatively low net yields due to the cost of processing claims. According to WHO (2010a), over the period 2000–2007, administrative costs in high-income country social insurance funds amounted to approximately 4%. Data on LMICs are sparse, but the share attributable to administrative costs has been found to range from 1% to 27%, with an average of 23% noted in middle-income countries. The monies generated are likely to be stable because they are earmarked for the health sector; however, they may not be flexible, again related to government restrictions and requirements.

While the value of social insurance premiums is generally based on income, social insurance contributions tend to be regressive in countries with universal systems, such as France, Japan, the Netherlands, Spain, and South Korea (O'Donnell et al., 2008; Wagstaff et al., 1999). This situation arises because contributions are typically subject to a ceiling. Social insurance premiums may be progressive if ceilings can be eliminated or if low-income groups are exempt from contributions. In LMICs, where social insurance tends to include only wealthier, formal-sector workers, contributions are progressive. This is the case, for example, in China, Indonesia, and the Philippines (O'Donnell et al., 2008). In these countries, however, the insurance coverage is largely restricted to the better-off segments of the population.

The coverage achieved by social insurance schemes in many LMICs has been limited, because premiums can be readily collected only from formal-sector employees. In addition, achieving high compliance of employers can be challenging—as found, for example, in a study in Laos (Alkenbrack, Hanson, & Lindelow, 2015). The limited coverage has given rise to much criticism of the equity of social insurance arrangements, since a relatively small proportion of the population has access to better services than much of the rest of the population, and sometimes also benefit from government subsidies to the social insurance program. One response to this problem has been to use income from general taxes to expand coverage of health services for those people outside the formal sector. For example, this has been the policy in Thailand (Tangcharoensathien et al., 2011). Over time, funding schemes for different population groups can be made more comparable, with some countries, such as Costa Rica, the Republic of Korea, and Taiwan, achieving universal or near-universal coverage by combining funds from social insurance contributions with general tax revenues in a single national scheme, so as to ensure that all population groups have access to the same types and levels of care.

Another response, for countries at an earlier stage of health system development, has been to allocate public subsidies to voluntary health insurance in an effort to expand enrollment. As explained later, community-based health insurance schemes have generally stayed small, but a few countries—notably Rwanda, Ghana, and China—have seen considerable gains in population coverage by subsidizing local schemes and bringing them into a national set of arrangements. Rwanda rapidly scaled up coverage of its "Mutuelles de Santé," China reached universal coverage of basic medical insurance in 2011, and Ghana has scaled up district-based health insurance schemes as part of the National Health Insurance Scheme, to the point that approximately 40% of the total Ghanaian population held valid membership cards in 2016 (Alhassan, Nketiah-Amponsah, & Arhinful, 2016). India has employed a different insurance approach: The introduction of heavily subsidized state schemes largely intended for those persons below the poverty line, through contracts with insurance companies that arrange the provision of care and payment (RSBY, 2017). In general, increases in population coverage have proved easier to achieve than reductions in out-of-pocket payments, due to limited benefit packages, continued exposure to fees, and in some cases quality of care concerns.

Private Sources of Financing

Direct household expenditures include all out-of-pocket payments or user fees paid by the consumer of health services directly to the provider (including private practitioners, traditional healers, and private pharmacists). Even services provided by the government or an insurance program may include some element of copayment, which may take a variety of forms. Coinsurance means that the consumer is responsible for paying for a certain percentage of the costs of all services received. Limited indemnity means that the insurer covers health service costs only up to a prespecified absolute amount (or ceiling), above which

the consumer is responsible for paying. A deductible is a specific amount that must be paid by the consumer, after which reimbursement starts.

The administrative efficiency of direct household expenditures is low, due to the labor-intensive task of collecting fees from individuals. The stability of household spending on health will vary according to household income, but it is likely to be fairly stable unless economic crisis causes widespread poverty. Household spending is extremely flexible and will be allocated to the most pressing health needs as they are perceived by members of the household. Such spending is horizontally inequitable, since it varies according to factors such as distance lived from health facilities and individual preferences. It also demonstrates vertical inequity: For example, Asante et al. (2016) found that out-of-pocket payment was regressive according to all studies included in their systematic review, with the exception of Zambia, where it was proportional.

There are, however, ways in which user fees can be made more equitable. For example:

- Full-cost charges can be levied on patients who bypass the referral system by going directly to hospitals without being referred or having a genuine emergency.
- Charges can be levied for private rooms at government hospitals that charge for the full costs.
- Clinics at government facilities can be opened outside normal working hours for those who are willing to pay and want to avoid queues.

Direct employer financing occurs when firms pay for, or directly provide, health services for their employees. Employers as agents are likely to be more efficient than households, though less efficient than compulsory purchasers of care (such as social insurance schemes) due to the former's fragmentation. While employer financing may be reliable (in the absence of economic crisis), it is relatively inflexible because employers are biased toward specific types of health services (e.g., curative care). Direct payment by employers contributes to horizontal inequity in the health system as a whole because employed workers are disproportionately young and healthy. Because the benefits of employer financing are generally restricted to employees within the formal sector, this method of financing is likely to have little impact on the redistribution of resources among different income groups. The quantity of resources mobilized by employers can be significant in some countries; for example, in Zambia, financing provided by private employers accounted for roughly 9% of the country's total health expenditures (World Bank, 2012). As governments implement social insurance schemes, these tend to replace employer financing of health services.

Voluntary health insurance consists of two main types. Private commercial insurance involves payment of regular premiums to private insurance companies in return for coverage of prespecified health service costs. This insurance typically does not cover the costs of frequent, predictable events (such as pregnancy). Experience rating means that premiums are based on an individual's actuarially determined likelihood of illness. Community rating means that the premium is based on the pooled risk of a defined group of people (e.g., inhabitants of a geographic area or employees of a firm).

Private commercial insurance tends not to be an efficient method of mobilizing funds for the health sector (Donaldson & Gerard, 2005). Its net yield is low because of the costs involved in assessing risk, setting premiums, designing benefit packages, distributing the insurance, marketing, processing claims, reinsuring, and detecting fraud. Indeed, the administrative costs of private insurers in high-income countries were found to be, on average, 12%—three times the corresponding costs of social insurance schemes (WHO, 2010a). In unregulated markets, administrative costs plus profits may account for a substantial share of the premiums. Private health insurance is a stable agent of financing because it is not subject to political allocation processes, and it must be flexible to respond to consumers' needs and to attract clientele.

Private commercial insurance premiums are an example of a horizontally inequitable source. Experience rating means that premiums will vary according to factors that are considered by the insurer to be related to risk of illness, such as age, sex, and occupation. Private insurance tends to be regressive because rates are adjusted for risk, and the poor are at highest risk of falling ill. The ability to mobilize resources through private commercial insurance is limited in poorer countries because these schemes are targeted to a small (although well-off) segment of the population—less than 2% of the population in most cases.

The second type of voluntary health insurance consists of community-based schemes targeting the informal, usually rural, sector. Although a number of such schemes exist in various countries, they have struggled to grow in size and scope. Historically, they were an important stage in the development of universal coverage of health services in Europe and Japan. Today, however, few LMICs have schemes that are sufficiently developed to offer this sort of promise in the near future—with the exception of those discussed earlier, which have developed as part of social

insurance arrangements. Voluntary health insurance contributions for those in the informal sector are generally found to be regressive (Asante et al., 2015).

Charitable contributions are contributions made in cash or in kind. Examples include cash contributions from wealthy families, business enterprises, or religious organizations; community labor for construction and maintenance of local health facilities, including clinics and environmental sanitation projects; and local help in specific disease eradication campaigns. Voluntary organizations or NGOs have high net yields, although their ability to generate funds may be unpredictable. The flexibility will vary from one voluntary organization to another, but generally these sources prefer to fund specific types of health services, not necessarily those most suitable for the community being served. Voluntary organization funding should be progressive, in that such organizations raise revenue from the better-off segments of society, although their ability to mobilize resources is limited.

Mixes of Financing Sources

No one source of financing stands out as being superior in terms of all the outcomes considered, nor is there an optimal mix of sources that can be prescribed for all countries. Countries vary in terms of the number of different financing agents and methods that are used, and the mix can change over time within a country. The mix of sources used will depend in part on the relative importance that policy makers place on the various objectives described previously and in part on the mix of sources historically used in that country. Most LMICs have more pluralistic health financing structures than are found in high-income countries (**FIGURE 13-2**). Low-income countries typically finance the bulk of their healthcare expenditures through (1) direct household expenditures, (2) general taxation, and (3) external financing. The most important financing agents are typically the ministry of health (and other government agencies), households, and firms. As countries grow richer, external concessionary financing disappears, an increasing share of health expenditures is pooled, and a decreasing share comes from out-of-pocket payments.

Although using a variety of sources may increase the resources available for health care and allow for better adaptation to the diverse social and economic conditions that may exist within a country, it makes the pursuit of health policy goals more complex than in a system where one source of financing dominates. The greatest risks in a pluralistic health financing system are those of duplication, overlap, and inconsistency in functions and coverage. These problems can adversely affect both efficiency, because of duplication and competition for scarce human resources between different arrangements, and equity, because of limited risk pooling and lack of cross-subsidies among various income groups.

Reform of health financing has been high on the policy agenda of many countries for many years. In the 1990s, the introduction (or raising) of user fees was advocated, on the grounds that they offered a significant source of additional revenue, with their harmful effects on access being countered by exemption policies. Expectations are now less sanguine and opposition to user fees is widespread: Administrative difficulties of fee collection have been significant; ability to pay has been a significant barrier to use, and exemption schemes have not been effective; and even if there is ability to pay, people have been unwilling to pay if service quality does not improve. As a consequence, attention has turned to other ways of seeking to ensure that public funds are targeted to the poorest segments of the population (a topic considered in the next section, in the discussion of resource allocation).

The introduction of social health insurance was a core element of health system reforms in central and eastern Europe following the collapse of the Soviet Union, and has also been a key financing strategy in the rapidly industrializing countries of Southeast Asia. Social health insurance has also been of considerable interest in a number of African countries and in the

Caribbean. Most recently, the focus has shifted to the financing strategies appropriate for making progress toward universal health coverage, with continuing debate over the relative merits of insurance contributions and general tax funding as means to incorporate the informal sector into pooled funding arrangements (Tangcharoensathien et al., 2011).

Resource Allocation

The significance of processes of resource allocation in a health system has been clearly acknowledged only in the past two decades or so. Financing agents, such as government bodies at various levels (ministries of health and provincial offices), social insurance agencies, and private insurers, have always been one of the components of a health system, channeling funds from sources (taxpayers, payers of insurance premiums) to health services providers. A more recent trend is the emphasis on their role as active purchasers of services rather than as passive allocators of funds (Figueras, Robinson, & Jabowski, 2005; RESYST, 2014). For government bodies, such as ministries of health, this shift has required the creation of a clear distinction between their role as purchasers of health services and their role as providers of health services. For other financing agents, this separation of responsibilities requires them to take a much more active role in decisions about which services should be paid for and how they should be paid for.

The Purchasing Role

An emphasis on the purchasing role has arisen for a number of reasons:

- Integrated systems of purchasing and provision, such as those created in 1948 in the United Kingdom's National Health Service and existing in many similar public systems across the world, are thought to operate more in the interests of providers than in the interests of the general public and to lack incentives to be technically efficient. Highlighting purchasing as a separate function helps redress the balance and strengthen the power of managers.
- Patients, who in markets for other goods and services would be the purchasers, are believed—for the reasons laid out earlier—to be in a weak position to be active purchasers.
- In health systems such as that in the United States, where there has been considerable third-party payment (i.e., insurance agencies pay providers), cost escalation has been a major problem because patients choose their health provider, who is then reimbursed by the insurer. Although the insurers fund a large volume of services, traditionally they did not use this power to influence either the quantity or the price of services provided. The development of the managed care approach has led to an emphasis on the role of the purchaser as managing the provision of health services and ensuring that there are incentives for efficiency and cost containment (and also for equity, where the purchaser has public responsibilities). "Strategic purchasing" has included, for example, strict control over utilization, especially of specialists and of inpatient care; controlling drug costs by creating drug formularies and using generic medications; and disease prevention and management programs.

Purchasers may be of different types and sizes. The most limited role would be that assumed by an insurance agency, whose concerns are solely the patient group it cares for and ensuring it maintains its position in the marketplace. The most extensive role occurs when a purchaser has responsibilities for the health services of the population of a defined geographic area, and hence can plan services on a population basis. This is the position of public purchasers in health systems where the roles of purchaser and provider are distinguished. Agreements with providers define the services needed; these agreements may be formal legal contracts (and need to be, where providers are private bodies) or, alternatively, may simply be management agreements.

An important issue in the design of a purchasing role is whether there should be a single purchaser or a number of purchasers that compete with each other for clients. Private insurance agencies compete for clients, and it can be argued that this competition creates pressures for efficiency and services that meet client preferences. It remains an open question for tax-funded and social insurance–funded health systems whether a single purchaser or multiple purchasers is desirable. Reasons for caution about encouraging competition among purchasers include the following:

- If the system of allocating funds does not provide adequate compensation for meeting the costs of the health risks covered, the purchaser will have an incentive to avoid enrolling those individuals who are considered more expensive risks; this problem is known as cream skimming. In reality, it is difficult to predict the health service needs of a given population and compensate purchasers appropriately.
- It can be difficult for individuals to choose between competing purchasers: The more superficial

aspects of the promised package of health services may influence them, rather than technical quality, which is more difficult to judge. This would then lead purchasers to compete on the superficial aspects.
- If there are economies of scale in purchasing, these may be lost.
- Transactions costs—the costs of agreeing on arrangements for purchasing services—may be higher.

Whatever the number of purchasers, information systems are crucial in enabling purchasers to carry out their role. Government health systems traditionally have poor information on cost and quality, so new systems have to be developed to underpin the purchasing function. Insurance agencies often have much information since they are paying for services, but rarely exploit these data to monitor providers. Purchasers need information to act as active purchasers, including information on provider performance (e.g., waiting times, specific health outcomes where this can clearly be related to services provided) and adherence to standard treatment protocols (e.g., with respect to use of antibiotics).

Payment Mechanisms

A key influence on the success with which the purchasing role is carried out is the method chosen to pay providers, whether these be bodies responsible for services for specific populations, individual providers, or specific facilities. Although financial remuneration is not the only influence on provider performance, it is certainly a powerful one.

Authorities responsible for the provision of services to a specific population can be assigned a global budget. A key issue, then, is how that budget is determined. There has been increasing interest in using a resource allocation formula to calculate the budget appropriate to the populations of different geographic areas. The most well-known example is found in the United Kingdom, where funds have been allocated from the national level to regions using a formula that reflects the need for health services of each region, as proxied by indicators such as size of population and standardized mortality ratios (Department of Health and Social Security, 1976). Similar formulas have been used in South Africa and Zambia to allocate funds geographically. This approach is combined with various methods of paying providers and facilities within each geographic area, and can be the means to ensure funding distribution reflects equity goals.

Providers can be paid by salary, fee for service, capitation, or bundled payment (Porter & Kaplan, 2016). Salary represents a fixed annual payment unrelated to workload. Salary scales allow an individual's remuneration over time to be increased. Although in theory pay raises can be given on the basis of performance, in practice it is common for years of service alone to determine pay increases and promotions, thus undermining providers' incentives to work hard. Another problem with salary payment that is not inherent in the method is the level of the salary. In low-income countries, healthcare providers often have low salaries, further weakening their incentive to work hard or to work the required number of hours, and encouraging staff members to find additional ways of generating income, such as demanding informal payments from patients.

Additional elements can be added to salary payments to encourage good performance. These can be financial, as when an element of performance-related pay is included (e.g., a pay increase or end-of-year bonus can be based on a performance assessment), or nonfinancial (e.g., award of certificates or other ways of giving recognition to high performers).

Salary is the basis for remuneration in public systems, especially in hospitals and in privately owned facilities for nonmedical staff and even for physicians in some high-income countries. Although evidence is scanty, it is probably not uncommon in LMICs for at least some of the physicians in private hospitals to be salaried.

Fee for service has traditionally been the payment method for general physicians and specialists in a number of countries in continental Europe and in North America and Japan. It has also been adopted in some new social insurance schemes in Asia and eastern Europe. Physicians usually prefer this method of payment because it does not involve an employer/employee relationship—a factor that explains its persistence despite known problems with this payment mechanism. Where a financial agent pays the bill, there will be agreement on the fee schedule, which is usually negotiated with the medical association.

From a patient's perspective—particularly a patient covered by insurance—the fee-for-service payment scheme is attractive. It readily permits free choice of doctors, since payment can follow the patient. It encourages the doctor to be responsive to the patient, and there is no incentive to underprovide. However, from a purchaser's perspective, fee-for-service payment may encourage doctors to provide more consultations and more expensive procedures, especially where an ethical framework for medical practice is not strongly established. Administrative costs can be

higher because of the need to monitor claims, and some degree of fraudulent claims is inevitable.

Some adjustments can be made to fee-for-service methods of payment to address some of these problems. For example, the overall budget can be fixed, as in Germany, so that volume of services in excess of that budgeted for will cause the fee per item of service to fall. Alternatively, copayments can be required from patients, although there is little good evidence that these act as a constraint on physicians' behavior; indeed, copayments may simply render care unaffordable for lower-income groups in the population.

Capitation is the most common payment strategy for primary care services and involves a fixed payment per year per person registered with the provider. It may differ depending on the nature of the patient—for example, a higher payment may be provided for the elderly and children, reflecting their greater needs for health services. Capitation payment has been the traditional form of payment for general physicians in much of Europe, sometimes supplemented by extra payments to encourage particular aspects of primary care services (such as primary care teams) or priority services (such as preventive care).

This payment system supports continuity of care and an emphasis on preventive services, not just curative care; it makes the general physician a gatekeeper for hospital care, thereby encouraging the provision of services at the lowest possible level. The capitation payment scheme leaves the doctor substantially free to practice medicine and to organize the primary care service with little interference and with minimum administration. From the patient's point of view, capitation can ensure a personal relationship with a doctor and a personal medical record, although changing doctors may be difficult. However, because payment does not depend on the number of times a patient is seen, it can also encourage doctors to minimize the volume of services given to patients and to refer patients to the hospital unnecessarily, subject only to the need to keep patients sufficiently satisfied that they do not change doctors. Doctors may also try to avoid registering the more demanding and expensive patients. The extent to which this is a problem will depend on how much of the cost of services is covered by the capitation fee (e.g., whether drugs are paid for separately) and to what degree the capitation fee is adjusted for the risks of specific patient groups, such as the elderly.

Hospitals may be paid a fixed annual budget (often called a global budget) or in a variety of ways that reflect workload. Fixed budgets have traditionally been paid to public hospitals, but some countries have introduced them even for private hospitals that are paid by an insurance fund. Budgets are a highly effective means of cost containment and can provide a manager with great flexibility if discretion is allowed on line-item expenditures. However, there can be little incentive to have a high turnover of patients (since this increases costs) or to provide good-quality service. These problems can be addressed by good monitoring systems.

Payments to hospitals that reflect workload can be based on itemized bill, daily rate (including all recurrent costs), average cost per patient, case adjusted for diagnosis, types of services, or block and volume contracts. These payment models range from the most detailed—and therefore the most demanding and costly to administer—to the least detailed and the simplest to administer. All have their own particular advantages and disadvantages.

Payment by itemized bill has the same inherent problems as fee for service for doctors: It can encourage excessive procedures and hospital stays. Per diem rates discourage excessive procedures but encourage unnecessary stays. Average cost per patient discourages long length of stay but does not encourage technical efficiency. Case-based payment, particularly as developed in the United States with the diagnosis-related group approach, reimburses hospitals for the "average" case but provides an incentive to classify patients in more expensive groups or to shift patients out of the hospital earlier. Case-based payment is also information intensive and hence costly to administer. Bundled payment has developed to address the issues of case-based payment, notably by "bundling" all care needed for a particular episode in one payment, and making payment contingent on patient outcomes.

The introduction of contracts into the United Kingdom health system was accompanied in the early years mainly by block and volume contracts. In the former, a provider is contracted to deliver one or more services (e.g., acute hospital services) to a given population for a fixed sum—it is, in effect, a capitation payment. A block contract transfers financial risk to the provider, so it may encourage cream skimming and the provision of too few services. This type of payment, which is often risk adjusted to a certain extent, is increasingly being used in managed care arrangements and between social insurance agencies and providers, as in Thailand. In contrast, volume contracts are appropriate where the purchaser wishes to limit the number of procedures paid for (e.g., elective surgery). Purchasers can use these contracts to take advantage of economies of scale that can be achieved by larger units with high volume.

These many different payment methods provide a confusing range of options. The key issues relate to the risks of undesirable consequences; they are summarized in **TABLE 13-4**. In particular:

- What are the incentives to overprovide or underprovide services to patients within the facility? A key issue is whether the purchaser or the provider bears the financial risk.
- What are the incentives to be technically efficient?
- What are the incentives to exclude altogether certain types of patients?
- Given these incentives, what are the administrative costs of the payment system together with the monitoring required to prevent abuse?

This provides a rather crude basis for evaluating methods—not least because financial remuneration, although important, is not the only factor affecting the behavior of providers. The effects of a method in practice will also depend on the system and context within which it is introduced—for example, the extent to which the following characteristics are present:

- Purchasers or patients can change providers.
- Strict ethical standards are adhered to and monitored by the medical profession, thereby limiting cream skimming and both under-provision and over-provision of services.
- The media are active in publicizing cases of medical negligence.
- Consumers are well informed and able to exercise their right to choice effectively.

Because each payment approach has its advantages and disadvantages, which also depend on the context in which it is introduced, it is difficult to be prescriptive. In practice, some of the problems with any one method may be addressed by combining methods (e.g., using capitation payment but with additional fees for certain procedures). Perhaps the strongest conclusion that can be drawn is that fee-for-service payment should be avoided as the main payment approach. Ensor et al. (1997) concluded that providing care on a fee-for-service basis costs one-third more than using capitation, without substantial differences in health

TABLE 13-4 Key Payment Methods and Their Consequences

Payment Method	Unit of Services Paid For	Key Undesirable Consequences
Salary	Usually one month's work	Restrict number of patients and services provided
Fee for service	Individual acts or visits	Expand number of cases seen and service intensity; provide more expensive services and drugs
Capitation/block contract	All relevant services (e.g., primary care; hospital care) for a patient in a given time period	Attract more healthy registered patients and avoid less healthy ones; minimize contacts per patient and service intensity
Fixed budget	All services provided by a facility in a given time period	Reduce number of patients and services provided; keep patients in hospital longer
Daily rate	Patient-day	Expand number of bed-days (through longer stays or more admissions)
Case payment	Cases of different types	Expand the less serious cases seen; decrease service intensity; provide less expensive services
Bundled payment linked to patient outcome	Single payment, contingent on outcomes, for all care required to treat condition, regardless of who provides care and where	Lack of clarity over episodes of care for chronic conditions; discourage necessary specialty care

Data from Bennett, S. (1997). Health-care markets: Defining characteristics. In S. Bennett, B. McPake, & A. Mills (Eds.), *Private health providers in developing countries* (pp. 85–101). London, UK: Zed Books.

outcomes, and that fee-for-service payment for outpatient care is associated with 11% higher expenditures in OECD countries. Other points are that no payment method will work well if providers think they are seriously underpaid, and the more complex the payment method, the greater the need is for a sophisticated information system that organizes payment and monitors provider behavior.

Innovations in Resource Allocation

Many countries have introduced changes to traditional approaches to allocating resources and paying providers. One of the most common features of health system strengthening programs has been the introduction of a purchaser–provider split in public systems that were previously integrated. For example, in Thailand, the social security office acts as a purchaser on behalf of the insureds and accredits and monitors the hospitals that they use. Along with the specification of the purchaser's role has come an emphasis on contractual arrangements between purchasers and providers. At one extreme, these arrangements may be seen as no more than the formalization of a management relationship, as where annual contracts are agreed upon between the ministry of health and a regional health authority (Trinidad), or between a province and a district (South Africa, Zambia, and Zimbabwe). At the other extreme, the contracts may be awarded on a competitive basis and may be legally binding. Despite the popularity of this type of reform, its value has not been well established, and reforms have experienced considerable implementation difficulties, especially where they were accompanied by a policy to decentralize employment contracts of health workers.

Another development has been the use of outsourcing or contracts—usually with NGOs, though sometimes with commercial providers—to improve or expand service provision in contexts where governments function poorly or have limited capacity (Liu, Hotchkiss, & Bose, 2008). The experiments with contracting district health services in Cambodia are widely quoted, and similar arrangements have been tried in Afghanistan and Rwanda, for example. Contracting with NGOs has also been used widely to expand availability of disease-specific services such as HIV prevention and TB treatment.

Health system reforms have commonly involved changes to traditional modes of payment, although the nature of the reforms has depended on the starting point and can be severely constrained by powerful interest groups; hence, a great variety of reforms are apparent in practice. Although, in general, fee-for-service methods of payment are seen to be undesirable, countries such as those in eastern and central Europe that previously provided salaries to primary care providers have sought to raise remuneration levels and encourage greater productivity by using a mix of salary, fee for service, and capitation. Indeed, capitation appears to be one of the areas where there is the most experimentation worldwide. Traditionally an approach for paying primary care providers, capitation has been extended to pay for hospital services as well (e.g., in Thailand) and is the basis for payment in many managed care arrangements.

Global budgets for hospitals have been a feature in Europe under different funding regimes. Concern that they do not provide incentives for efficiency has led to the introduction of mechanisms that relate payment to measures of hospital activity, such as bed-days, cases, or even specific services. Some similar reform trends can be seen elsewhere; Thailand, Taiwan, and Korea have all tried case-based payments, with Thailand adopting the approach nationwide.

"Pay for performance" (also known as P4P and as results-based financing) to both individual workers and facilities has also attracted considerable interest. It can be distinguished from fee-for-service or case-based payment by its aim to use measures of performance rather than merely activity, though in practice this distinction may not be clear. Many individual studies have been done of various P4P schemes, and various systematic reviews are available as well. For example, Oxman and Fretheim (2009) concluded that there is good evidence that financial incentives targeting recipients and providers can be effective in the short term in achieving well-defined behavioral goals, such as increased provision of specific primary care services. There is less evidence that they can sustain long-term change. There is also concern, and some evidence, of unintended consequences, including reducing the provision of non-incentivized services and gaming of the system (e.g., false reporting).

Concern that the poorest members of a population often do not benefit from public funding has led to the use of various approaches to improve targeting, including geographic targeting through resource allocation formulae, focusing additional funding on specific programs targeted at populations with the least access, equity funds that reimburse health facilities for exemptions, social funds that often involve local communities in decisions on spending (World Bank, 2003, 2004), and vouchers or cash payments that channel purchasing power directly to those in need, such as vouchers for pregnant women that reduce the price of an insecticide-treated mosquito net, or

cash to pregnant women to help cover the costs of accessing safe delivery services. An evaluation of one of the world's largest financial incentive programs (Powell-Jackson, Mazumdar, & Mills, 2015) found that such cash payments to women in India were associated with increased use of maternity services, but not with reduced neonatal deaths, possibly because women predominantly sought care from faculties that were not equipped to handle complex cases.

In those countries introducing compulsory insurance and those engaged in reforming their existing systems, a key—and controversial—issue has been whether to encourage competition between insurance funds and to encourage choice of insurer. In Colombia and Argentina, for example, there is competition among insurers to enroll individuals in social insurance, with insurers compensated by a risk-adjusted capitation payment (Londoño & Frenk, 1997). A study in Colombia found some evidence of sickness fund selection based on health status, confirming fears that cream skimming can be a problem in the presence of competitive pressures on insurers (Trujillo & McCalla, 2004). In India, the huge RSBY scheme uses competitive bidding to identify the insurer that will manage the scheme at the district level; this insurer is then required to enroll eligible households within the district (RSBY, 2017).

A trend that is likely to accelerate in the future is the increasing prominence of healthcare companies interested in breaking into LMIC markets. Options for involvement include contracting with governments or social insurance agencies to manage health programs for particular population groups, covering groups that are allowed to opt out of social insurance arrangements, or simply taking advantage of the growing demand for private hospital care, especially in South and East Asia. These developments are addressed in more detail in the *International Trade and Health* chapter.

The specification of basic or essential packages of interventions, which purchasers require providers to make available, was first proposed in the World Bank's World Development Report 1993. This approach involves analyzing the burden of disease and the cost-effectiveness of interventions, so as to identify high-priority interventions that governments should ensure are universally available. It has been followed by the Disease Control Priorities Project, which in 2017 completed its third iteration. This project has introduced several new features, most notably systematic assessment of priorities for intersectoral interventions as well as health-sector interventions, and for the latter, allocation to five platforms—population-based care, community-level care, health center, first-level hospital, and referral hospital (Jamison et al., 2018). A "model" concept of essential universal health coverage has 244 interventions that provides a starting point for country-specific analysis of priorities. Of these interventions, a total of 104 are considered to constitute a model highest-priority package.

While the global analyses have been replicated in a number of countries, shifting allocation of public subsidies away from lower-priority services such as tertiary hospital care has proved politically difficult, and there is as yet inadequate evidence of the successful implementation of this approach to priority setting. Perhaps as a consequence, attention has turned to the institutions needed by countries to support the priority-setting process and embed health technology assessment processes in routine public decision making. Both NICE (the U.K. National Institute for Health and Care Excellence) and HiTAP (the Thai Health Intervention and Technology Assessment Program) have provided examples of how this aim might be achieved (Tantivess, Teerawattananon, & Mills, 2009).

Provision of Services

Health service providers in LMICs can be categorized into seven main groups:

1. Government-run health services for the general public (including the services of the ministry of health and those services coming from other government ministries, such as local government and education).
2. Services run by social insurance agencies for the insured and their dependents.
3. NGO services, including those run by church organizations and charitable groups.
4. Occupational healthcare providers (medical services provided by employers for their employees). This includes services for the armed forces and police, which come under government ministries. Universities may also provide services for their own staff.
5. Private, for-profit allopathic providers, both individuals and facilities.
6. Traditional systems of medicine, such as Ayurveda, homeopathy, and Chinese medicine; and traditional healers of various types, including traditional birth attendants.
7. The informal sector of drug peddlers and unqualified practitioners.

In general, the richer a country, the more organized and structured and the less diverse the system of health services provision. For example, over time

government-run services may be brought under the aegis of a single structure, as they were in the United Kingdom under successive rounds of reorganization; alternatively services of the ministry of health and social insurance agency may be amalgamated, as they were in Costa Rica. As government services and services for the insured improve, there is less reason for employers' health services to provide general medical care. Moreover, as regulatory structures strengthen, the informal sector becomes much smaller. Finally, as the availability and quality of prepaid health care improve, there is less reason for households to purchase care directly.

Information on the physical supply of health services in LMICs is sorely lacking, and indeed these data resources are much weaker than information on the demand side. At an aggregate level, for example, there is information on beds and health professionals. The number of hospital beds (acute and chronic) per 1,000 people ranges from 0.10 in Mali and Iran, to 13.7 in Japan, and the number of physicians per 1,000 people ranges from .01 in Liberia to 7.74 in Qatar (Index Mundi, 2017). But interpreting such data is difficult: The type and quality of health service inputs are varied, and there is no agreed benchmark for what constitutes under-provision or over-provision of services.

Another lens that can be used to examine the supply of health services is the level of use. This information is more readily available from country surveys, but difficult to summarize because health services comprise many different types of services aimed at different age groups. However, countries can be assessed by, for example, the extent to which groups with specific needs, such as women and children, have high levels of coverage of antenatal care, immunizations, and so on. The Countdown to 2015 (now the Countdown to 2030), for example, has systematically assessed country performance on health outcomes and services for women and children (Countdown to 2015, 2015), and WHO is now tracking universal coverage progress including basic hospital access and health worker density (ratios of beds and physicians to population).

One of the key issues in health services provision has been what is called the public–private mix—that is, the relative numbers and performance of providers in the public and private sectors and how the two sectors interact. McPake (1997) has suggested that there may be at least three different patterns. Among the lowest-income countries, the formal private, for-profit sector is small, but especially in Africa there is a rather larger NGO sector. The informal sector is large, consisting of unregistered allopathic providers, drug sellers, and a variety of traditional practitioners. Most formal health services are provided by the government, but health workers often have their own private practice.

In some LMICs, especially in Asia, the private, for-profit sector plays a much more important role in health services delivery; this constitutes the second pattern. For example, in India 70% of total health expenditures comes from private sources, and of this amount 89% takes the form of out-of-pocket payments (WHO, 2017). An estimated 93% of hospitals and 63% of hospital beds are privately owned, mainly by individual physicians (Peters et al., 2002). Large and concentrated populations may be one explanation for this pattern; another may be a longer history of Western health services and training of professionals, together with government health services that have never extended to provide coverage of the whole population. However, even in these countries, private provision is still concentrated at lower levels of the health system. For example, in India, private-sector providers are generally lacking at the tertiary care level, and the private sector provides 79% of outpatient care for those persons below the poverty line, much of it of low quality and provided by untrained providers including drug sellers.

McPake (1997) has also identified a third pattern of provision, in countries with rather higher per capita GNP. This pattern usually includes a major role for social insurance (funding services either through its own facilities, as is common in Latin America, or through mixed public and private providers, as is more common in Asia) and a private sector that is playing an increasingly important role in healthcare provision (certainly at the secondary level and sometimes also at the tertiary level).

Because the relative roles of public and private sectors have been a key policy question, there has been much interest in whether private providers are more efficient than public providers. Basu et al. (2012) undertook a systematic review of this issue in relation to the themes of accessibility and responsiveness; quality; outcomes; accountability, transparency, and regulation; fairness and equity; and efficiency. This review confirmed some existing views: Private providers had poorer medical standards of practice and patient outcomes, but patients valued their more speedy care and greater responsiveness. Efficiency tended to be lower in the private sector than in the public sector, in part because of incentives in the former to provide unnecessary tests and drugs. Public-sector services were more likely to suffer from lack of resources: equipment, drugs, and trained health workers. If the private sector is defined broadly, to include unlicensed

and uncertified providers, more care was obtained in the private sector than in the public sector; however, if unlicensed healthcare providers are excluded, the majority of people accessed public-sector care.

This review demonstrates the challenge of comparing the public sector with a private sector that is enormously diverse, both within a country and across countries. In India, for example, at one end of the spectrum are private hospitals delivering services of international standard; at the other end are unlicensed and unqualified practitioners using Western prescription drugs. In between are trained physicians and Western-style hospitals whose quality of care can be extremely poor (Bennett, 1997). Private clinics, although in theory run by doctors, in practice often depend on staff with little training because, in many countries, doctors will also have a public post where they spend at least some part of their time, as well as a stake in several clinics. Financial relationships between different types of facilities are also a concern in a number of countries; hospitals, laboratories, and diagnostic centers may pay general practitioners to refer patients to them or may pass a share of their fee to the referring physician.

While public-sector services show less extremes of performance, they also commonly demonstrate problems of inefficiency. While absolute lack of resources can limit their costliness, there is considerable evidence of poor resource use, such as low staff productivity and waste of drugs and supplies (WHO, 2010b). As in the case of private facilities, a variety of explanations can be posited for observed public provider inefficiencies, some of which do not relate to ownership per se. In particular, decision making may be centralized and staff at hospital level given little power to control resource use. Low salaries also contribute to poor performance, because they reduce staff motivation, and staff may need to spend time generating income in other ways to ensure an income adequate for survival.

Innovations in Service Provision

Initiatives to strengthen service provision have included decentralization, increasing competition and diversity of ownership, strengthening primary care services, and quality improvement.

Decentralization of management of services has been an almost universal theme for many years. At the national level, decentralization has taken the form of restructuring the role and functions of the ministry of health. For example, some countries have created executive agencies to take over management responsibility at the national level (e.g., Ghana), leaving the ministry to concentrate on regulation, policy, and monitoring. Some form of decentralization to intermediate and local levels is also a common theme. Most countries taking this tack have chosen to decentralize services within a hierarchical structure with the ministry of health at the top, although there are some notable examples of devolution of health to local government (e.g., the Philippines). Finally, decentralization to the hospital level is a common trend in countries with centrally funded, public systems of health provision (Mills et al., 2001). In the lowest-income countries, because of limits on management capacity, this reform may be confined to teaching hospitals, but in some countries, such as Indonesia, a wider range of hospitals have been made "autonomous" or "corporatized."

Competition between providers is also being widely promoted as a means to encourage efficiency, albeit with rather more caution and doubts about its effects than in the case of decentralization. Likewise, diversity of ownership is promoted as a means to increase competitive pressures, especially within poorly performing public systems of provision. African governments have been urged to give greater emphasis to NGOs. In a number of Southeast Asian countries, tax incentives have been provided for the construction of private hospitals (e.g., India, Philippines, Thailand), although from the perspective of the health sector as a whole there are considerable doubts about the desirability of this policy (Mills et al., 2001).

Strengthening the role of primary care has long been a theme in reforms in many countries, although often without substantial changes in resource allocation patterns. Comparative historical studies of countries that have seen considerable improvements in the health status of their populations, while spending only a relatively modest amount per capita, have highlighted the role that an effective primary care system played in these health gains (Balabanova et al., 2013). The recent emphasis on universal coverage has also focused attention on the critical importance of ensuing everyone has access at least to good-quality primary care and referral to a local hospital. The United Kingdom's reforms of the 1990s, which gave funds to primary care doctors to purchase other services, have aroused much interest, although efforts to create high-quality primary care services, with a gatekeeper role for the primary care provider, do not as yet appear to feature strongly in reforms in most LMICs, with the exception of Thailand. Policies haves focused on more incremental changes, such as integrating disease-specific services into primary care.

Included in many country plans have been measures to improve the quality of the services provided. In high-income countries, a range of approaches is being used, including evidence-based medicine, technology assessment, clinical guidelines, medical audits, quality assurance methods, and payment incentives. These are beginning to appear in less wealthy countries as well, but in the lowest-income countries more basic problems have been addressed, such as availability of drugs and supplies, improvement of staff skills, and maintenance of equipment.

Increasingly, human resources are being highlighted as an area where improvements are most needed. In many of the poorest countries, the number of trained health providers is grossly inadequate to provide even a basic package of services to the whole population. The international brain drain has also had a devastating effect on some countries (Cometto, Tulenko, Muula, & Krech, 2013). Brain drain is one symptom of a widespread problem in many countries whose health systems are characterized by low financial remuneration of health workers, low motivation, poor working conditions, and poor performance. To remedy this problem, it has to be tackled by action on a number of fronts. Promising approaches include greater use of nonphysician clinicians and community-based workers; improved working and living conditions; and support for circular migration, in which migrants are encouraged to return to their home country having gained valuable skills and experience elsewhere.

Countries have also sought to increase the influence of users and communities over health providers—to encourage patient-centered care, and to hold providers accountable for good performance—although there are few well-evaluated examples. In many of the poorest countries, local government structures are weak, ruling them out as an immediate means for ensuring local representation. Some reforms include the introduction of health or hospital boards with citizen representation. Often community involvement is seen to occur via NGOs rather than government health services. Little attention has been paid to patient rights, and patients tend to appear as the object of reforms, rather than as the subject.

Performance of Different Types of Systems

The previous sections have demonstrated that the design of health systems varies greatly between countries, particularly with respect to the following:

- The sources of funding (e.g., balance between general taxes, insurance contributions, and out-of-pocket payments)
- The number and degree of integration of financing agents and providers (are there large numbers of financing agents or one major one, such as a ministry of health or single social insurance agency; are financing agents and providers integrated or separated?)
- The ownership of providers (public; private, not-for-profit; private, for-profit)
- The extent to which the whole population of a country has access to the same services, or different groups in the population have different entitlements and use different providers

Perhaps not surprisingly, these marked differences have led to intense debate over whether any one design can be shown to perform better—in terms of criteria such as efficiency and equity—than any other design. Attention has particularly focused on differences between the U.S., Canadian, and British systems. The United States has historically relied heavily on voluntary insurance organized largely through employers, plus publicly funded programs for low-income patients and older adults. Canada has a compulsory national insurance system, whereas the United Kingdom relies largely on general tax revenues to finance its health system. Whereas most services in the United Kingdom are publicly owned, privately owned services play an important role in Canada and especially the United States.

TABLE 13-5 shows some key comparative indicators for the United States and Canada for 2009 or a similar time frame (Folland, Goodman, & Stano, 2013). As seen in the table, Canada had substantially lower per capita spending on health and GDP share than the United States. The United States spent 82% more on health care per capita than Canada, even though 19% of its population had no health insurance in 2009. Health status indicators such as life expectancy were better in Canada. Studies of waiting times and physician practice patterns show that in some instances Canadians got less health care or had to wait longer for services, but there were few observable effects on mortality and other outcome indicators.

Explanations as to why Canada spent less highlights two key differences between the U.S. and Canadian health systems. First, physician fees and hospital costs were significantly lower in Canada, no doubt because these charges are regulated. Physician fees are negotiated between physician associations and provinces, and hospital budgets are set by the provinces.

TABLE 13-5 Comparative Data on U.S. and Canadian Health Systems

Indicators	Canada	United States
Population, 2010 (in millions)	33.6	309.1
GDP per capita, 2010 (2010 $US)	39,400	47,200
Per capita health expenditure, 2009 ($US PPP)	4,363	7,960
Health spending, 2009 (% of GDP)	11.4	17.4
Percentage of health spending, 2008:		
Public expenditures	70.2	46.5
Inpatient care	27.3	24.5
Outpatient care	25.4	44.2
Pharmaceuticals	17.2	11.9
Acute care inpatient beds/1,000 population, 2007	1.8	2.7
Average length of stay, 2007 (acute care days)	7.5	5.5
Uninsured population, 2009 (%)	0.0	18.7
Out-of-pocket payments per capita, 2009 ($)	636	976
Private insurance expenditures on health, 2009 (%)	13.4	34.4
Life expectancy (years) at birth: females, 2005	83.0	80.4
Life expectancy (years) at birth: males, 2005	78.3	75.4

Note: Financial data are given in U.S. dollars.

Modified from Folland, S., Goodman, A. C., & Stano, M. (2013). *The economics of health and health care* (7th ed.). Upper Saddle River, NJ: Prentice Hall.

Second, the Canadian system had substantially lower administrative costs. Administrative costs accounted for an estimated 31% of total healthcare spending in the United States in 1999, as compared to 16.7% in Canada. Studies comparing expenditures in a larger number of rich countries have found that countries in which health services are financed primarily by private payments have the highest expenditures, but there is no evidence that this higher spending translates into better health status. Health systems where there is comprehensive risk pooling based on compulsory insurance or tax finance and covering the whole population appear to be more cost-effective (McPake et al., 2013).

Similar, detailed comparisons have not been done for LMICs. They can take two key lessons from richer countries:

- A significant public share in financing enables greater control over expenditures, meaning that higher population coverage can be achieved at lower cost.
- The greater the fragmentation of the health system and the greater the reliance on private insurance, the greater the proportion of total health expenditures consumed by administrative costs.

However, rich countries demonstrate that there are a variety of ways in which a strong public role and

coordinated health system can be achieved, and that the traditional model prevalent in many LMICs of an integrated public system financed from general taxation is only one approach.

Universal Health Coverage and Global Health Security

Two themes are currently dominating health systems concerns in LMICs, and are considered here because they concern the system as a whole rather than the individual functions that were considered separately earlier in this chapter. These themes are universal health coverage and global health security.

In 2010, the World Health Organization urged its members to aim to provide affordable universal coverage and access, defined as ensuring that all people can use the promotive, preventive, curative, and rehabilitative health services they need, of sufficient quality to be effective, while ensuring that the use of these services does not expose the user to financial hardship. This call to action accelerated a new global movement, which gradually became endorsed by all the major global players in global health. Universal health coverage was recognized in the SDGs, with goal 3, target 3.8, specifically assessing progress toward it. Existing initiatives relating to donor coordination and health system strengthening were built on to establish the International Health Partnership for UHC 2030. The WHO and World Bank support the global coordination of UHC 2030.

Universal health coverage requires countries to address health system weaknesses and limitations on a number of fronts. In terms of governance and regulation, two aspects are critical. First, governments need to commit to support the development of the social solidarity that is required to underpin a universal health coverage goal. Although universality is most likely to be achieved via a combination of arrangements and through prioritizing a limited range of services, it still requires governments to demonstrate a commitment to equity that has often not been visible in the past. Second, given that resources need to be deployed across both the public and private sectors, strengthening the regulatory role of government will be critical in enabling resources currently in the private sector to be deployed to support universal health coverage.

Financing poses major challenges given the cost of even a limited basic package of services. Jamison et al. (2018) calculate that achieving full implementation in 2030 (assuming 80% effective coverage) of their highest-priority package would cost $25–$45 (in 2012 dollars) per capita per year on top of what low-income countries are already spending; implementing the essential package would cost $57–$103 per capita. Even the high-priority package would require low-income countries to spend an additional 3% to 5.5% of their current gross national income on health care. In lower-middle-income countries, this increase would be 1.3% to 2.1%, a more affordable level.

While economic growth should help generate some of the resources, Ly et al. (2017) have identified a major challenge by analyzing the changes in the composition of health expenditures in sub-Saharan Africa from 1995—namely, the increase in government expenditures on health since 1995 has not been sufficient to compensate for the reduction of development assistance for health as countries "graduate" from low-income to middle-income status. Indeed, Ly et al. found that out-of-pocket expenditures increased during this transition. These authors argue for an approach to universal health coverage based on "progressive pragmatism," consisting of governments and donors agreeing on feasible targets based on the economic situation of the countries and donor finances, adapted to the sociopolitical realities at the national and global levels. Their list of recommendations for different countries demonstrates the changes also required in the resource allocation and provision functions to underpin universal health coverage, as well as in the broader economy:

- Middle-income countries that can afford the resource package (such as South Africa) need to focus on governance, service quality, reduction of income inequality, and strengthening of tax systems to reduce dependency on natural resources.
- Low-income countries that will soon graduate to middle-income status (such as Kenya) face the challenge of decreasing donor support before they have developed sufficient domestic resource mobilization strategies. Apart from agreeing on transitional amounts of external funding and improving domestic resource mobilization, these countries need to address issues of insurance pool fragmentation, management capacity, and the delivery of cost-effective, high-quality services.
- Low-income countries that will not be able to afford an essential package of services by 2030 (such as Madagascar and Sierra Leone) will still rely on donor financing, but should focus their attention on economic growth.

The second theme is that of global health security. During the 64th General Assembly in 2011, WHO

adopted a resolution to strengthen national health emergency capacities and health system resilience. Threats to health include emerging infectious diseases, human-made and natural disasters, and conflicts. There is increasing recognition that to respond to health emergencies effectively, a health system needs to be resilient (Kruk et al., 2015). In a review of health system resilience, Bayntun et al. (2012) found that each of the health system building blocks includes elements to build resilience, but also important aspects that have not been considered. For instance, while there has been recognition of the importance of training health workers on disaster management, less attention has been paid to establishing the commitment and ensuring the welfare of health workers during such events. Health workers are at high risk of infection in pandemics, for example, and need to be reassured that they will have access to the right equipment, prophylaxis, and treatment. Other areas that need improvement include incorporating ethical decision making into leadership and governance structures, improving the use of information systems and communication, carefully considering the suitability of a mass vaccination campaign, having clear financing policies as part of disaster preparedness plans, investing in community preparedness capabilities, and safeguarding medical records.

Despite these commitments and needs assessments, the health systems of the three countries most affected by the 2013–2016 Ebola outbreak (Sierra Leone, Liberia, and Guinea) were weak and underfunded (Kieny, Evans, Schmets, & Kadandale, 2014). Most external funding was given to support HIV, malaria, TB, and maternal health, with insufficient investment in health system capacity. Their health systems' weaknesses had devastating consequences not just for the three countries' capacity to diagnose and treat infected individuals, but also to cope with routine work such as deliveries, malaria, and chronic conditions.

A group of experts, reflecting on the aftermath of the Ebola outbreak in West Africa, conceptualized health security as both collective security (epidemics crossing national borders) and individual security (access to safe and effective health services, products, and technologies) (Heymann et al., 2015). In particular, the authors pointed to the importance of addressing the quality of drugs, better allocation of resources, and management of migration, and called for global action in achieving universal health coverage. Health security and concepts of resilience are addressed in greater detail in the *Public Health Infrastructure* chapter.

Conclusion

This chapter has outlined the main components of health systems in LMICs. It has focused mainly on the healthcare system, with little attention (due to lack of space) given to the sectors that supply resources to the health system (such as education and training institutions, and the pharmaceutical, medical supplies, and medical equipment industries) or to broader influences on health, such as government policies on smoking, alcohol consumption, and transport—all of which have major impacts on health. Other chapters of this text provide complementary material that addresses those topics.

The key functions of health systems are governance and regulation, financing, resource allocation, and health services provision, and the key actors as the government, populations, financing agents, and providers. Although these core elements can be identified in all systems, the number of bodies involved in each one, and the way they relate to each other, differs enormously in practice, making it difficult to draw clear conclusions on whether any one arrangement of functions and actors is better than any other.

The key problems of health systems in LMICs can be summarized as follows:

- In many low-income countries, resources and funds are grossly inadequate to provide even a basic level of care for the population, with a number of sub-Saharan African governments spending less than $20 per capita on health services.
- Levels of health produced by health systems are often lower than what is technically possible.
- Many activities funded by the public sector are not cost-effective, and coverage of interventions that are highly cost-effective is inadequate (Jamison, 2015). Conversely, too high a share of the budget is spent on hospital care, especially higher levels of hospital care.
- Health systems operate with low or variable levels of technical efficiency. Studies of facility costs invariably show great variation in costs across similar types of services, to an extent that is not easily explained by differences in quality but is more likely to be due to problems of managing resources.
- Quality of services is poor in public facilities, especially in the poorer countries where funds are limited, health service inputs are in short supply, equipment is poorly maintained, and staff are poorly paid and hence poorly motivated; staff are often criticized for their lack of courtesy to

patients and lack of responsiveness to their needs. Many private services are also often of low quality and almost completely unregulated.
- The possibilities for health interventions created by technological developments place ever-increasing demands on limited funds, accentuating the need for governments to consider ways of setting priorities and defining limits on which services can be provided.
- New problems, such as the growing importance of chronic diseases, are putting even greater pressure on health systems.
- Numbers of healthcare workers are grossly inadequate in most countries, and their unequal distribution means that rural services have even worse staffing levels.
- Most LMICs fare poorly in terms of both equity of access to health services and equity of payment for services, with a few notable exceptions. Poorer households commonly use health services less frequently, especially in rural areas where access is more difficult and expensive, and spend a much higher proportion of their income on health services, partly because public subsidies do not meet their needs well.

In recent years, health systems have been characterized by the following trends:

- An emphasis on the regulatory and enabling role of the state
- An emphasis on increasing public control over sources of funding and increasing risk pooling
- More explicit prioritization of which services can be financed and provided, especially by the public sector and in terms of cost-effectiveness criteria
- A desire to improve targeting of public subsidies to those persons most in need of healthcare services
- A greater role of the private sector, especially in the provision of health services
- Greater decentralization of the management of provision within the public sector
- Creation of arrangements that encourage competition between providers, in an attempt to improve efficiency and quality
- Greater emphasis on the role of consumers and patients, as informed purchasers, in patient-centered care, and as citizens to whom providers should be accountable

A 2011 study by the OECD concluded that "there is no single type of healthcare system that performs systematically better in delivering cost-effective health care, as both market-based and more centralised command-and-control systems have strengths and weaknesses. It seems to be less the type of system that matters, but rather how it is managed" (p. 221). However, there is a tendency for ideology rather than good empirical evidence to drive reform policies. While values do and should play an important role in decisions relating to health systems, the relatively limited empirical evidence on how best to improve the performance of health systems makes it challenging to resolve ideological arguments by reference to evidence. Moreover, reforms affect the position of powerful interest groups, which are likely to mobilize to block change. Far greater understanding is needed of the best ways both to introduce reforms and manage these various interests.

Discussion Questions

1. How can the concepts of efficiency and equity be used to assess the performance of a health system?
2. Access to health care can be viewed as similar to access to other goods and services—that is, as dependent on an individual's success in gaining or inheriting income, or as a right of citizenship that should not depend on individual income or wealth. Debate the relative merits of these two positions.
3. What should be the respective roles of the government and the private sector in the health system of a LMIC of your choice?
4. What are the relative strengths and weaknesses of the main financing sources in a LMIC of your choice?
5. Outline the pros and cons of pay-for-performance mechanisms.

CHAPTER 14

Public Health Infrastructure

James Whitworth, Siobhan Leir, Sakib Rokadiya, Osman Dar, and David L. Heymann

Introduction

Infrastructure is "the basic services of social capital of a country, or part of it, which make economic and social activities possible" (Rutherford, 1992). In the context of public health, infrastructure can be described as "formal and enduring structures that support public health, having both tangible and intangible aspects and existing inside and outside the government sector," comprising three main elements (Powles & Comim, 2003):

1. *Institutions* and institutional capacity (encompassing both state and nonstate actors) appropriate to predict, prevent, and respond to health problems:
   - Public health activities require legal and regulatory frameworks to enforce public health measures, coupled with the broader contribution of health-related civic organizations.
   - Public health institutions must have the capacity to monitor and respond to changing patterns and determinants of disease. For example, infectious disease surveillance requires appropriate laboratory facilities to identify pathogens.
2. *Knowledge*, as acquired and put to use both by the general population and by professionals:
   - The capacity of a country to take up and apply knowledge is a powerful predictor of mortality decline. Countries must devise systems to harness and effectively implement global technological and intellectual developments.
   - A capable and qualified health workforce is a crucial component of a strong public health infrastructure. The quality of vocational and research training in public health disciplines is a key determinant of staff competency. The ability of professionals to acquire and assimilate the latest knowledge and developments in public health—increasingly via the use of digital technologies—also determines their effectiveness.
   - A well-informed and well-educated general population brings health benefits by contributing to changes in behavior.
3. *Commodities:* Resources or physical infrastructure
   - For example, diagnostic tests, effective sewers, and safe water supplies.

Perhaps the most widely accepted definition of public health was provided by Donald Acheson in the 1988 report on Public Health in England: "Public health is the science and art of preventing disease, prolonging life and promoting health through organised efforts of society." This definition captures the hallmarks of modern public health theory and

practice—an emphasis on collective responsibility for health and the key role of the state, a population-level perspective, a concern for the underlying socioeconomic determinants of health and disease linked to an emphasis on prevention, and an underscoring of the notion of public health as a multidisciplinary subject (Beaglehole & Bonita, 2004). Successfully translating public health theory into practice requires the establishment of all three main elements of strong and reliable public health infrastructure as outlined previously.

A robust public health infrastructure provides part of the necessary foundation for a well-functioning health system. The World Health Organization (WHO, 2000) has defined health systems as encompassing all activities whose primary purpose is to promote, maintain, or restore health. This broad definition captures both formal *healthcare services* focused on personal healthcare and *public health capabilities* focused on promoting health and preventing sickness. The public health branch of a health system, which is the focus of this chapter, has been defined as "all public, private, and voluntary entities that contribute to the delivery of essential public health services within a jurisdiction" (Centers for Disease Control and Prevention [CDC], 2014). It is important to distinguish between the two components of a health system, yet one must also understand that both must work effectively and synergistically to give rise to a well-functioning health system. These two components are inextricably linked. To illustrate, in the case of an infectious disease outbreak, a healthcare system without the support of strong public health capabilities will lack the ability to monitor disease trends and predict impending threats and, therefore, will be unable to plan and mobilize the response required (Heymann et al., 2015). Conversely, a public health system without strong primary and secondary healthcare services lacks both the "radar screen" to pick up the initial cases and the delivery system to execute an effective response (Commission on a Global Health Risk Framework for the Future, 2016). Thus, both sets of services and capabilities are necessary to address public health threats. Indeed, healthcare systems require the flexibility to be scaled up in times of crisis. Meaningful investment in both health system branches is critical; however, in most countries, healthcare services—preventive, curative, and palliative interventions—account for the bulk of expenditure and activity (WHO, 2000). As discussed in the "Strengthening Public Health Systems" section of this chapter, it is generally agreed that there is a need to seek a better balance.

The WHO framework describing health systems in terms of six core components or "building blocks"—that is, service delivery, health workforce, health information systems, access to essential medicines, financing, and leadership/governance (WHO, 2010)—does not help ensure that public health receives the appropriate attention. Indeed, it obscures the dynamic links between each component. It also fails to acknowledge the differences between the healthcare and public health branches of a health system, suffers from the lack of a community focus, and does not address either the underlying social and economic determinants of health or the role of non-health-sector actors.

Adoption of the Sustainable Development Goals (SDGs) by the United Nations in 2015 presented an opportunity to develop an ambitious agenda for global health system reform grounded in intersectoral cooperation, resilience, human rights, and country ownership (Schäferhoff, Suzuki, Angelides, & Hoffman, 2015). The SDGs place people at the center, and one goal (SDG 3) relates explicitly to health: To "ensure healthy lives and promote wellbeing for all at all ages" (United Nations, 2015). Recognizing the broad determinants of health, attainment of the health targets contained within SDG 3 is dependent not only on actions within the health sector, but also on economic, social, educational, and environmental factors. The field of public health practice is well placed to address these complex, multidisciplinary challenges. Indeed, it can be argued that each of the 17 SDGs has significant public health implications; thus, the SDGs can be interpreted as an agenda for public health to create the conditions in which people can be healthy (Bellagio District Public Health Workshop Participants, 2016; Fried, 2015).

Chapter Outline

In this chapter, we take a systems approach first to define essential public health functions, and then to review current practice and initiatives to strengthen the public health capabilities of health systems in low- and middle-income countries (LMICs). This discussion includes universal health coverage; global, regional, and community-based initiatives; laboratory capacity; human resources; and consideration of responding to disasters and emergencies. We then examine the International Health Regulations, the Global Health Security Agenda, and Joint External Evaluations. These derive from a public health perspective of *health security*, whereas the early sections of the chapter assume a *human rights* perspective. Most of the new funding for public health in recent years has been focused on these health security initiatives, and this is where much

of the progress in strengthening public health infrastructure has been seen.

Essential Public Health Functions

Public health requires effective action by many different organizations and players at all levels of governance, whether local, national, or international. While the balance of responsibility will vary by context, the basic functions or services that must be assured in every locality remain broadly constant. The "10 Essential Public Health Functions," first described by the CDC in 1994, serve as benchmarks for the activities that all public health agencies should undertake, and are organized under the three core functions of public health: assessment, policy development, and assurance (CDC, 2014). These functions, which are listed in **EXHIBIT 14-1**, are discussed in more detail in the remainder of this section. The consensus is that countries and regions should adapt this list to produce a set of context-specific essential public health functions based on local stakeholder input (Bettcher, Sapirie, & Goon, 1998; Bishai et al., 2016).

It is imperative that public health services monitor and measure the health status of the community they serve. An accurate and periodic assessment of the population's health through surveillance of disease and risk factor trends underpins the promotion of health and prevention of sickness. This may involve the use of a variety of methods and technologies to collect, store, interpret, and communicate data. Effective monitoring and analysis of trends allow for the timely identification and investigation of potential health threats. Further, a functioning health information system allows for future health needs to be anticipated, thereby enabling preventive measures to be implemented. The ability to respond effectively to an emerging health problem rests upon the availability of quality diagnostic services, including laboratory capacity, and appropriate action plans to address major health threats. Mechanisms should also be in place to disseminate raw data and research results that may have value in combating the health threat. This sharing of information facilitates a coordinated response and helps to ensure that any actions taken are informed by the evidence.

Public health activities cannot function effectively without community participation and buy-in from an informed, educated, and empowered population. A key component of the public health infrastructure, this support may be established through the implementation of initiatives to build knowledge and skills and by promoting the adoption of behaviors associated with favorable health outcomes. It is also necessary to stimulate the community to take appropriate actions to address health issues and ensure conditions present in the community are conducive to good health. Communities can be engaged in this way through the mobilization of formal or informal community partnerships to support public health. Education at the individual and community levels is critical, as many public health problems are associated with human behaviors and lifestyles.

EXHIBIT 14-1 The 10 Essential Public Health Functions

Assessment

1. Monitor health status to identify and solve community health problems.
2. Diagnose and investigate health problems and health hazards in the community.

Policy Development

3. Inform, educate, and empower people about health issues.
4. Mobilize community partnerships and action to identify and solve health problems.
5. Develop policies and plans that support individual and community health efforts.

Assurance

6. Enforce laws and regulations that protect health and ensure safety.
7. Link people to needed personal health services and assure the provision of healthcare when otherwise unavailable.
8. Assure a competent public and personal healthcare workforce.
9. Evaluate the effectiveness, accessibility, and quality of personal and population-based health services.
10. Conduct research for new insights and innovative solutions to health problems.

Reproduced from Centers for Disease Control and Prevention. (1994). *The public health system and the 10 essential public health services.* Retrieved from https://www.cdc.gov/stltpublichealth/publichealthservices/essentialhealthservices.html

The formulation and enforcement of sound plans, policies, laws, and regulations are essential to support public health efforts, guide public health practice, and protect health. For example, these may include emergency response plans, policies mandating the reporting of highly transmissible diseases, or the regulation of environmental hazards. The review, evaluation, and revision of current regulations and laws should be conducted regularly as appropriate. Compliance efforts and enforcements should also be supported as needed. It is important to be aware that influencing politics, and thereby policy making, is an essential function of public health.

Actively linking people to health services and assuring the provision of healthcare when it might otherwise be unavailable or difficult to access are paramount given the health inequalities evident within every society. Achieving this goal requires identifying barriers to care, facilitating entry into a coordinated system of clinical care, assuring ongoing care management, and providing appropriate and targeted health information for at-risk population groups. As health disparities, particularly with regard to communicable diseases, can affect society as a whole, there is a pragmatic as well as ethical rationale for addressing health inequalities at national and international levels.

Central to the operation of an effective public health system is a competent public and personal health workforce. To assure such a workforce is available, health workers must be assessed regularly, standards maintained (e.g., through licensing requirements), and continual education provided, including supporting the development of leaders with the vision essential to ensure the health of society and the implementation of innovative public health measures. Linked to this element is the need for ongoing evaluation of the effectiveness, accessibility, and quality of health services.

Research is critical to the advancement of public health, as this is the way in which we refine current interventions and practices, and identify, monitor, and support the development of innovative solutions, incorporating cutting-edge technologies to address health issues. Given the explosive growth in the volume and complexity of data generated by health and other systems, new strategies and methods will be required to manage and analyze the massive amounts of data to glean insights of public health importance. It is therefore essential that public health practitioners continue to push the frontiers of science and technology to develop sophisticated research strategies. Subsequently, it is critical to ensure that such research knowledge is disseminated to and applied by public health practitioners and policy makers. Facilitating linkages between researchers and public health practitioners and policy makers is important to ensure the timely translation of research advances into health policy and practice.

It is worth noting that items 7, 8, and 9 in Exhibit 14-1 all refer to a healthcare system, recognizing the aforementioned interlinkage between public health activities and healthcare services. All 10 items link directly to, and are dependent on, the existence of an effective public health infrastructure.

Strengthening Public Health Systems

Currently, healthcare systems (medical services focused on treating the sick) are given priority over public health systems (services responsible for protecting people from becoming sick) all over the world (WHO, 2000). In other words, treatment tends to crowd out prevention. However, there is a broad consensus among public health experts that improving and maintaining population health cannot be achieved through a health system that focuses predominately on the sick. While a sickness-based system is necessary, it is not sufficient to identify and treat cases of high-burden conditions such as coronary heart disease, tuberculosis, and cancer. To anticipate evolving health threats and organize a timely response, human resources must be devoted to the monitoring and analysis of epidemiological data. In this sense, the public health system acts as the first line of defense against health crises, such as outbreaks of infectious diseases.

The Economic Case

Despite its crucial role, public health remains acutely under-resourced in most parts of the world. Being adequately prepared for future health threats has significant economic benefits as well as the obvious health benefits. To illustrate, the Commission on a Global Health Risk Framework for the Future (2016) estimates that an extra $4.5 billion per year is required to strengthen global and national preparedness and response efforts just to combat epidemic diseases. This figure includes expenditures for strengthening national public health systems, financing global coordination and contingency efforts, and funding for research and development.

To put this figure into perspective, the World Bank has estimated the cost of a severe pandemic (i.e., one on the scale of the 1918 influenza pandemic, which killed between 50 million and 100 million people in a

global population of less than 2 billion) at more than $3 trillion, or 4.8% of global gross domestic product (GDP) (Jonas, 2014). Even this figure could be an underestimate: Aggregate GDP losses for Sierra Leone, Guinea, and Liberia in 2014 and 2015 as a result of the Ebola epidemic are estimated at more than 10% of those countries' GDP (United Nations Development Group, 2015; World Bank, 2014). Indeed, scenario modeling conducted by the Commission on a Global Health Risk Framework for the Future suggests that during the 21st century, global pandemics could cost in excess of $6 trillion, with an estimated loss of more than $60 billion per year.

The economic impact of infectious disease outbreaks is expected to increase in tandem with greater human and economic connectivity, as transnational supply chains, increased travel, and access to communication technologies facilitate the spread of the pathogen itself, and of fear (Commission on a Global Health Risk Framework for the Future, 2016). The latter point is particularly important: Most of the economic impact of outbreaks stems not from mortality or morbidity, but rather from behavioral changes driven by fear of infection (Burns, van der Mensbrugghe, & Timmer, 2008). In turn, this fear is driven by a mix of heightened awareness and ignorance. For example, the 2015 outbreak of Middle East respiratory syndrome (MERS) in South Korea caused widespread panic and resulted in a substantial change in consumer behavior (World Bank, 2017a). The leisure and entertainment sectors were particularly hard hit: Cinema visits dropped by 52% on a year-on-year basis in the first two weeks of June, and tourism fell by 41%. Indeed, in June 2015, the consumer sentiment index compiled by the Bank of Korea dropped below the neutral 100 mark for the first time since 2012, signifying a deteriorating economic outlook. This highlights the need to strengthen public health systems: A healthcare system alone is not configured to address these social issues, whereas the public health system is well positioned and equipped to allay public concerns and address any misconceptions.

Estimating the economic costs of an outbreak and the savings accrued by investing in strong public health systems is fraught with challenges and uncertainties. However, investing in public health systems for outbreak preparedness is hardly wasted money: Strengthening the core foundations of public health and primary care systems are crucial to achieving many other health objectives (Commission on a Global Health Risk Framework for the Future, 2016). For example, a robust surveillance system and improved laboratory diagnostic capabilities will help health systems tackle endemic diseases such as malaria and tuberculosis, as well as noncommunicable diseases. Underinvestment in these core capabilities, in contrast, puts a country at perpetual risk of disaster and, because infectious diseases do not respect national borders, leaves everyone in the world vulnerable. There is therefore a strong economic case for investing in public health infrastructure at all levels of governance.

Universal Health Coverage

One of the targets contained in Goal 3 of the SDGs is to achieve universal health coverage (UHC) (United Nations, 2015). UHC is a broad concept that can be most simply defined as all people receiving the essential health services they need, without suffering financial hardship (WHO, 2013). Today, an estimated 400 million people lack access even to essential health services (WHO & World Bank, 2015). Every year, approximately 100 million people—more than 60% of whom reside in India alone (Berman, Ahuja, & Bhandari, 2010)—are forced into poverty as a result of healthcare-related fees, with a substantial number choosing to avoid seeking medical advice entirely because they do not possess the financial means to do so (Dar, Buckley, Rokadiva, Huda, & Abrahams, 2014; Mills, 2014). It is estimated that investments to expand services toward UHC could prevent 97 million premature deaths globally between now and 2030, and add as much as 8.4 years to life expectancies in some countries (WHO, 2017d). These health gains tend to be greater in less developed countries, and accrue predominantly to the poorest population groups.

Along with these health gains, the achievement of UHC can bring significant economic and political benefits. Politicians have recognized the role of UHC in maintaining social order and strengthening national security by improving the social solidarity of the population (Heymann et al., 2015; Nicholson, Yates, Warburton, & Fontana, 2015). Uncertainties associated with the financial consequences of poor health and inequitable access to care represent significant welfare losses to populations, sometimes giving rise to civil unrest. For example, the primary motivation for the Chinese public health reforms undertaken in 2009 was to ensure "a harmonious society" (Cheng, 2008).

On a practical level, UHC can be achieved only within the context of a strong health system. Thus, the pathway to UHC necessarily requires a fundamental strengthening of a country's health system, including the development of a skilled and motivated healthcare workforce and a supply of, and access to, medicines and equipment (Nicholson et al., 2015).

UHC is integral to the achievement of the goals of global health in general. Given the interconnectedness of the world today, the availability of accessible and universal health services in all countries is a crucial first line of defense against global health threats (Heymann et al., 2015). The emergence of many infectious diseases of international concern (e.g., Ebola and artemisinin-resistant malaria) have occurred in settings without UHC and, therefore, without health systems that are able to effectively perform the essential public health functions or deliver medical services. Given the weakness of their preexisting health infrastructure, such countries are ill prepared to cope with public health emergencies, which fuels the spread of disease and its resulting death toll. Inadequate health coverage also encourages people to travel across borders to seek care in better-serviced countries, thereby increasing the potential for infection to spread and posing social and economic burdens in recipient nations.

UHC is also integral to instilling community trust in health systems and subsequently influencing health-seeking behavior. If, for example, communities cannot access quality health services such as diabetes care or maternal services in normal, non-emergency situations, that failure erodes their faith and trust in the same systems when health authorities attempt to manage emerging health threats, such as Ebola. Ultimately, without the provision of horizontally integrated primary care—a key component of UHC—the health security threat of both communicable and noncommunicable diseases cannot be adequately mitigated.

UHC may also play a key role in the tackling of specific health issues—for example, antimicrobial resistance (AMR), which represents a growing global public health threat. Evidence has shown that out-of-pocket (OOP) health expenditures are strongly correlated with AMR in LMICs (Alsan et al., 2015). This association was found to be driven by countries that require copayments for antimicrobials in the public sector. It is suggested that this policy shifts demand from the public sector to the less well-regulated private sector, where supply-side incentives to overprescribe are greater and quality assurance less standardized. Such practices facilitate the development of AMR through overconsumption, inappropriate dosing, shortened therapy courses, and use of substandard or counterfeit drugs. Therefore, progress toward UHC—a key tenet of which is the implementation of robust financing structures to reduce OOP expenditures—may help to control AMR in LMICs. The *Pharmaceuticals* chapter covers AMR issues in greater depth.

Regional Initiatives to Strengthen Public Health Practice

Over the past two decades, WHO regional offices have led the majority of public health performance improvement efforts (Bellagio District Public Health Workshop Participants, 2016). Regions are generally characterized by countries with broadly similar epidemiologic features and health systems organization, and often share a common language, culture, and level of economic development. Consequently, it often makes sense to pool resources and expertise to design and implement regional-level health system strengthening initiatives.

Such initiatives have a number of advantages over global or national-level initiatives. First, through the development of collaborating centers and establishment of local task forces, initiatives can be tailored to regional priorities and, therefore, made more relevant than global initiatives. WHO regional offices also have the ability to convene international expertise and collaboration through regional international partnerships such as the Economic Community of West African States (ECOWAS) or the South Asian Association for Regional Cooperation (SAARC). This facilitates coordination and collaboration among the countries of that region, which is particularly important in the control of infectious diseases and for smaller or island nations that are unable to build sufficient capacity independently (World Bank, 2017a). The sharing of information, expertise, and specialist facilities is both more cost-effective (as it is less expensive to develop high-level expertise at the regional multicountry level rather than at the individual-country level) and strengthens preparedness and response activities. Examples of regional initiatives for preparedness include the Mekong Basin Disease Surveillance network and the Southern Africa Center for Infectious Disease Surveillance.

The development of regional partnerships also helps to build capacity in other areas. For example, Thailand is a regional leader in the field of workforce development, and delivers a number of training programs to its fellow Southeast Asian countries. Since 1998, Thailand has offered an International Field Epidemiology Training Program (FETP) to trainees from neighboring countries, and has facilitated the expansion of national FETPs throughout the region (Field Epidemiology Training Program, 2017).

In addition, regional technical meetings and conferences are regularly convened to share knowledge and experiences. Moreover, with regard to WHO operations, by implementing initiatives through regional offices and

by deploying local technical officers, member states may have more confidence in requesting technical assistance and may be more likely to take up the recommendations proposed (Bellagio District Public Health Workshop Participants, 2016).

For sustainability, it is critical to build institutional support for such regional initiatives and to ensure that regional platforms are well resourced—factors that have hampered past efforts (Bellagio District Public Health Workshop Participants, 2016; World Bank, 2017a). In addition, it is useful to promote collaboration and cooperation between regions. Many such collaborations are already in place; for example, efforts at public health practice improvement in Europe and the Americas have informed efforts to measure and improve practices in the Eastern Mediterranean (WHO Eastern Mediterranean Regional Office, 2017). However, cross-regional partnerships (and intraregional partnerships) could be facilitated with greater investment and support from global organizations such as WHO and the International Association of National Public Health Institutes (IANPHI) (Bellagio District Public Health Workshop Participants, 2016). This is particularly necessary in cases where political rivalries complicate or hamper collaborations between neighboring countries.

Strengthening Public Health Systems at the Community or District Level

Traditionally, centrally controlled national health systems and top-down vertical health programs have dominated the healthcare landscape. Consequently, efforts to strengthen public health systems have focused on central levels of government. More recently, the need to develop strong public health systems at the district or community level has been increasingly recognized.

While it is difficult to accurately measure outcomes associated with increased community engagement, many benefits from strengthening public health systems at the local level have been observed. By building community capacity and rural social capital, community participation enables more locally responsive health services to be developed, leading to improvements in health services quality, knowledge, and health-related outcomes, as well as providing local employment opportunities (Kenny et al., 2013; Kulig, 2011). Further, by marshaling local resources and local political will to address the root causes of poor population health, and by offering community members input and ownership of the decisions regarding their health, horizontally integrated public health programs often prove more resilient and sustainable than corresponding vertical initiatives (Alford, 2009; Sherry, Ghaffar, & Bishai, 2017). Increased resilience and sustainability of local health systems, together with a corresponding growth in rural economies and improved fiscal responsibility, is in the interests of the national government as well as the community itself (Alford, 2009).

Community perceptions, behavior, and compliance with control measures are key parameters in effective disease control (Heymann et al., 2015). The 2014–2016 Ebola epidemic clearly highlighted the importance of community engagement and empowerment in combating disease outbreaks, and community resistance to control efforts is considered to be a key factor responsible for fueling the spread of the virus (WHO, 2015c). For example, patients were often hidden from the authorities in their homes, contact tracing was complicated by lack of compliance, and strikes by local hospital staff and burial teams further impeded control efforts. This resistance stemmed, in part, from a lack of trust in the health authorities (as discussed later in Exhibit 14-3), coupled with inadequately resourced local health workers and a lack of consideration given to cultural beliefs and behavioral practices. Further, the management of the outbreak was largely taken out of the hands of the affected communities, with local faith- and community-based organizations—which often have a high reserve of trust and are able to address issues in a culturally sensitive manner—generally excluded from control efforts (Kennedy & Nisbett, 2015).

District health systems, which often serve as the first point of contact for patients, play a key role in infectious disease control. District-based surveillance systems that can rapidly detect an infectious disease outbreak at its source can make a critical difference in determining the course and scale of an outbreak (Bellagio District Public Health Workshop Participants, 2016). For example, patient zero of the Nigerian Ebola outbreak in 2015 was diagnosed within 24 hours of his entry at Lagos airport, and, serendipitously, the local health department was able to reassign a team of contact tracers that was already in place for the polio eradication program (Bellagio District Public Health Workshop Participants, 2016). As a result of this prompt response at the district level (and also an element of good luck), Nigeria's Ebola outbreak was quickly contained.

Another advantage associated with strengthening district- or community-level public health systems is, simply, due to the sheer number and variety of districts and communities in place in a country. In a

failed state, national-level strengthening efforts can be slow moving and ineffective. Nevertheless, successful communities may be found within failed states; thus, one may be able to accomplish at the subnational level what cannot be done at the national level (Sherry et al., 2017).

District-level public health systems face four key challenges (Bellagio District Public Health Workshop Participants, 2016):

- Lack of continuity of leadership
- Lack of visibility of public health work
- Lack of multisectoral involvement
- Lack of public health governance

A lack of continuity in leadership (both administrative and technical) is characteristic of centralized health systems or countries where political considerations dominate the health landscape. Central decision makers can transfer key district-level personnel with little or no consideration of the local situation and the interruptions to services that might result. Therefore, district-level health systems may be strengthened by decentralizing control, such that local public health units are managed and financed by an authority at the subnational level—for example, out of a governor's or mayor's office or by a local board of health. The central government may still provide guidance and technical support in terms of policies and strategic objectives, as well as supplementary funding for priority programs, but the basic operations should be under local control to assure continuity of leadership. Further, when public health units are part of the local governance structure, collaboration with local stakeholders is more easily facilitated.

To address the lack of multisectoral involvement in district-level health systems, an intersectoral local public health committee should be created (Bellagio District Public Health Workshop Participants, 2016). This provides a platform to link various sectors together, and facilitate collaborations in the planning and implementation of public health programs. Sectors involved may include agriculture, education, transportation services, and water boards, for example. Additionally, public health system strengthening efforts can be facilitated by linking public health practitioners to a community of practice, enabling the exchange of ideas and knowledge (Bellagio District Public Health Workshop Participants, 2016).

Community Public Health Platforms

Community platforms facilitate partnerships among health professionals, politicians, and community members, enabling information to be shared and local resources convened to support public health programs. The engagement of community members in health initiatives ensures that programs and data collection are aligned with the community's needs, that data are shared with the community to guide actions, and that such actions marshal all of a community's capital and human resources as well as public revenue. Community public health platforms have been defined as "the partnerships formed in order to assess and assure population health" (Sherry et al., 2017).

The ability of a community platform to improve health outcomes depends on a number of factors: engagement in power sharing, formation and maintenance of collaborative partnerships, deployment of multicultural- and gender-sensitive health workers for services delivery, incorporation of the voice and agency of beneficiary communities in research protocols, and facilitation of bidirectional learning (Cyril, Smith, Possamai-Inesedy, & Renzaho, 2015). Five key features integral to the development of effective community platforms have been identified (Sherry et al., 2017):

- Level of community engagement
- Health system context and role of the government
- Breadth of intersectoral partnerships
- Sustainability
- Leadership and platform structure that promotes integration across all partners

These, in turn, rely on access to data about health problems and health threats, the means and will to share data and control with community members, balance between delivering clinical services and preventing disease in whole populations, and advocacy to maintain community engagement against pressure to consolidate control (Sherry et al., 2017). **EXHIBIT 14-2** describes the environment and structures for community platforms in low-functioning (Haiti) and high-functioning (Indonesia) scenarios.

Laboratory Services and the National Reference Laboratory

A credible and accessible laboratory service (comprising both public health and clinical laboratories) capable of producing timely, reliable, and accurate results is a cornerstone of any country's health services capacity. Under the International Health Regulations, countries are required to develop the capacity to detect, investigate, and report to the international community public health emergencies, such as disease outbreaks (WHO, 2016b).

At present, the laboratory infrastructure of many LMICs remains weak, characterized by limited quality

EXHIBIT 14-2 The Functioning of Community Public Health Platforms in Haiti and Indonesia

Haiti

Haiti has suffered from decades of political, economic, and social instability, exacerbated by frequent natural disasters and disease outbreaks. Haiti remains the poorest country in the Americas, and is one of the poorest and most socioeconomically unequal countries in the world (World Bank, 2017d). It is dependent on external development assistance, with nongovernmental organizations (NGOs), faith-based organizations, and informal providers—all with varying agendas—dominating the healthcare arena. To illustrate the scale of external involvement, *prior* to the 2010 earthquake, an estimated 8,000 to 9,000 NGOs were working in the country (Zanotti, 2010). Health services are delivered in a fragmented and unregulated manner, with the Ministry of Public Health and Population relegated to a marginal role (Hill, Pavignani, Michael, Murru, & Beesley, 2014). The weakness of the state and reliance on development partners has created an environment in which external entities often drive priority setting and resource allocation (Sherry et al., 2017). Without effective government leadership, coordination among these entities and between sectors is poor. Lack of service integration and cooperation has led to further fragmentation and duplication of efforts (Hill et al., 2014). This has, in turn, made it difficult for communities both to engage meaningfully in the public health process and to hold the government accountable for health services quality. As such, communities often favor traditional medicine over "formal" healthcare providers (Hill et al., 2014).

Given that NGOs provide the majority of health-related services, a significant challenge for Haiti is the quest to create sustainable solutions. Addressing community needs requires a flexibility in agenda setting that not all NGOs possess. Nevertheless, several NGOs have been successful in building capacity in the areas of development, health, and education (Sherry et al., 2017). These NGOs had several factors in common (Zanotti, 2010):

- Local, Haitian origins
- Connected to a diverse international network of donors and not accountable to a single agency
- Focused on addressing local needs and the needs of the most vulnerable
- Sharing a vision that tied economy, politics, and human rights

For example, Partners in Health created an agricultural arm in 2002—Partners in Agriculture (Zanmi Agrikol [ZA])—which aims to tackle malnutrition (Zanotti, 2010). Along with providing emergency food supplies, ZA teaches Haitians agricultural best practices and provides farmers with tools and seed to cultivate their land. It also buys seeds back from them, thereby supplying families with the money needed to maintain a sustainable livelihood. In turn, excess seeds are saved and donated to other farmers for the following sowing season. This has created a positive expansion of access to locally produced food.

This case study illustrates how, in the absence of a strong and stable government, NGOs and donor agencies can promote (or hinder) the development of successful community platforms for health.

Indonesia

In 2005, the Lumajang district health office in Indonesia led the launch of the Gerbangmas movement—a platform for communities, public health authorities, and other government sectors to work collaboratively to achieve 21 indicators of concern. Only about one-third of these are traditional health indicators; the remainder address determinants of health such as poverty reduction, literacy, and waste management. This multisectoral movement has resulted in improvements in all indicators, and has proved to be sustainable even in the context of changing economic and political landscapes (Blas, Sommerfeld, & Kurup, 2011; Commission on Social Determinants of Health, 2008).

The development of the Gerbangmas movement stemmed from decentralization of the Indonesian health system, which allowed for peripheral innovation (Sherry et al., 2017). The district health office acted as the initial champion for the movement. It provided technical and financial support and coordination during the initial scale-up, through which stakeholders could collaborate around common goals, without competing for resources. As the initiative evolved, the district office relinquished leadership to an NGO.

The partnership structure of the initiative provided clear roles for each sector, with the creation of a common pool of funds that communities were able to draw on to invest in interventions in multiple sectors (e.g., the purchase of iodinated salt, food supplements for children younger than the age of 5 years, or family planning educational materials) (Blas et al., 2011). With the community at the center of the partnership (with power over program management and priority setting), a structure in which all sectors stood on an equal footing, and a common set of objectives to strive for, the Gerbangmas movement facilitated effective collaborations between sectors (Sherry et al., 2017). The district governor mandated that all community empowerment programs use Gerbangmas as an entry point, thereby reducing competition and preventing outside interests from affecting the success of the partnerships across sectors (Blas et al., 2011).

(continues)

EXHIBIT 14-2 The Functioning of Community Public Health Platforms in Haiti and Indonesia *(continued)*

The design of the Gerbangmas movement also ensured its sustainability. With resources, funding, and training provided by partnering organizations, the initiative did not depend on grant funds or external donor assistance. Further, the partnership structure improved the resilience of the platform, as it reduced reliance on any single organization or leader. The greatest hurdle to sustainability was the turnover of government officials, with the future of the initiative resting on each new district governor's approval in the subsequent 5-year plan. An approach to address this issue was to include the policy of Gerbangmas in the District Regulation, which was ratified by the District Legislative (Blas et al., 2011).

This case study illustrates that to establish a successful community platform that addresses the multiple social determinants of health, it is important to consider nonsectoral mechanisms that can accommodate multisectoral interests.

assurance and control protocols, insufficient funds, and a lack of standardized methods, suitably trained staff, and laboratory supplies. In many countries, the absence of networking mechanisms to link and coordinate laboratories has hampered data-sharing efforts and resulted in disconnected and unsupervised peripheral laboratories of dubious quality, which have negative implications for disease surveillance (Ndihokubwayo, Kasolo, Yahaya, & Mwenda, 2010).

A strong laboratory system is underpinned by a comprehensive national laboratory policy covering laboratory organization, structure, and coordination; staff motivation and retention (including training requirements and career development); integration of services; essential facilities, equipment, and maintenance; and biosafety and biosecurity (Ndihokubwayo et al., 2010). A national strategic plan should then be formulated to implement the national laboratory policy.

A national reference laboratory sits at the heart of an effective laboratory system, acting as a linchpin for surveillance, detection, response, and accurate diagnosis to guide treatment and prevention. This reference laboratory should set laboratory norms and standards, and participate in public health research and policy making. However, despite the threat from emerging and reemerging diseases, few laboratories in LMICs have capabilities for diagnosing highly infectious diseases. Indeed, many LMICs must ship specimens to other countries for confirmation, contributing to delays in suitable patient management and response to outbreaks (Ndihokubwayo et al., 2010). Thus, as part of the international public health infrastructure, it is critical to establish sufficiently staffed and well-equipped national public health reference laboratories that can operate as centers of excellence for laboratory services.

In addition to providing diagnostic services, the national reference laboratory should take responsibility for producing and distributing quality assurance programs to identify and address gaps in the quality of subnational laboratories. Engagement in quality assessment schemes could be linked to annual laboratory registration and renewal processes to incentivize participation. Further, to facilitate communication with and coordination of the national laboratory infrastructure, and to enable timely data sharing for purposes of surveillance efforts, laboratories at all levels of the health system should be linked through a network led by the central reference laboratory. To facilitate regional surveillance efforts, the national reference laboratories should also be connected and coordinated through a regional laboratory network.

The newly established Africa Centers for Disease Control (Africa CDC) has advocated that each African country should establish a national reference laboratory that can then be linked to form regional networks. In a first step toward realizing this goal, existing laboratories, including private laboratories, are being mapped to gauge how they might contribute to these networks. Recognizing that individual countries may lack the technological capabilities required to detect emerging threats, Africa CDC aims to establish five Regional Collaborating Centers, each equipped with laboratory and advanced diagnostic capacity to rapidly detect known and unknown pathogens (Nkengasong, 2017). These national and regional laboratory networks should also connect public health and clinical laboratories with their animal health counterparts under the One Health approach.

There is also a need to strengthen the laboratory workforce at all levels, including ensuring that technicians are trained in the operation and preventive maintenance of laboratory equipment. Unfortunately, many LMICs have the capacity to provide only basic laboratory training, greatly limiting the level of technology available on an in-country basis. To fill this gap, a number of initiatives have been set up to support the training of laboratory personnel in LMICs. For example, the Pacific Paramedical Training Centre (PPTC) based at Wellington Hospital, New Zealand, was established to support laboratories in Pacific Island countries through training and development assistance (PPTC, 2017). Since 2006, the PPTC and WHO have jointly provided distance-learning courses, including an online diploma in medical laboratory

science for Pacific laboratory workers. This course is delivered through the Pacific Open Learning Health Net (POLHN), an e-learning platform established in 2003 to deliver online learning and continuing professional development for geographically dispersed and remote health workers in the Pacific (POLHN, 2017). Currently, the platform links and provides thousands of free courses to approximately 30,000 health workers from 15 Pacific island countries. The PPTC also provides a Regional External Quality Assessment (REQA) program to help laboratories identify areas of weakness and provide solutions to improve the quality of service. Training programs such as these, and the availability of other opportunities for career development, also act to keep laboratory staff motivated, so they help LMICs retain qualified personnel in their national systems.

Another strategy to improve the delivery of quality laboratory services involves establishing or strengthening monitoring and evaluation systems with targets and measurable indicators. Monitoring and evaluation efforts should take into account activities such as adherence to standard operating procedures and safety guidelines, quality assessment activities, laboratory performance and workload, and utilization of supervisory tools.

These capacity-building activities require adequate and sustainable funding. Public health laboratory services should be funded through government budgetary provision. In LMICs, additional funding may be required through donor partners and income-generating activities. The integration of public health laboratory programs through national and regional networks can also help to alleviate financial issues through the sharing and optimal use of available resources (Ndihokubwayo et al., 2010).

Diagnostic Capability

Capacity to detect known pathogens, alongside rapid sharing of international knowledge, is key for detection of novel disease. For newly emerging pathogens, there is a need not just for reference laboratory diagnostic services with standardized testing, but also for rapidly deployable tests, ideally for point-of-care (POC) use within affected communities (POC testing is also covered in the *Innovation, Technology, and Design* chapter).

At the laboratory level, multiplex platforms that can test simultaneously for a wide array of pathogens as well as the use of whole-genome sequencing are likely to play an increasing role in future diagnosis, although their realization will require advances in computational power (Hasin, Seldin, & Lusis, 2017). For completely novel pathogens, reference microbiology services will need to offer more traditional techniques such as viral cell culture, polymerase chain reaction (PCR) amplification, serological techniques, electron microscopy, and animal models. For example, the severe acute respiratory syndrome (SARS) coronavirus was first diagnosed through cell culture in a reference microbiology laboratory, with random-amplification PCR and subsequent sequencing and comparison to other known coronaviruses (Drosten et al., 2003).

During future outbreaks, assuming they have appropriate sensitivity and specificity, POC tests could be used for rapid exclusion of pathogens and direction of patients to either mainstream health services or prompt isolation (Walker et al., 2015). POC tests are particularly useful in remote, under-resourced settings that lack the laboratory infrastructure or capacity to conduct traditional diagnostic testing. Not only could they quickly inform a prescriber whether a patient has an infection, but also identify whether it is viral or bacterial, and even indicate antimicrobial susceptibility, allowing practitioners to administer the most appropriate available therapy. This type of information would not only improve outcomes, but also facilitate infection-control efforts by shortening the time that an individual is infectious, and ensure that antimicrobial drugs are used only when indicated.

Taking diagnostic testing outside of the traditional laboratory environment requires tests to be independent of the need for a power supply and sufficiently robust that they do not need to be stored in temperature-controlled environments (Boeras, Nkengasong, & Peeling, 2017). Frontline health workers are also required to perform these tests and interpret the results with minimal training. Thus, decentralizing testing in this way can place considerable strain on fragile health systems in terms of supply chain management, training, quality assurance, and monitoring impact. As such, POC tests have been described as a double-edged sword, necessitating that technological innovations be accompanied by innovations in health service delivery.

The national reference laboratory is best positioned to take the lead on such technology introduction and implementation. A national system of training and quality assessment needs to be established in which testing data and quality assessment results are linked to the laboratory information system. This system can, in turn, be linked to the supply-chain management system to optimize timing and frequency of supply restocking to avoid stock-outs and wastage, and improve the efficiency of the health system.

Laboratories also have a key role to play in building connectivity and communication systems to facilitate the translation of raw data into intelligence to optimize disease-control efforts. Many new POC diagnostics have in-built data transmission capabilities via cellular networks or Wi-Fi. This allows results to be automatically uploaded to a central, secure health information system, enabling real-time surveillance (Boeras et al., 2017; Mazzola & Pérez-Casas, 2015). Smartphones offer fast computing, a user-friendly interface, wireless communication, and connectivity to data stored in the "cloud," all at declining prices—characteristics that have promoted their increasing uptake in LMICs. For example, Laksanasopin et al. (2015) have developed a low-cost smartphone dongle that can perform a full laboratory-quality enzyme-linked immunosorbent assay (ELISA), with all power drawn from the smartphone. Piloted in Rwanda, the tool was found to generate results in 15 minutes, and rivaled the gold-standard human immunodeficiency virus (HIV) tests with a sensitivity of 92% to 100% and a specificity of 79% to 100%. Further, 97% of patients preferred the dongle to laboratory-based tests, with most pointing to the convenience of obtaining quick results with a single finger-prick. Technologies like this are making diagnostic tests accessible to almost any population with access to smartphones.

So far, progress in diagnostic capacity has generally been slow to materialize. It is more expensive for patients and more time-consuming for doctors to use a diagnostic test than to prescribe a drug immediately, even if the test could help save costs and reduce waste at the health-system level. Further, in many parts of the world, a culture of self-medication is deeply entrenched. Where antimicrobials can be bought over the counter without prescription, it is difficult to incentivize people to pay for a test, wait for the results, and then pay for the treatment (if indicated), rather than just pay for the drug straight away. Moreover, few pharmaceutical companies have a commercial interest in the advent of rapid diagnostics, which would reduce the number of antimicrobials prescribed, or in the development of diagnostics for poverty-related diseases that offer little return on their investment.

Nevertheless, a number of recent initiatives have sought to incentivize development and catalyze innovation in this field so as to tackle antimicrobial resistance in particular. For example, the Longitude Prize will be awarded to an entrant that can develop a cheap, accurate, rapid, and easy-to-use POC test kit for bacterial infections that will allow health professionals worldwide to administer the correct antibiotics at the right time (Longitude Prize, 2017). The winning tool must be portable, easy to use anywhere in the world with minimal training, give an accurate result within 30 minutes, and be affordable to everyone who needs it. Ultimately, the full impact of investments in such technologies will be realized only if these tests are adopted, scaled up, and evaluated at all levels of the health system. It is also critical to understand the local context within which the tool will be used, with attention paid to economies, acceptability, and individual and community needs and impact (Boeras et al., 2017).

Evaluating Essential Public Health Functions

To ensure best practice in public health, performance evaluation should be developed and integrated into all levels of a country's public health infrastructure (Bellagio District Public Health Workshop Participants, 2016). However, the complexity of public health practice and the services that they provide do not easily lend themselves to a simple approach to quality improvement (Gunzenhauser et al., 2010). This perhaps explains why the field of public health quality improvement has lagged behind clinical quality assurance efforts. Yet, ongoing evaluation of public health practices is critical to ensure a well-functioning health system, and by delegating this task to a specific unit or body the likelihood of efforts being put into practice is increased. Such units should conduct assessments of the essential public health functions (EPHF) (see Exhibit 14-1) and the results shared with relevant health workers to facilitate improvement efforts.

Many toolkits are available to conduct such assessments at regional, national, and subnational levels; however, these need to be adapted to the local context and made actionable if the results are to effectively guide quality improvement strategies (Bellagio District Public Health Workshop Participants, 2016). One such assessment tool has been developed by WHO's Eastern Mediterranean Regional Office (EMRO) to evaluate the implementation of EPHF in countries of the region. The initial request for assessment is made by a member state on a voluntary basis, and the state provides funding for the assessment to ensure ownership. The involvement of a national team throughout the process secures high-level commitment, thereby contributing to strengthening national capacity in this area and ensuring sustainability. Further, the two-tier assessment process (self-assessment followed by external assessment), coupled with the involvement of all technical departments within WHO EMRO, ensures all relevant information is available and an all-inclusive approach to the inter-related functions is followed (WHO Eastern Mediterranean Regional

Office, 2017). This process is similar to that adopted by the Joint External Evaluation (JEE) process described later in this chapter. However, the former covers a wider range of public health functions, whereas the latter mainly focuses on prevention and control of outbreaks of infectious disease.

Evaluation instruments have been developed for use at subnational (district) health system level. This consideration is particularly important in LMICs with decentralized health systems (or where decentralization is in process), as it increases the complexity of operations at the district level. Bishai et al. (2016) have developed and piloted a district health system self-audit tool that can provide quantitative data on how district health authorities perceive their performance of the EPHFs. This tool was developed in partnership with local health authorities and stakeholders to ensure that it described the EPHF specific to the local health system. District health offices then used the tool to assess their performance of the EPHF, identifying gaps and weaknesses and enabling the creation of an improvement plan to address the issues flagged. The self-assessment approach facilitates local ownership of the evaluation process. It also takes advantage of local knowledge, enabling priority areas to be identified, and affords the opportunity for the broader inclusion of frontline workers on district health teams, whose views are often not heard by the central ministry. This tool has been used on a trial basis in Mozambique and Botswana, but could be adapted to meet the needs of other countries in strengthening public health practice or for the monitoring of district-level performance (Bishai et al., 2016). Methods of evaluation are also covered in the *Evaluations of Large-Scale Health Programs* chapter.

Workforce and Leadership

A sufficiently sized, qualified, and well-resourced health workforce is one of the building blocks of a strong public health infrastructure. Countries need a dedicated workforce with a defined scope of work and clear career paths to facilitate continuous learning and professional development (Bellagio District Public Health Workshop Participants, 2016). Strengthening of the public health workforce is particularly important, as its multidisciplinary nature—encompassing a diverse range of professionals from epidemiologists to public health nurses, as well as clinically qualified doctors—requires specialized training programs and targeted recruitment strategies to fill any gaps in the workforce (Bellagio District Public Health Workshop Participants, 2016).

Today, many LMICs suffer from an acute shortage of public health workers, particularly in rural areas. To address this gap, many countries have chosen to deploy community health workers, who can provide basic primary care outreach services in rural areas. The Ethiopian health system, for example, is renowned for its focus on strengthening the primary health sector, which has been achieved by deploying health extension workers (HEWs) at the community level (Reich, Javadi, & Ghaffar, 2016). HEWs provide preventive and basic curative care, and also conduct promotional work (Admasu, 2016). The work of HEWs is complemented by the Health Development Army (HDA), which engages women's groups to disseminate health information and facilitate uptake of critical health services (Admasu, 2016). The implementation of this dual-cadre community health worker program, including both HEWs and HDA volunteers, has facilitated health leadership at the local level with impressive results: Ethiopia is a leader in Africa both in delivering healthcare to communities (99% of the population has access to primary healthcare) and in advancing indicators of health (Admasu, 2016).

India is another example of a LMIC that has made considerable progress in public health recently, evidenced by accelerating declines in infant and under-5 mortality rates, and in maternal mortality ratios (Kumar, Bothra, & Mairembam, 2016). Such progress has been facilitated by the establishment of the Public Health Foundation of India (PHFI) in 2006 (PHFI, 2015). The PHFI was born out of the need to redress the limited institutional capacity in India for strengthening public health training, research, and policy development, and has as a key mission the development of the public health workforce. The value of training in public health is shown by the southernmost state of Tamil Nadu, which has among the best public health outcome indictors for states in India, performing consistently above the Indian national average (Balabanova, McKee, & Mills, 2011). This achievement has been credited, in no small part, to the presence of a distinct public health management cadre at the district level. Staff are charged with the management of primary health institutions and undergo a series of training programs in public health and allied subjects, including managerial skills. Staff members are also expected to qualify for a diploma in public health, enabling them to climb the career ladder. The main advantage of the public health cadre is that it provides managerial continuity at the district and higher levels of primary healthcare. Managers are therefore familiar with the issues faced by their area and understand how they should best be managed. This has resulted in the speedier allocation and more

effective use of resources received from the central government in Tamil Nadu in comparison with most other states, enhancing access to care. The importance of such cadres is becoming increasingly recognized, as reflected in the 2017 National Health Policy's proposal to create a public health management cadre in every state of India, both rural and urban, within 10 years (Ministry of Health and Family Welfare, 2017).

Given chronic shortages in health workers, it is also necessary to use human resources efficiently (Sales, Kieny, Krech, & Etienne, 2013). One way to do this is to apply the concept of "task-shifting," which involves the redistribution of specific tasks among health workers (WHO, 2008b). Often tasks are moved from highly qualified health workers to colleagues with less training and fewer qualifications, enabling more efficient use of the existing human resources and easing bottlenecks in service delivery. Task-shifting has been implemented as a pragmatic response to health workforce shortages in a number of LMICs. For example, in Uganda and Malawi, an HIV/AIDS basic care package is delivered to patients by nonspecialist doctors or nurses supported by community health workers and people living with HIV/AIDS (WHO, 2008b). This approach can also ensure an optimal skill mix of health workers in services delivery by blurring the boundaries of job roles (e.g., allowing community health workers to take on duties normally performed by nurses), although this practice can be met with strong opposition from professional bodies. Incentives can also be provided to health professionals to work in rural areas, or in less lucrative or prestigious health fields (Crisp, 2010).

The integration of indigenous, non-allopathic health workers into the primary health sector has been promoted as another method to boost workforce capacity and strengthen district health systems. India, in particular, has realized the potential of Ayurveda, Yoga and naturopathy, Unani, Siddha, Homeopathy (AYUSH) practitioners who can help to address the acute shortage of human resources if adequately trained, and who can play a key role in health promotion (Patel et al., 2015). Further, traditional healers are often held in high regard in the community; thus, integrating their services into the general public health system may help to instill trust in the system and encourage service uptake. Commitment to this cause in India is reflected in the creation of a national mission on AYUSH to strengthen the AYUSH network in the public sector (Ministry of Health and Family Welfare, 2014b), and the accordance of separate ministry status for indigenous medicine (previously a department of the Ministry of Health and Family Welfare) (Ministry of Health and Family Welfare, 2014a). Therefore, traditional healers can help support the work of trained health workers, and act as a valuable link between community members and the formal health system. However, this can be a risky practice unless these healers can be persuaded to forgo their harmful traditional practices (Crisp, 2010).

Of course, a strong public health workforce requires strong leadership. Effective leadership in times of crisis is particularly important, and, in light of recent public health incidents, a number of new approaches to leadership have been advocated. For example, using Liberia as a case study, Nyenswah et al. (2016) describe "distributed leadership," which views leadership as a "collective and social process" rather than focusing on an individual leader. Such a leadership model involves strategically engaging stakeholders and sharing responsibility and authority. In an analysis of the Liberian experience during the 2014–2016 West Africa Ebola virus epidemic, a shift from the traditional hierarchical leadership approach to a distributed model during the emergency phase of the epidemic is credited with bringing the crisis under control more rapidly in Liberia than occurred in Sierra Leone and Guinea. Unfortunately, in the aftermath of the outbreak, efforts were largely directed toward restoring the old hierarchies and decision-making structures that existed prior to the outbreak. A lack of institutional learning and memory is a key issue with this approach to leadership; finding ways to address obstacles to such learning is a high-priority task for public health leadership (Reich et al., 2016).

Given the multitude of actors engaged, public health systems goals can indeed be achieved only through distributed or "participatory" leadership, which is realized when diverse groups are empowered and free to contribute to the functioning of the health system (WHO, 2016d). Within each of these groups, individual leadership does matter—but such leadership has to foster an open, consultative process of decision making to bring out the collective strength of participatory leadership. Participatory leadership also allows for democratic debate and the free exchange of ideas, enabling established modes of working to be questioned or challenged—behavior that would otherwise be seen as deviant in rigid hierarchical systems. This type of leadership can also act to stabilize the health system against internal or external turbulence, as discussed in the next section.

Building Resilient Health Systems

A strong health system is one that is able to withstand shocks and maintain operations despite large perturbations. The United Nations Office for Disaster Risk

Reduction (UNISDR, 2017b) defines *resilience* as "the ability of a system, community or society exposed to hazards to resist, absorb, accommodate, adapt to, transform and recover from the effects of a hazard in a timely and efficient manner, including through the preservation and restoration of its essential basic structures and functions through risk management." This definition captures the need to build the resilience of people and communities, as well as the physical health system infrastructure. It also extends to the adaptive capacity of infrastructure, which is gained from an understanding of the risks and uncertainties in the environment (Cabinet Office, 2011).

While recent global crises have drawn attention to the necessity of resilient public health systems that can withstand acute, external shocks, it is equally important to ensure that health systems are resilient in the face of routine challenges—so-called "everyday resilience" (Gilson et al., 2017). These routine challenges may include drug stock-outs, funding constraints, patient complaints and changing expectations, unpredictable staff, compliance demands, organizational instability linked to decentralization processes, and frequently changing, and sometimes unclear, policy imperatives. Although unstable governance structures and inadequate resources certainly sow instability, everyday resilience is derived from new forms of distributed leadership (as discussed in the previous section) that reframe challenges to support problem solving; embody respect and empower others, particularly frontline health workers; facilitate learning and innovation; and develop and draw on social networks across, within, and outside the health system.

The need to take a resilience approach to health system strengthening was first brought to attention in the World Health Assembly's 2011 call to member states to "strengthen the resilience of the health system and society at large." Yet, within the public health field, the concept of resilience remains poorly conceptualized and under-researched.

The UNISDR definition of resilience refers to the need to build the resilience of both people and communities and the physical health system infrastructure. A resilient health system requires those who work within the system and those who use the system to exhibit flexibility in their roles or actions (Martineau, 2016). The capacities of health workers to reprioritize their clinical activities, of people who are unwell to alter their care-seeking practices, or of nontraditional health actors to take on new health roles, all contribute to building a resilient health system. Such systems are heavily dependent upon a strong and committed health workforce, characterized by personnel who are properly trained, equipped, and willing to deal with difficult and potentially dangerous situations. This involves training and deploying a sufficient number of health workers, and maintaining a stock of social capital in the health system before a disaster strikes. In the health system context, social capital has two aspects: (1) a sense of worth, community, and responsibility among health actors, and (2) robust community engagement with the health system. Health systems that are trusted and respected by the population they serve have a powerful resilience advantage (Kruk, Myers, Varpilah, & Dahn, 2015). Thus, strengthening the resilience of health systems is "more than simply providing assets or technology. It is about developing people's agency, it is about governance and power" (Béné, Wood, Newsham, & Davies, 2012). In other words, resilience is not just a function of what a system has, in terms of its physical infrastructure, but of what it does and how it does it (Gilson et al., 2017).

With regard to the physical infrastructure and operation of a health system, resilience can be seen to be made up of four components: resistance, reliability, redundancy, and response and recovery (**FIGURE 14-1**). In building resilience, the contribution made by each of these components needs to be considered (Cabinet Office, 2011).

The *resistance* component of resilience is concerned with providing protection. The objective is to prevent damage or disruption by providing in-built strength or protection to resist the hazard or its primary impact. However, resistance strategies have significant weaknesses, as protection is often developed against the types of threats that have been previously experienced rather than those that might occur in the future (Cabinet Office, 2011).

A *reliable* infrastructure is inherently designed to operate under a range of conditions, mitigating the service disruptions that might result after an event. Design standards can be set to ensure that the infrastructure can operate in the range of conditions likely to be experienced in a country or region. Service standards, in turn, protect users from disruptions in supply. However, infrastructure and service delivery

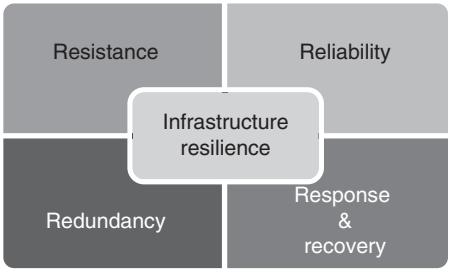

FIGURE 14-1 The four components of infrastructure resilience.

Data from Cabinet Office. (2011). *Keeping the country running: Natural hazards and infrastructure. A guide to improving the resilience of critical infrastructure and essential services.* London, UK: Author.

can adapt only so much. That is, events that exceed the specified reliability range will test the system and may stretch it beyond its capacity. Further, by focusing on a specific range of events only, the system will be ill prepared to deal with events outside of this range, leading to wider and more prolonged impacts. Thus, although reliability cannot be guaranteed, it does play a role in managing a situation at a tolerable level until full services can be restored (Cabinet Office, 2011).

The *redundancy* element of resilience is concerned with the design and capacity of the network or system. The availability of a variety of backup systems allows operations to be switched to alternative branches of the network in the event of a disruption. Having built-in redundancy ensures continuity of services. The switch to these alternative services should be made as swiftly and smoothly as possible to minimize service interruption.

Redundancy is, however, a foreign concept to the public health field, with the word "redundant" often carrying negative connotations. Operating with significant spare capacity is often deemed wasteful and inefficient; thus, in the pursuit of efficiency and as part of cost-cutting activities redundancies are often the first targets for elimination (Walker, 2010). However, by simplifying production in this way the system becomes more vulnerable to shocks and stressors, which, in the long term, works to make the system less cost-effective. Although maintaining resilience necessarily incurs costs, designers of health systems must appreciate that there is a "trade-off between foregone short-term benefits of high efficiency under narrowly constrained circumstances and the long-term persistence of the existing regime with reduced costs of crisis management" (Anderies, Walker, & Kinzig, 2006). Yet, in other areas of work, redundancies are recognized as critical elements. For example, redundancy has served as a central tenet of high reliability engineering for decades (Downer, 2009). Redundancies are also integral to natural systems. To quote Nassim Taleb (2012): "Layers of redundancy are the central risk management property of natural systems. We humans have two kidneys . . . extra spare parts, and extra capacity in many, many things (say, lungs, neural system, arterial apparatus)'" in short, "[n]ature likes to overinsure itself."

Ultimately, redundancy ensures that if a critical system fails, another is there to pick up the slack. The same principle could, therefore, be applied to the design of public health systems. To understand how such an approach might be implemented, it can be useful to look at examples of health systems that perform well under stress, such as in Palestine. This system (particularly in the Gaza Strip) consists of a distributed architecture with embedded redundancies that enable healthcare provision to withstand stressors. These redundancies include multiple service delivery points, a variety of delivery models, dispersed decision-making centers, informal power structures, multiple funding sources, and diversified supporting bodies.

The effectiveness of the *response and recovery* component depends on the thoroughness of efforts to plan and prepare in advance of events. Infrastructure owners must understand the weaknesses in their systems and have arrangements in place to respond quickly to restore services. Further, post-disaster recovery and reconstruction offers a prime opportunity to "build back better" by integrating disaster risk reduction measures into the restoration of public health infrastructure and systems so as to increase resilience (UNISDR, 2017b). This idea was first conceptualized in the aftermath of the Indian Ocean tsunami of 2004, quickly becoming the recovery effort's guiding principle, and has been advocated in many other disasters since (Fan, 2013).

All-Hazards Approach to Emergencies

Public health infrastructure must be sufficiently resilient to withstand emergencies of all types. These can threaten health directly or indirectly through the disruption of health services and critical infrastructure. Threats include natural hazards (hydrologic, geologic, climatic, and atmospheric), industrial accidents, and malicious attacks, including the use of chemical, biological, radiological, and nuclear (CBRN) weapons (Cabinet Office, 2011). While the nature of such events may vary significantly, they give rise to similar problems; thus, preparedness and response strategies for each type of disaster have much in common (Adini, Goldberg, Cohen, Laor, & Bar-Dayan, 2012). During a crisis, the need to manage resources and information, and to maintain effective lines of communications, is the same regardless of the type of incident. WHO therefore advocates a generic, "all-hazards" approach to emergency preparedness and response, while still recognizing that managing each type of crisis will require specific scientific and technical expertise (WHO, 2012).

In the coming decades, a growing number of people are expected to be affected by disasters of all types, particularly those in LMICs (Department for International Development, 2011). Disasters are expected to grow in frequency and intensity, and hazards will become more complex and unpredictable, in part due to climate change (Intergovernmental Panel on Climate Change [IPCC], 2014). However, there is

increasing recognition that disasters are not natural events, but rather the product of the interaction between the hazard and socially constructed vulnerabilities[1] and exposures[2] (Aitsi-Selmi & Murray, 2016b). The severity of a disaster depends on the level of exposure and vulnerability of the affected population, which are in turn shaped by economic, social, environmental, geographic, demographic, cultural, institutional, and governance factors (Aitsi-Selmi et al., 2016). Social vulnerability is also dynamic, in that it has been shown to vary temporally with the disaster stage and hazard context (Rufat, Tate, Burton, & Maroof, 2015). For example, in the midst of a flood, men and middle-age people tend to be most vulnerable due to risk-taking behavior and involvement in rescue operations; in the aftermath, however, women, single-parent families, and the elderly are most vulnerable due to limited resource availability and difficulties coping with disruptions to long-term care and services. Further, poor development practices, including environmental mismanagement, urbanization in hazardous areas, rapid demographic and economic changes, and ineffective governance, coupled with limited livelihood options, particularly for the poor, are all associated with increased exposure and vulnerability to disasters (IPCC, 2012). Evidence indicates that exposure of persons and assets in all countries has increased faster than vulnerability has decreased (UNISDR, 2015). This has generated new risks and a steady rise in disaster-related losses, with significant health, social, economic, and environmental short- and long-term impacts. These impacts are often felt most strongly at the local and community levels, and disproportionately affect vulnerable groups, as well as single-sector economies (UNISDR, 2015). In LMICs, where the mortality and economic losses from public health emergencies are greatest, disasters significantly impede progress toward sustainable development (UNISDR, 2015).

A single event will often give rise to a variety of cascading effects beyond the initial incident (Cabinet Office, 2011), which can have a multiplying effect on losses. For example, a prolonged period of hot weather carries the risk of thunderstorms and flash flooding. Disasters can also have adverse secondary effects that extend beyond national borders. Increasing global economic interdependence, including linked production and consumption operations, means that the impacts of a disaster can have widespread impacts on distant locations (Aitsi-Selmi, Blanchard, & Murray, 2016). To illustrate, in 2011, severe floods in Thailand stalled local manufacturing production, which in turn brought global computer supply chains and manufacture to an effective standstill (Chongvilaivan, 2012).

Consequences of Disasters on Public Health Systems

Ensuring continuity of routine care after a disaster is often a severe challenge. Population displacement and overcrowding, coupled with damage to critical infrastructure such as sewer systems, increases the risk of infectious disease outbreaks (Aitsi-Selmi & Murray, 2016b). These risks are compounded in cases where health facilities are overwhelmed or damaged, and unable to maintain normal services. Loss of medical personnel and critical infrastructure, combined with reduced service access, can result in increased morbidity and mortality. The insecure working environment for healthcare workers (HCWs) and supply-chain distribution challenges also contribute to interruptions in service delivery (Ochi, Hodgson, Landeg, Mayner, & Murray, 2014).

The ability of a health system to effectively manage a public health incident is also heavily dependent upon the degree of confidence that the affected population has in the health services, and authorities in general. This challenge attracted particular attention during the 2014–2016 West Africa Ebola epidemic (see **EXHIBIT 14-3**).

Disaster Risk Reduction

Disaster risk reduction (DRR) strategies should be "aimed at preventing new and reducing existing disaster risk and managing residual risk, all of which contribute to strengthening resilience and therefore to the achievement of sustainable development" (UNISDR, 2017b). Such efforts must consider the full spectrum of threats, including those related to rapid and unmanaged urbanization and globalization, as well as a population's social vulnerability and capacity to respond (Aitsi-Selmi & Murray, 2016b).

Countries can reduce their risk of disaster by implementing the recommendations of the Sendai Framework for Disaster Risk Reduction 2015–2030 (UNISDR, 2015). The Sendai Framework places a strong emphasis on disaster risk management (both

[1] Vulnerability is defined as the "characteristics and circumstances of a community, system, or asset that make it susceptible to the damaging effects of a hazard" (UNISDR, 2017b).

[2] Exposure is defined as the "people, property, systems, or other elements present in hazard zones that are thereby subject to potential losses" (UNISDR, 2017b).

EXHIBIT 14-3 Public Health Infrastructure Collapse During the 2014– 2016 Ebola Epidemic in West Africa

During the 2014–2016 West Africa Ebola outbreak, a serious breakdown in trust between communities and the health system was observed (Elston et al., 2015). People felt let down by the health system, which was patently unprepared for an outbreak of this scale, and also feared engaging with the health system. Rumors abounded that health facilities were deliberately infecting people, creating societal pressure to refrain from seeking help. Disengagement with the health system led to significant under-utilization of available health services, with marked reductions in patients seen at community health centers and hospitals. In the Moyamba district of Sierra Leone, the United National Children's Fund (UNICEF) reported a 10% reduction in fourth antenatal clinic attendance and a 16% reduction in births reported from May to September 2014 (UNICEF & Ministry of Health and Sanitation, 2014).

The outbreak also severely affected the healthcare workforce. Ebola-affected regions were already chronically understaffed prior to the outbreak; therefore, losses of medical personnel during the outbreak were particularly serious. In Sierra Leone, up to 28% of the total healthcare workforce was reported to have been infected with Ebola. Resources, district health management teams, and community health workers were largely reassigned to Ebola-related activities and, therefore, were unable to provide their normal services. This affected the delivery of health services, with both vertical programs and critical infrastructure being disrupted. All major health programs, including tuberculosis, HIV, malaria, and nutrition initiatives, were adversely affected, and immunization schedules were disrupted. In the Koinadugu district of Sierra Leone, the mean monthly number of children receiving all recommended childhood vaccinations by age 1 year fell from 1,152.5 during the months of January–June 2014, before the outbreak took hold, to 507.7 in the final 6 months of the year.

Disruption to communication systems also jeopardized response efforts. For example, HCWs could not call emergency ambulances or report cases, resulting in a nonfunctional surveillance system. The reductions in vaccine coverage coupled with reduced surveillance capacity raised the risk of outbreaks of vaccine-preventable infectious disease.

These factors all contributed to heightened all-cause mortality during the Ebola outbreak. In the Moyamba district of Sierra Leone, the number of deaths recorded between November 2014 and mid-April 2015 was more than 3.4 times greater than the average number of deaths registered during the same period from the previous 4 years, yet only 2% of these fatalities were confirmed Ebola cases. The cessation of usual healthcare services for malaria as a direct result of the epidemic is estimated to have led to 3.5 million additional untreated cases of malaria in Guinea, Liberia, and Sierra Leone, with 10,900 additional malaria-attributable deaths (Walker et al., 2015). The outbreak also had wider, indirect social consequences. For example, in Moyamba district, an increase in teenage pregnancies in 2014 compared to 2013 has been attributed to widespread school closures.

This case demonstrates the impact that a disaster can have on an already compromised health system, in particular through the diversion of resources and attention to disaster-related activities and the resultant reduced provision of leadership, support, and governance to the health system. It also illustrates the importance of community trust in health services, and the maintenance of this confidence during the acute phase of an incident.

preventing new risks and reducing existing risks) through pre-disaster preparedness efforts, including the need to conduct detailed risk assessments, improve early warning capabilities and impact-based forecasting, build public commitment, and establish supportive institutional frameworks (Aitsi-Selmi et al., 2016). The scope includes human-made as well as natural hazards, and related environmental, technological, and biological hazards and risks. It also recognizes the need for DRR practices to be multisectoral and transdisciplinary, engaging with relevant stakeholders at all levels, including the community. In particular, it calls for greater collaboration with the science and technology community to better understand disaster risk patterns, causes, and effects; to develop advanced methods and tools for disaster risk modeling and multiple-hazards monitoring; and to inform DRR decision making and policy.

The Sendai Framework identifies a main outcome and corresponding goal to be achieved over the next 15 years. To address the health-related aspects of the Sendai Framework, seven recommendations, known as the Bangkok Principles, were agreed in 2016 (UNISDR, Royal Thai Government, & WHO, 2016):

1. Promote systematic integration of health into national and subnational DRR policies and plans and the inclusion of emergency and disaster risk management programs in national and subnational health strategies.
2. Enhance cooperation between health authorities and other relevant stakeholders to strengthen country capacity for disaster risk management for health, the implementation of the International Health Regulations (2005), and building of resilient health systems.

3. Stimulate people-centered public and private investment in emergency and DRR, including in health facilities and infrastructure.
4. Integrate DRR into health education and training and strengthen capacity building of health workers in DRR.
5. Incorporate disaster-related mortality, morbidity, and disability data into multiple-hazards early warning systems, health core indicators, and national risk assessments.
6. Advocate for and support cross-sectoral, transboundary collaborations, including information sharing, and science and technology for all hazards, including biological hazards.
7. Promote coherence and further development of local and national policies and strategies, legal frameworks, regulations, and institutional arrangements.

The Sendai Framework and two other landmark agreements on sustainable development and climate change reached in 2015 (the SDGs and the Paris Agreement on Climate Change, respectively) provide an opportunity to build coherence across these policy streams. Indeed, the Sendai Framework and Bangkok Principles specifically highlight synergies with health, sustainable development, and climate change and the need to facilitate mutually beneficial capacity development and joint policy initiatives (Aitsi-Selmi et al., 2016).

Implementation of the Sendai Framework

The Sendai Framework is a voluntary agreement, so its implementation ultimately depends on political will, the availability of funds for DRR activities, and the willingness to collaborate across institutional and country boundaries (Aitsi-Selmi & Murray, 2016a). The framework defines precise global targets, but measuring progress may prove challenging, as the framework does not specify how these targets should be measured or which data sources to use. Only two of the targets specify a referent baseline, and none is measured in absolute terms. The minimal availability of disaster loss data is also a challenge. At present, the ability to monitor the human and economic damage from disasters is limited, and at the national level, few countries have any sort of disaster loss accounting in place (Cutter & Gall, 2015).

Progress on the Sendai Framework is due to be reviewed biannually at the Global Platform for Disaster Risk Reduction. This forum functions to enable governments, NGOs, scientists, practitioners, and UN organizations to share knowledge and experiences, and to formulate strategic guidance for the implementation of the Sendai Framework (UNISDR, 2017a).

Chemical, Biological, Radiological, and Nuclear Incidents

Acute environmental emergencies resulting from exposure to CBRN material can have hugely detrimental effects on health and life. The Bhopal gas tragedy in India, considered the world's worst industrial disaster, occurred when more than 40 tonnes (44 tons) of methyl isocyanate gas leaked from a pesticide plant, killing at least 3,800 people (Broughton, 2005). In addition, it resulted in significant morbidity and premature mortality of many more thousands of people. Incidents involving exposures to abandoned radioactive sources in LMICs have also been reported, such as the cesium incident in Brazil (International Atomic Energy Agency, 1988). The global production, trade, and use of chemicals are predicted to increase six-fold by 2050, especially in developing and transitional economies, where chemical production, extraction, processing, and use are closely linked to economic development (Marchal et al., 2011).

Radiation overexposure accidents are rare and decreasing compared to chemical incidents, but their health consequences can be severe and long term (Coeytaux et al., 2015). The Fukushima Daiichi nuclear power plant accident demonstrated the health risks of unplanned evacuation and relocation for vulnerable people, such as hospital inpatients and elderly people requiring nursing care. Furthermore, the displacement of people that followed this event created a wide range of public healthcare and social issues (Hasegawa et al., 2015).

Adequate legislation needs to be in place in LMICs to mitigate future risks of significant environmental incidents. Following the Bhopal gas tragedy, the government of India amended three key acts that deal with industrial hazards and also passed a comprehensive new environmental law (Government of India, 1986). This law has vastly improved regulatory coverage of hazardous technologies and substances.

In today's world, perhaps the most salient issue is the weaponization of CBRN materials. CBRN weapons are some of the most indiscriminate and deadly weapons in existence (Unal & Aghlani, 2016). Along with the physical damage they can inflict, these weapons generate significant economic and societal disruptions by instilling widespread fear in the populace and sowing the seeds of social, economic, and political uncertainty and instability (Cornish, 2007). Indeed, a major incentive for use of these weapons is their capacity to cause significant disruption across multiple sectors, as

well as revenue loss for governments (Unal & Aghlani, 2016). For example, decontamination after the 2001 U.S. anthrax attacks—which produced almost 3,000 tonnes (3307 tons) of contaminated waste—cost an estimated $800 million (The Royal Society, 2004).

While such incidents are rare, the likelihood of these weapons being deployed is growing, fueled by heightened terrorist activity combined with advances in technological and scientific capabilities, and the accessibility of dual-use materials (which can be used for both civilian and military purposes) (Unal & Aghlani, 2016). Inadequately secured stockpiles of decommissioned military CBRN material, and increases in the trafficking of radiologic and nuclear materials have augmented the risk in recent years (HM Government, 2010). The probability and nature of such a threat vary geographically, and are linked to the intentions, incentives and disincentives for acquisition, and capabilities of a potential perpetrator (Unal & Aghlani, 2016). The scale of the impact that can be potentially achieved through the deployment of a CBRN weapon is a clear incentive for their use; thus, despite the rarity of such incidents, there is an ongoing need to develop a robust public health infrastructure so as to reduce the risk of such an incident occurring, and to effectively respond to an event if one should occur.

Stages of an Emergency Response

The all-hazards approach to disaster preparedness and response allows for a generic framework, regardless of the cause, to guide how countries should prepare and respond to a public health emergency, be it a natural disaster or a terrorist-related CBRN incident. This framework should include the following elements:

- *Pre-disaster planning.* Examples include the European Union's Seveso Directive (European Commission, 2016) and the International Health Regulations (WHO, 2016b).
- *Exposure and risk assessment.* In the event of an incident, immediate risks to health should be addressed by advice given at an early stage (Bradley, Meara, & Murray, 2015).
- *Countermeasures and risk management techniques.* These should include measures to prevent or reduce people's exposure, and to treat and transfer casualties and vulnerable subpopulations.
- *Communicating with the public.* Prompt, honest, and informative communication with clear messages for the public during an emergency is a key factor in allaying concerns. **EXHIBIT 14-4** outlines the basic principles of good communication during public health emergencies.
- *Recovering from an incident.* The importance of the recovery phase of a disaster is highlighted in the Sendai Framework, which advocates for the need to "[enhance] disaster preparedness for effective response and to 'Build Back Better' in recovery, rehabilitation, and reconstruction" (UNISDR, 2015).
- *Follow-up of affected populations.* There are two key reasons to undertake follow-up of populations affected by public health emergencies: (1) as part of the response phase of a disaster to help and provide services for those affected, and (2) for

EXHIBIT 14-4 Basic Principles of Good Communication During Public Health Incidents

- Determine the best organizations and individuals to deliver the public health messages.
- Commence communication as soon as possible, while acknowledging inevitable uncertainties.
- Set up national telephone helplines that have sufficient capacity to deliver the public health messages and answer questions.
- Take into account people's desire to find out about the safety of family and friends.
- Comparing unfamiliar risks with familiar ones can help put risks into context. However, care must be taken to ensure that elective risks are not used as the comparison for unavoidable risks.
- Always be truthful, or give the reasons why the truth cannot be disclosed. For example, for security purposes, some facts cannot be shared.
- Develop public generic information materials in "peacetime" that can be adapted quickly during an incident to expedite delivery of public health advice. These materials should include information about the mechanisms of harm, where harm may occur, and the measures people can take to protect themselves and how effective those measures are likely to be.
- Develop skills and experience in using modern communication methods, such as social media, to deliver health messages.
- Remember that emergency responders, as well as the public, may need information and support.

Modified from Bradley, N., Meara, J., & Murray, V. (2015). Principles of public health emergency response for acute environmental, chemical, and radiation incidents. In R. Detels, M. Gulliford, Q. A. Karim, & C. C. Tan (Eds.), *Oxford textbook of global public health* (6th ed., pp. 1608–1620). Oxford, UK: Oxford University Press.

scientific purposes, by collecting information regarding the health effects of an exposure.

- *Disseminating the lessons learned.* Reporting incidents is important to share lessons learned, reduce the likelihood of the incident reoccurring, and inform future emergency responses. Reports should be published and made publicly available to enable maximum benefit.

Health Security

Health security—essentially protection from health threats—is recognized as one of the most important nontraditional security issues (Heymann et al., 2015). The notion of health security has developed and been applied to public health from a different perspective than the human rights perspective discussed earlier in this chapter. That is, health security approaches public health from the need and responsibility for authorities, whether local, national, or global, to protect the health of their citizens.

History

As cross-border trade, pilgrimage, and war intensified throughout history, international travel increased, and along with it the international spread of disease. By the 14th century, it was understood that waves of epidemic disease such as plague were seeded by international travel.

Protection of populations against the importation of these diseases soon became an important part of national security for established governments. Defense mechanisms were first developed by individual countries in an attempt to prevent the entry of disease at their borders, and later collectively by countries to provide for global health security—that is, to protect against the international spread of disease. The 14th-century city-state of Venice was the first to introduce quarantine measures, whereby arriving ships were not permitted to dock, and people at land borders were held in isolation, for 40 days.

By the mid-19th century, governments had become concerned that quarantine measures were not preventing the importation of another disease—cholera. They recognized that better cooperation between countries was required to decrease the risk of international spread of these diseases. In turn, a series of international agreements were developed, initially in Europe, to apply certain measures at international borders. These included the first International Sanitary Convention in 1892, which dealt with cholera, and the 10th International Sanitary Conference in 1897, which sought to prevent the spread of plague. Obligatory telegraphic notification of cases of cholera and plague, shortly followed by the inclusion of yellow fever as a notifiable disease, was initiated among countries in the Americas. International agreements were soon broadened to include both Europe and the Americas.

During the early 20th century, two major international sanitary bureaus were created to support the development of regional public health capacity against infectious diseases—one for the Americas, called the Pan American Sanitary Bureau (now the Pan American Health Organization), and one for European countries, called the Office International d'Hygiène Publique. Cooperation between these two sanitary bureaus continued and, after the creation of WHO, broad International Sanitary Regulations were developed as a means of fostering international cooperation in the control of cholera, plague, yellow fever, and smallpox.

The International Health Regulations

In 1969, WHO developed the International Health Regulations (IHR), which were specifically aimed at better ensuring public health security with minimal interruption of travel and trade. Under the IHR, countries were required to report to WHO whenever an outbreak of plague, cholera, smallpox, or yellow fever occurred within their borders, and other countries could then apply control measures at their border posts. If a country reported an outbreak of yellow fever, for example, information about the outbreak was published in the WHO weekly epidemiological bulletin, and all other countries could then require evidence of yellow fever vaccination before travelers from that country were allowed to cross their international border. Under the IHR, countries were also required to take other actions that would prevent the proliferation of disease vectors such as rodents and mosquitoes, and international conveyances were required to have up-to-date sanitary certificates.

The IHR provided a legal framework for global surveillance and response, with the potential to decrease the world's vulnerability to four infectious diseases that were known to cross international borders. It soon became evident, however, that countries often reported outbreaks late, or not at all, because of fear of stigmatization and economic repercussions. It was likewise understood that the IHR did not meet the challenges caused by emerging infectious diseases and their rapid global transit.

The IHR were subsequently reviewed and revised, with a change in focus from stopping disease at borders to developing the national capacity to detect and respond to disease outbreaks where and when they occur. The revised IHR (2005) introduced a

requirement that each country develop and maintain a set of core capacities for surveillance and response so that it could rapidly detect, assess, notify, report, and contain the events covered by the regulations, thereby minimizing their potential for international spread and negative economic impacts. Countries were to be monitored as to whether they had developed these core capacities by annual voluntary reports to the WHO, based on a standardized self-assessment tool.

The importance of the IHR was clearly demonstrated when the Ebola virus crossed national borders during the West African outbreak (2014–2016). There was a clear understanding that outbreaks in West Africa were a threat to health security everywhere; people with infection traveled across borders within Africa and to Europe and North America, where they unintentionally caused small chains of transmission far from the epicenter of the outbreak. This outbreak underlined the importance of strong national public health capacity to detect and respond to disease outbreaks where and when they occur, as well as the importance of a functioning safety net of collective global action as required by the IHR.

Collective health security has been the focus of attention as described previously—that is, the centuries-long, commonly understood conceptualization of national health security. But there is a second, equally important aspect to health security that is less appreciated: individual health security. This type of security comes from access to safe and effective health services, products, and technologies. Ebola-infected health workers from developed countries were repatriated from West Africa for care in their own countries, where hospitals could provide them with safe and effective access to life-saving medicines and services. Meanwhile, Ebola-infected West Africans (health workers and others) had to accept that their healthcare was not always safe, not always effective, and not always accessible. As the Ebola epidemic unfolded, the part played by substandard infection control and inadequate access to effective health products and services clearly demonstrated the wider scope of health security, in the form of the intertwining of collective and individual health security. In the future, attempts to strengthen global health security must take into account not only the need for fully implemented IHR, but also the need for strong and resilient health systems for patient management and UHC (as highlighted in the first part of this chapter).

Public Health Emergencies of International Concern

The IHR (2005) require collective action by all WHO member states in the event that an emerging or reemerging infectious disease begins to spread internationally, and the free sharing of information pertaining to this threat. In this way, the IHR provide a safety net against the international spread of emerging or reemerging infections, requiring collaboration between all countries to ensure the timely availability of surveillance information and technical resources that better support international public health security. Collective action begins with mandatory reporting of any public health emergency of international concern (PHEIC), and continues with the use of real-time evidence to recommend measures to stop their international spread.

A PHEIC is defined as an extraordinary event that could spread internationally or might require a coordinated international response. Each newly identified outbreak is evaluated for its potential to become a PHEIC by the country in which it is occurring, even though reporting might legitimately come from elsewhere, using a decision tree instrument developed for this purpose.

Once a potential PHEIC is identified and reported to WHO by the country or countries concerned, a mandatory ad hoc Emergency Committee is set up to review the evidence available to WHO and to conduct a risk assessment. A recommendation is then made to the WHO Director-General as to whether the criteria for a PHEIC are met. The Director-General then uses this recommendation, and other sources of information, to decide the course of action.

An Emergency Committee was first established when influenza A (H1N1) was reported as a PHEIC by Mexico in 2009, after which the Director-General declared a pandemic. Emergency Committees have also been set up for other potential PHEICs: MERS, the continued spread of poliomyelitis, Ebola, Zika virus and microcephaly, and yellow fever.

Under the revised IHR, countries are required to notify WHO of even a single occurrence of a disease that would always threaten global public health security—smallpox, poliomyelitis caused by a wild-type poliovirus, human influenza caused by a new virus subtype, and SARS. In addition, a second list includes diseases of documented—but not inevitable—international impact. An event involving a disease on this second list, which includes cholera, pneumonic plague, yellow fever, Ebola, and the other hemorrhagic fevers, still requires the use of the decision tree instrument to determine whether it is a PHEIC.

In summary, it is now understood that the best defense is rapid detection and response to all public health hazards when and where they occur or emerge, with a global safety net of collaboration should a disease outbreak begin to spread internationally.

Strengthening the International Health Regulations

The IHR (2005) became legally binding in 2007, with all WHO member states required to develop certain minimum core public health capacities (WHO, 2016c). To achieve this goal, member states were initially encouraged to assess their own existing national structures and resources. The results of the self-assessments were intended to form the basis of action plans to increase core capacities and improve functioning.

Unfortunately, noncompliance with these regulations is rife. In public health emergencies that have occurred since adoption of the revised regulations, decisions have been made by states that were neither scientifically sound nor consistent with WHO guidance, and the IHR principles obligating countries to respect human rights and cause minimal disruption to the international flow of people and goods have been often dismissed (Katz & Fischer, 2010) (see also the *International Trade and Health* chapter). For example, during the 2009 H1N1 influenza pandemic, several countries suspended flights to North America, and 20 countries imposed bans on the importation of pork products from Mexico, Canada, and the United States. More recently, during the West Africa Ebola epidemic, many countries imposed unjustified trade and travel restrictions, and few countries notified WHO that they were implementing additional measures or justified their reasons for doing so (as required under the IHR), significantly interfering with international traffic (WHO Executive Board, 2015). Domestic politics can also play a role in the imposition of trade and travel barriers. During the H1N1 outbreak, democracies with weak health infrastructure were more likely to erect barriers and to do so quickly to prevent a loss of domestic political support (Worsnop, 2016).

IHR noncompliance also affects how quickly outbreaks are declared by countries. States are often reluctant to declare outbreaks for fear of being subjected to trade and travel sanctions, and the subsequent economic repercussions of such restrictions, especially on tourism and food exports. This hesitation may have serious implications for the scale of the response mounted. If a government refuses to cooperate, there is little WHO can legally do to remedy the situation.

Like most international agreements, the IHR do not contain enforcement mechanisms and WHO does not have the authority to impose sanctions on countries flouting the regulations (Wilson, Brownstein, & Fidler, 2010). The World Trade Organization, while able to enforce trade regulations, does not work fast enough to apply sanctions in the context of health emergencies. Consequently, there is a need to strengthen the incentives and disincentives so that governments report disease outbreaks early and are dissuaded from implementing trade and travel restrictions without a scientific basis (Moon et al., 2015). To enhance compliance with the IHR, it has been suggested that WHO publicly request countries to justify additional measures undertaken and urge businesses to reconsider restrictions (Gostin, DeBartolo, & Friedman, 2015). To encourage good behavior and promote transparency, WHO could publicly acknowledge the nations and businesses that comply with recommendations, while publicly disclosing lists of those that do not. However, doing so would require a delicate balancing act between WHO's role as trusted interlocutor with governments on sensitive information and its role as guardian of the IHR.

To further encourage compliance with the IHR, funding bodies could create economic incentives for early reporting by committing to the rapid provision of emergency funds to assist countries when emergencies strike and compensating them for any economic losses that might occur (Moon et al., 2015). Moreover, insurance plans offered, for example, by the World Bank's proposed Pandemic Emergency Financing Facility, could mitigate the economic costs linked to outbreak reporting.

It has also been suggested that state parties consider pursuing dispute mediation from the Director-General or compulsory arbitration for economic losses incurred. Successful cases by countries affected by travel or trade restrictions or human rights violations would establish a strong precedent that would likely enhance compliance (Gostin et al., 2015). Moreover, the World Health Assembly could amend the IHR to raise temporary recommendations to a binding status.

As private actors, such as shipping companies and airlines, are not directly bound by public international law, alternative governance mechanisms are needed to prevent steps to isolate countries during outbreaks (Moon et al., 2015). The onus rests on state parties to instill confidence in private service providers by responding appropriately to emergencies, following WHO guidance, and abiding by the IHR (Garrett, 2015). It also falls on WHO to prove its competence in handling such situations so as to increase private actors' confidence in its ability to manage PHEICs.

However, as seen in both the H1N1 and Ebola epidemics, no matter how comprehensive or well embedded the IHR governance structures, the issue of national sovereignty endures. Ultimately, nations can and will make their own decisions in response to a public health emergency, regardless of the global health governance structures in place (Katz & Fischer, 2010).

For example, in 2007, the Indonesian government decided to stop sharing avian influenza virus strain information with WHO (Fidler, 2008). This decision stemmed from Indonesia's unsuccessful attempt to obtain a vaccine based on the strain that it had provided to the international surveillance network for influenza. Indonesia argued that this situation exposed inequities in the global influenza surveillance system, whereby LMICs provide vital information but do not get to share in the benefits because they are unable to afford the resultant vaccine. Indonesia asserted sovereignty over the samples originating within its territory, in accordance with the Convention on Biological Diversity. The enforcement of sovereignty is further supported by the Nagoya Protocol on Access and Benefit Sharing (Secretariat of the Convention on Biological Diversity, 2011). Sovereignty is often the only card that LMICs can play to ensure that their voices are heard on the world stage. This has many implications for data and specimen sharing, and for the expansion of research and development in LMICs.

Global Health Security Agenda

Launched in February 2014, the Global Health Security Agenda (GHSA) is a growing partnership of more than 50 nations, international organizations, and nongovernmental stakeholders to help build countries' capacity as required by the IHR (GHSA, 2017a). The GHSA takes a multisectoral, multinational approach, aiming to reduce infectious disease threats, promote global health security as an international priority, and make concrete commitments to other frameworks such as the IHR and the World Organization for Animal Health's Tool for the Evaluation of Performance of Veterinary Services (OIE PVS) (CDC, 2016; GHSA, 2017a; World Organization for Animal Health, 2017). The GHSA was a U.S. initiative conceived and established by the Obama administration, with an initial focus on ensuring the capacity of countries to take effective action against emerging threats, particularly in light of the 2009 pandemic flu response. It grew from a view that the world was not able to mount an effective response to such threats; that the core capacities integral to the IHR were not in place in many countries, especially in LMICs; and that WHO was not able to monitor effectively, or enforce compliance with, the IHR.

Whilst the GHSA is a U.S.-led initiative, it was always intended to be multilateral in nature. In its early stages, the United States approached partner countries to support the "Agenda" and commit to increasing capacities globally, including by providing funding or technical expertise to countries in need of assistance. Membership is now open to all countries, with the decision to join made by national governments and often led by the Ministry of Health. As more countries joined the initiative, the United States recognized the need for others—particularly those outside of the "global north"—to take on leadership roles within the alliance. This issue has further been addressed by increasing emphasis on the GHSA as a *support* to WHO's leadership in IHR work and health security in general.

The relationship between the GHSA and WHO has often been tense. At its inception, a widely held view was that the GHSA had a bias against WHO and that it aimed to supplant WHO as the lead organization for global health security. The counter-view was that WHO was not effectively tackling the key issues in health security (such as failing to fully implement the IHR), that WHO leadership would not (or could not) face up to this issue (because of WHO's governance position with member states), and that WHO was not fit for purpose with regard to international outbreak response (bearing in mind that this was before the Ebola outbreak in West Africa).

The GHSA's work is organized into a discrete set of agreed "Action Packages." All GHSA member countries participate in one or more Action Packages either as a "leading" or "contributing" country. Each package is accompanied by a 5-year target, indicators by which to measure progress, and lists of baseline assessment, planning, monitoring, and evaluation activities to support successful implementation (GHSA, 2017b). A Steering Group oversees the work, with a rotating country chair. The countries on the Steering Group, particularly the chairing country, fund the organizational arrangements (although in reality, activities are largely dependent on U.S. funding).

The Action Packages that constitute the GHSA's work at the country level are largely funded through a combination of country funding and donor funding, with the additional element that the United States has specific GHSA funding from Congress to support activities in line with GHSA priorities and in countries with which the United States wants to partner. The major change that the GHSA has driven is that funding for this aspect of health strengthening targets activities that are an agreed priority for the country, is part of an agreed action plan, and is monitored independently.

Response to Outbreaks: Linking Global, Regional, and National Perspectives

Though there were significant strengths in the international response to the 2014–2016 West African Ebola

outbreak, the delay between the initial Mèdecins Sans Frontières (MSF) warning in March 2014 and the WHO declaration of a PHEIC in August of the same year was lengthy and problematic (Grepin, 2015; WHO, 2014). In a retrospective reflecting on the response to the outbreak, many important lessons regarding better coordination and collaboration have been highlighted (House of Commons Science and Technology Committee, 2016).

International assistance in the event of a public health emergency can be facilitated through the Global Outbreak Alert and Response Network (GOARN), in the case of an infectious disease outbreak, or through the Global Emergency Medical Team (EMT) Registry, in the case of a humanitarian crisis. GOARN is a collaboration of existing institutions and networks that pools human and technical resources for the rapid identification, confirmation, and response to outbreaks of international importance (WHO, 2017b). WHO may coordinate an international outbreak response using resources from GOARN. Many countries and organizations have also developed Emergency Medical Teams (EMTs)—groups of health professionals who are able to provide direct clinical care to populations affected by emergencies (WHO, 2017a). EMTs often have a strong trauma and surgical focus, and have a long history of responding to sudden-onset disasters such as the Indian Ocean tsunami and the Haitian earthquake.

To coordinate the rapid deployment of highly qualified and adequately equipped medical teams in the event of a disaster, WHO has developed the Global EMT Registry. This Registry consists of EMTs that meet WHO technical standards and that have been classified according to capacity and capability. The Global EMT Registry enables a country affected by a crisis to call on quality-assured teams capable of providing the assistance required. The Registry also acts as a coordination mechanism for all partners who aim to provide clinical care in crises, and ensures the deployment of teams with the required skill set.

The United Kingdom, for example, has two mechanisms by which to deploy cadres of professionals trained in humanitarian and outbreak response. One is a new dedicated team of public health experts (including infectious disease specialists, epidemiologists, microbiologists, and logisticians) that has the capacity to deploy within 48 hours of notification. Known as the U.K. Public Health Rapid Support Team (UK PHRST), it is a partnership between Public Health England (PHE), the London School of Hygiene and Tropical Medicine, King's College London, and the University of Oxford, which brings together response, research, training, and capacity-building activities. The second mechanism involves a broader group of medical and public health reservists, deployable through UK-Med, a charity hosting the U.K. International Emergency Medical Register (Reece et al., 2017). UK-Med is certified by WHO as an EMT and is listed on the Global EMT Registry.

Internationally, WHO has developed a similar emergency response for infectious disease threats by forming the Emerging Diseases Clinical Assessment and Response Network, through which clinical scientists can be deployed to rapidly assess unknown clinical management questions or public health response challenges (WHO, 2016a). The U.S. CDC has a longstanding Epidemic Intelligence Service (EIS) field epidemiology training program, and the European Centres for Disease Control (ECDC) has founded a European Programme for Intervention Epidemiology Training (EPIET). Within the United Kingdom and some other countries, Field Epidemiology Training Programs have trainees ready to be deployed to assist with initial assessment of evolving outbreaks.

During the West African Ebola outbreak, a cornerstone of the response was the formation of a central command and control structure to host the coordination of all aspects of the outbreak response, from active case management to safe burial, and from contact tracing to quarantine activities (Brown et al., 2016). More broadly, since 2015 WHO has developed a framework for a Public Health Emergency Operations Centre (EOC) Network to ensure that novel outbreaks are appropriately resourced with a designated "public health emergency management personnel," who can rapidly come together to "coordinate operational information and resources for strategic management of public health events and emergencies" (WHO, 2015g).

Notwithstanding the array of international response options available, individual countries must develop their own capacity for meaningful surveillance and outbreak response, as highlighted by the IHR (WHO, 2016b). International response mechanisms can assist both with this process and with incident response, but sustainable control of public health threats is underpinned by the core pillars of countries' own public health systems. Consequently, investments in underlying health systems improvements, including human resources for health, postgraduate training for staff, and frontline support including surveillance officers and diagnostic facilities, are critical (Oxfam, 2015).

Bilateral partnerships are an important mechanism through which to support capacity development. For example, the U.K. Department for International Development (DFID)–funded Health Partnership

Scheme, which is managed by the Tropical Health and Education Trust (THET), links National Health Service (NHS) healthcare facilities and academic bodies with overseas partners (DFID, 2013). There are also many regional surveillance platforms and partnerships that allow for an improved and integrated outbreak response, such as the Asia Pacific Strategy for Emerging Diseases, a common framework for countries in the region to develop coherent strategies appropriate to local and national contexts (WHO Regional Office for the Western Pacific & Regional Office for South East Asia, 2010).

Many other regional organizations and alliances, such as the Africa CDC and African Union, promote strategic and operational responses to novel threats across a region. The African Field Epidemiology Network (AFENET) is a public health network established in 2005 as a nonprofit networking alliance of Field Epidemiology and Laboratory Training Programs (FELTPs) and FETPs in Africa supporting ministries of health in health system strengthening in partnership with global public health experts. During the Ebola outbreak in West Africa, African Union Support for the Ebola Outbreak in West Africa (ASEOWA) supported FETP graduates from Uganda, Zimbabwe, Ethiopia, and Tanzania as they undertook the investigation and control of the outbreak in Liberia (Lubogo et al., 2015). Further, in the wake of the outbreak, the World Bank invested $390 million in West Africa in the Regional Disease Surveillance Systems Enhancement (REDISSE) program. The program is focused on enhancing surveillance and information systems, and strengthening laboratory capacity. The project aims to support the development of national surveillance systems and their interoperability at the different tiers of the health system, and establish networks of efficient, high-quality, accessible public health, veterinary, and private laboratories for the diagnosis of infectious human and animal diseases, and to create a regional networking platform to improve collaboration for laboratory investigation (World Bank, 2017c).

Finally, many bilateral research platforms contribute to research and training for future emerging infectious disease response. These initiatives include the Southeast Asia–Europe Joint Funding Scheme for Research and Innovation (SEA-EU-NET) and the European and Developing Countries Clinical Trials Partnership (EDCTP).

Funding for Public Health Emergency Response

A major constraint to ensuring emergency response infrastructure exists in LMICs is the (lack of) availability of funding. Such funds tend to be obtained through grants from international donors, as well as borrowed from international financial institutions such as the World Bank after a disaster has occurred (Ghesquiere & Mahul, 2007). These mechanisms are often slow to mobilize and, therefore, unlikely to provide the quick liquidity needed immediately after a disaster. An alternative financing strategy would be for LMICs to commit funding for emergency response mechanisms before a disaster, which can then be rapidly released when needed. Ideally, this would be sourced from domestic funds to be sustainable.

In 2008, the WHO Global Assessment of National Health Sector Emergency Preparedness and Response found that fewer than half of all national health sectors had a specific budget allocation for emergency preparedness and response (WHO, 2008a). The Global Facility for Disaster Reduction and Recovery and the Overseas Development Institute have estimated that between 1991 and 2010, only $13.5 billion (0.45%) of the total amount of international aid ($3.03 trillion) was spent worldwide on disaster prevention and preparedness (Kellett & Caravani, 2013).

EXHIBIT 14-5 outlines some recently proposed and implemented solutions for financing disaster risk reduction strategies.

EXHIBIT 14-5 Practical Solutions to Finance Disaster Risk Reduction

- The WHO Contingency Fund for Emergencies (CEF) provides immediate funding at the beginning of an emergency until resources from other mechanisms begin to flow (WHO, 2015a).
- The World Bank Pandemic Emergency Financing Facility (PEF) provides surge funding for low-income countries to assist response efforts to help prevent rare, high-severity disease outbreaks from becoming more deadly and costly pandemics (World Bank, 2017b).
- Some countries are engaging in disaster preparedness by working collaboratively and engaging local stakeholders. For example, the Horn of Africa Risk Transfer for Adaptation (HARITA) Program is an innovative microfinance scheme being piloted in Ethiopia (Oxfam America, 2010). HARITA offers a holistic approach to risk management, integrating financial aspects such as risk transfer (i.e., insurance), prudent risk taking (e.g., credit), and risk reserves (e.g., savings) alongside risk reduction activities (e.g., improved agricultural practices and conservation activities).

Evaluation of the International Health Regulations

The 2014–2016 outbreak of Ebola virus disease in West Africa laid bare the shortcomings of the global health security strategy and the IHR. The disaster exposed challenges that nations had previously failed to handle, including sustaining and deepening global health as a political priority, reforming WHO, and improving compliance with international health laws (Heymann et al., 2015).

The last issue has since been addressed by restructuring the IHR monitoring and evaluation process through the development of the Joint External Evaluation (JEE) tool (WHO, 2015f, 2016c). The JEE is a collaborative process to assess a country's capacity under the IHR to prevent, detect, and rapidly respond to public health threats. This tool is more comprehensive than the original IHR assessment, and was developed in partnership with the GHSA. A JEE assessment measures individual countries' IHR compliance status in 19 key areas (**FIGURE 14-2**); identifies the most urgent needs, opportunities for improved preparedness, and responses and action; and should engage with current and prospective donors and partners to target resources effectively (JEE Alliance, 2017a).

Complementing the GHSA partnership is the JEE Alliance, which facilitates engagement between all relevant actors involved in WHO's assessment process for IHR capacity strengthening. The JEE Alliance promotes use of the JEE tool, and links it with other assessment processes for health security. It promotes transparency in exchanging information on the results of assessments, in particular for donors interested in funding the development and strengthening of national-level capacities and capabilities. It is envisioned that a strengthened IHR monitoring and evaluation framework, with the JEE at its center, alongside after action reviews, simulations and exercises, and annual reporting, would make compliance and implementation easier to track (**FIGURE 14-3**).

The JEE is a voluntary process initiated at the request of the recipient country. It consists of an initial national self-assessment, which is followed by an external evaluation conducted by a team of international subject-matter experts. A report is then drafted to identify gaps, opportunities, and challenges in the implementation of the IHR. The final report is made publicly available by WHO, supporting transparency and openness of data and information sharing. This evaluation assists countries to identify the most urgent needs within their health systems and prioritize efforts for enhanced preparedness, response, and action, and it facilitates engagement with current and prospective partners to target resources effectively (JEE Alliance, 2017a). The collaborative and voluntary nature of the JEE helps to make the process politically more acceptable.

The JEE works alongside the OIE PVS tool (see the section on the Global Health Security Agenda). The latter assessment framework is designed to assist veterinary services to understand their "current level of performance, to identify gaps and weaknesses in their ability to comply with OIE international standards, to

form a shared vision with stakeholders (including the private sector), and to establish priorities and carry out strategic initiatives" (World Organization for Animal Health, 2017).

WHO covers most of the funds (via regional offices) for financing JEEs, although some countries are also able to contribute. Nevertheless, there is a need for funding to be specifically earmarked for JEEs and for the subsequent strengthening of health systems. The GHSA provides funding indirectly to the JEE through participation of its own staff in the evaluations. Further, some organizations and countries, notably Finland and the U.S. CDC, fund their own participation.

Post-JEE evaluation, countries must take action to address the gaps highlighted by the assessment. A comprehensive national plan of action should be devised and implemented. Implementation is the critical step, but the necessary activities need to be adequately funded. Inevitably, most LMICs will require additional financial resources to achieve the JEE targets and full IHR compliance, but often no concrete sources of funding or assistance are in place. This is currently a significant stumbling block to progress, as many countries are financially unable to follow through on the plans of action. Put simply, there is a need for comprehensive, clear implementation plans and sustainable funding sources to remedy this problem.

The collaborative and country-led nature of the JEE and post-JEE national action plan process is critically important. Building IHR capacity is a significant undertaking for any country, and particularly so for LMICs, where resources are scarce and competing priorities exist (Wilson, von Tigerstrom, & McDougall, 2008). An opportunity cost is incurred with any initiative, and IHR capacity building is no exception. Consequently, the IHR planning and prioritization process must be country led, with national experts deciding where to apportion their limited resources along the IHR spectrum of prevention, preparedness, detection (surveillance), and response. The collaborative process of the post-JEE national action planning, whereby national and external teams work together to set priorities and ensure synergies with existing broader national health strategies and development initiatives, supports this principle. **EXHIBIT 14-6** provides an innovative example of this collaboration in practice. To have lasting success, however, countries require sustained technical and financial inputs, which can be secured only through increased domestic financing and reduced reliance on external donors (Sands, Mundaca-Shah, & Dzau, 2016). By adopting a high-level, multisectoral approach, the JEE process intends to elevate IHR on national political agendas, paving the way for greater domestic financial commitment and sustainability.

The reformed IHR monitoring and evaluation process remains in its infancy. However, by May 2017 (just over a year after its launch), more than 40 countries had undergone a JEE assessment, with many more planned. The toolkit itself is iterative, with improvements and amendments already incorporated since it was first piloted, and plans for further refinements (JEE Alliance, 2017b).

Antimicrobial Resistance

Antimicrobial resistance (AMR) is recognized as a complex issue of increasing concern, threatening

EXHIBIT 14-6 Political and Institutional Economy Analysis of the Implementation of the IHR and Integrated Disease Surveillance and Response in Pakistan

Political and institutional economy analysis (PIEA) is a well-recognized development tool (DFID, 2009; McCulloch et al., 2017) that can be used to inform understanding and planning of health interventions. In 2016, Public Health England commissioned a PIEA of the implementation of WHO's IHR and the Integrated Disease Surveillance and Response (IDSR) in Pakistan (Public Health England & Contech International, 2017). The work was intended to answer a series of key questions at the federal level and in Punjab province, thereby facilitating planning of future activity. The PIEA addressed the following key questions:

- Why is Pakistan not compliant with the IHR?
- Why have previous recommendations for IDSR not been implemented?
- Why is progress slow?
- Who is responsible for IHR compliance and delivery of IDSR, and what influences them?
- What has or has not worked well to date, and why?

This work complemented a JEE in Pakistan undertaken in April–May 2016 (WHO Alliance for Country Assessment, 2016) and detailed situational analyses of existing disease surveillance and response systems in Pakistan (Public Health England & Contech International with the Punjab Government, 2016). It was the first time that formal political economy analysis had been used to study implementation of the IHR.

The findings of the PIEA from stakeholder interviews and desk review identified the following key governance issues:

- Expressed political commitment that had not translated into implementation
- Lack of a system-wide approach to the IHR and IDSR
- The need to improve the governance of delivery (e.g., defining roles, responsibilities, and standards, as well as systems for accountability and management)
- Deficient specialized workforce, HR planning, support, and career structures
- The role/approach of donors and technical agencies, with their dominance of the health landscape giving donors undue influence over domestic agendas and priority setting, undermining efforts for long-term sustainable system change
- Limited fiscal space for IHR compliance and IDSR implementation

Based on the PIEA diagnosis, the following recommendations and key actions were proposed to improve delivery of IHR capacities and an IDSR system:

- Ensure political prioritization of the IHR and IDSR so as to push the agenda at all levels, and improve communications around the IHR and IDSR to political leaders.
- Develop and deliver a system-wide approach to the IHR and IDSR, and coordinate institutions, partners, and individuals around this approach. IDSR strategic and operational plans should be developed in conjunction with provinces and wider stakeholders.
- Develop and put in place clear governance and accountability structures for individuals, organizations, and tiers of the health system for IDSR and delivery of IHR capacities with well-defined roles and responsibilities for delivery.
- Strengthen workforce planning, support, and career structures; develop specific eligibility and qualification standards for various cadres of the public health workforce; assess if there are immediate training needs.
- Encourage donors and technical agencies to work together and align their support to system-wide national plans for delivery of IHR capacities and IDSR. Governance mechanisms should be developed to assess whether donor assistance will support or hinder national plans.

These PIEA recommendations informed roadmap development and strategic and operational planning that occurred subsequent to the technical JEE assessment and IDSR situational analyses.

health and biosecurity across multiple sectors (OECD, 2017). It is an explicit technical area covered in the JEE, and increasing political awareness of this threat has placed AMR firmly on the global agenda, with numerous initiatives and policies established to tackle this growing crisis. Indeed, the Global Action Plan on Antimicrobial Resistance has called on member states to put into place national plans to combat AMR within 2 years (WHO, 2015d). The goal is to "ensure, for as long as possible, continuity of successful treatment and prevention of infectious diseases with effective and safe medicines that are quality-assured, used in a responsible way, and accessible to all who need them" (WHO, 2015d).

Since AMR is a shared, global problem, preserving antibiotic susceptibility will depend largely on the strength of the weakest national efforts. The development of comprehensive national action plans by LMICs hinges upon the availability of information pertaining to the etiology and prevalence of AMR in

these contexts. However, large information gaps in the global governance of AMR remain, concerning both the magnitude of the issue and national responses to it (Wernli et al., 2017). Surveillance data from LMICs are often scarce or incomplete (Tadesse et al., 2017), and even where epidemiologic data are collected, the full complement of information—particularly from private hospitals and laboratories—is often unavailable. Methodological inconsistencies in data collection and reporting further hamper comparability of data between laboratories, countries, and regions. Consequently, our understanding of the overall clinical and public health burden of AMR, as well as the state of national response efforts, is limited.

As will be discussed in more depth in the "Surveillance and Health Information Systems" section, it is important to strengthen the capacity of LMICs to monitor AMR. Efforts should also be made to ensure harmonization of data collection and reporting across countries, as this improves the comparability of information and enables countries to benchmark their performance against others. For example, laboratories in Europe are encouraged to use the European Committee on Antimicrobial Susceptibility Testing (EUCAST) breakpoints and methods to ensure consistent clinical reporting of antimicrobial susceptibility results and comparability for surveillance purposes (European Centre for Disease Prevention and Control, 2015). Improved situational monitoring may also result in greater engagement of health professionals and consumers, whose participation is critical to tackling AMR (Wernli et al., 2017). However, equally as important as improving the capacity of countries to monitor AMR, is deciding which factors should be measured in the first place. Given the diversity among and within countries (from the ecological determinants of AMR to social and political systems), it has been proposed that national monitoring efforts focus on three main components (Wernli et al., 2017):

- The epidemiologic situation and its impact on human health (outcomes)
- Drivers and practices (processes)
- Regulations and control policies (structures)

A variety of measurements, drawn from human, animal, and environmental health, can be attached to each of these components. For example, measurements of the drivers of AMR encompass access to sanitation and consumption of meat products, whereas the adoption of a national action plan and the enactment and implementation of regulations are measurements of structures.

AMR monitoring in LMICs can be bolstered through engagement with the GHSA, which supports country capacity to collect data. Another strategy is to exploit synergies with successful disease-specific surveillance programs (such as tuberculosis surveillance) to expand AMR surveillance. Data from each country should be collated and synthesized on a common platform, with methodologic differences addressed transparently to ensure comparability of results. As the information collected is aimed at informing policy, attention should be paid to communicating the findings clearly and widely through various media outlets (Wernli et al., 2017).

Improvements in AMR monitoring ultimately requires the engagement and participation of a number of global actors. For example, the recently launched Conscience of Antimicrobial Resistance Accountability (CARA) initiative aims to track national responses to AMR (Gelband, 2016). CARA comprises an alliance of multisectoral organizations (public, private, and nonprofit) from the human, animal, and environment sectors. Each member organization will commit to reporting on mutually agreed indicators in countries around the world, so as to monitor the state of national AMR responses.

Antimicrobial Stewardship and Infection Prevention and Control

Hand hygiene (as part of infection prevention and control [IPC]) and antimicrobial stewardship are thought to be two of the most effective evidence-based interventions in tackling AMR. Whilst antimicrobial stewardship programs (ASPs) are increasingly common in higher-income settings, they are more difficult to implement in LMICs due to multiple factors—for example, a lack of investment, human workforce, logistical infrastructure, and strong surveillance mechanisms (Bebell & Muiru, 2014), as well as lack of access to life-saving antimicrobials in some areas (Laxminarayan et al., 2016). The last issue is particularly important: Simultaneously expanding appropriate access to antimicrobials and restricting inappropriate access to these agents is a key challenge, requiring new approaches to financing and delivering healthcare services (addressed in detail in the *Pharmaceuticals* chapter).

Although antibiotic consumption is increasing worldwide, driven by economic growth and prosperity, access to these medications is not uniform. Indeed, more deaths are currently caused by limited access to antibiotics than by antibiotic resistance (Laxminarayan et al., 2016). For example, pneumonia-related deaths in children younger than age 5 years are strongly correlated with availability of antibiotics, and it is estimated that universal provision of antibiotics could reduce deaths due to community-acquired

pneumonia in this age cohort by 75%. Although ASPs that act to restrict the use of quality-controlled antimicrobials, while also enabling effective monitoring and offering alternative therapies (e.g., vaccinations), are essential in ensuring good antimicrobial stewardship (Buckland Merrett, 2013), such policies should be implemented with caution: Achieving child survival goals will depend on continued and even expanded access to effective antibiotics for pediatric patients (Laxminarayan et al., 2016).

Further, creative solutions are required that recognize the limited regulatory capacities in many LMICs. For example, banning the sale of nonprescription antibiotics is likely to be counterproductive—as well as unenforceable—because it would restrict access for poorer populations that rely on private drug sellers for healthcare (Laxminarayan & Heymann, 2012). In Nigeria, for example, drug vendors are the first source of care for as many as 55% of cases of under-5 illnesses, and in some parts of sub-Saharan Africa drug shops provide as much as 83% of all child health services (Webster, 2017).

New tools to provide highly specific diagnoses of pathogens can decrease diagnostic uncertainty, improving clinical management and stewardship efforts. Rapid, low-cost, and readily available diagnostic tools should be an essential component of ASPs. Currently, however, the vast majority of antimicrobial prescriptions are written without the use of a diagnostic tool. The decision as to whether an antimicrobial is prescribed is often based on an "empirical diagnosis," whereby expertise, intuition, and professional judgment are used to "guess" the causative agent of an infection. This behavior stems from the length of time traditional diagnostic tests take to confirm the offending pathogen (e.g., many types of bacteria must be cultured for a number of days before an infection can be confirmed). Acutely ill patients cannot afford to wait this long, and even in non-urgent cases time, patient, and financial pressures often force prescribers to address needs much faster (Review on Antimicrobial Resistance, 2016). As a consequence, huge quantities of antimicrobials are wasted globally on patients who do not need them (driving AMR) and on microbes against which they are ineffective. One solution to this problem is the development of rapid point-of-care diagnostic tests, as discussed in depth in the "Diagnostic Capability" section.

Surveillance and Health Information Systems

Disease surveillance is a cornerstone of the IHR (WHO, 2016b). Countries must be able to detect threats within their own borders if they are to implement effective control measures and forewarn other countries of potential risks. Data generated from both public health and clinical laboratories are essential for public health surveillance activities, and should feed into a national health information system. Countries need to establish a robust interoperable and interconnected electronic reporting system that can link and analyze multisectoral surveillance data including epidemiologic, clinical, laboratory, environmental testing, and bioinformatics data (GHSA, 2017b). An electronic reporting system capable of generating automatic reports or alerts will also facilitate real-time surveillance efforts. A strong health information system is necessary to track progress toward health-related goals, to monitor the performance of the health system, and to inform policy makers and health system managers. Unfortunately, health information systems in many LMICs are weak and fragmented, so they cannot supply sound data in a timely manner (Mbondji et al., 2014).

To facilitate information sharing and the subsequent analyses, laboratory protocols and data collection, coding, and storage need to be standardized. Within countries, data are often collected or produced by multiple actors and stored on various information management platforms. To streamline data sharing, identify gaps in data collection, and avoid duplication of efforts, there is a need to ensure greater complementarity and coordination between agencies.

For example, in India, health information data are collated by many different agencies and surveillance systems (Patel et al., 2015). Little coordination exists between these actors, and there is little integration and reconciliation of diverse data sources. Health workers often collect several types of health metrics to meet the divergent requirements of central, state, and local governments. Data collection is also incomplete and restricted to public health facilities. Failure to collect data from the private sector excludes the major provider of healthcare in India from the surveillance system. Recognizing these limitations, India's 2017 National Health Policy outlined the need for an integrated health information system, which necessitates private-sector participation (Ministry of Health and Family Welfare, 2017). The National Rural Health Mission has established an integrated nationwide health information portal that facilitates the flow of information including more than 300 data elements, and maintains a repository of published reports from national data sets (Patel et al., 2015). This system has been expanded to capture monthly information from 195,000 facilities across almost all states of India. The government aims to establish a federated national

health information architecture to link systems across public and private health providers at the state and national levels.

Surveillance is a particular issue for monitoring AMR, because AMR surveillance in LMICs is limited. The lack of data constrains national governments and international organizations in their efforts to devise action plans and detect evolving trends and emerging threats. However, a number of initiatives have been established to build surveillance capacity. For example, the Global AMR Surveillance System (GLASS) collects and reports data on AMR rates aggregated at the national level (WHO, 2015e). This system aims to collect comparable, validated data on AMR, which are then analyzed and shared to inform evidence-based action and decision making. Similarly, a roadmap has been created for implementation of this system in LMICs, as these countries may not have the resources or capacity to implement all components in the GLASS manual (London School of Hygiene and Tropical Medicine, 2016). Further, regional AMR surveillance networks have been established in Latin America (Red Latinoamericana de Vigilancia de la Resistencia a los Antimicrobianos, ReLAVRA) and Central Asia and Eastern Europe (CAESAR), and successes have been achieved in India through the National Programme on Antimicrobial Surveillance and in Kenya, South Africa, and Mozambique. Nevertheless, significant hurdles to AMR surveillance remain in many LMICs—namely, weak health systems, difficulty in enforcing regulations, healthcare worker recruitment and retention, poor public health infrastructure with a higher burden of infectious disease, and limited resources (Abdula, Macharia, Motsoaledi, Swaminathan, & VijayRaghavan, 2016). An integrated, multisectoral approach combining leadership, training, supervision, and laboratory quality assurance (including site visits and panel testing) would facilitate strengthened laboratory capacity in LMICs (Dacombe, Bates, Bhardwaj, Wallis, & Pulford, 2016).

Given the close ties between AMR and animal husbandry, and recognizing that the majority of infectious diseases are zoonoses (Jones et al., 2008), it is valuable to take an integrated or "One Health" approach to surveillance activities. WHO (2017c) defines One Health as "an approach to designing and implementing programmes, policies, legislation, and research in which multiple sectors communicate and work together to achieve better public health outcomes." This approach recognizes that the health of humans, animals, and ecosystems is interconnected (**FIGURE 14-4**), and has been gaining momentum ever since the Asian avian influenza outbreak in 2005. An added value of this holistic approach is the resultant shift in the paradigm of emergency response upstream, toward prevention and preparedness, through management of the risks that lead to disease emergence (Dixon, Dar, & Heymann, 2014; Heymann & Dar, 2014).

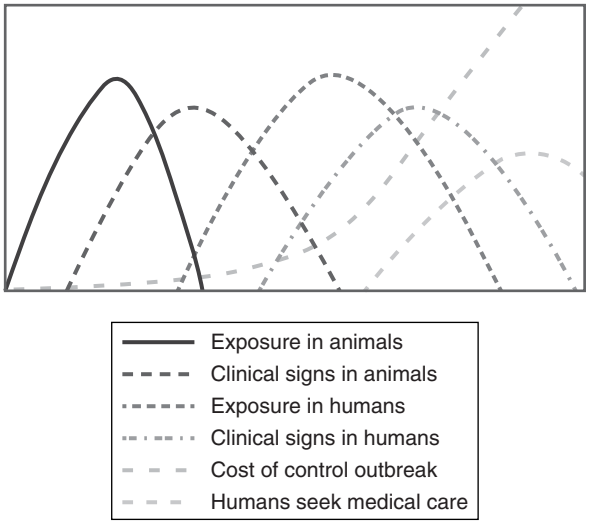

FIGURE 14-4 Early control of zoonotic infections is cost-effective and reduces human disease.

Reproduced from Heymann, D.L., & Dar, O.A. (2014). Prevention is better than cure for emerging infectious diseases. *BMJ, 348,* g1499. Copyright © 2014 with permission from BMJ Publishing Group Ltd.

One Health surveillance comprises the systematic collection, validation, analysis, interpretation, and dissemination of data collected on humans, animals, and the environment so as to inform decisions for more effective evidence- and system-based public health interventions (Stark et al., 2015). Integrating surveillance in this way can be achieved by aggregating databases at the human–animal interface. For example, the Global Early Warning System (GLEWS) database includes animal or zoonotic events for which information has been jointly gathered by the Food and Agriculture Organization (FAO), World Organization for Animal Health (OIE), and WHO, and confirmed by national authorities (GLEWS, 2017). Another example is the "four-way linking" platform implemented in Egypt, Vietnam, and Indonesia (Forcella et al., 2015). This project promotes the development of a framework for data sharing, risk assessment, and risk communication among governmental public health and animal health influenza laboratories as well as epidemiology units. The need to integrate human and animal interventions to better prevent, detect, and control human diseases is also reflected in the adoption and promotion of One Health approaches by the GHSA, IHR, and JEE (GHSA, 2017b; WHO, 2016c).

Experience from recent major outbreaks has shown the need for a wide array of surveillance systems and diagnostic capability, alongside the ability to implement emergency response mechanisms (Crawford, Rutz, & Evans, 2016). Novel surveillance

tools, such as mobile phone technology to track and monitor outbreaks (Jia & Mohamed, 2015), multimedia platforms including image and pattern recognition to monitor mass gatherings (Al-Salhie, Al-Zuhair, & Al-Wabil, 2014), and use of Internet search terms to predict outbreaks (Cook, Conrad, Fowlkes, & Mohebbi, 2011), are also likely to be applied more frequently in the future.

Networks such as the International Severe Acute Respiratory and Emerging Infection Consortium (ISARIC, 2017b) are developing standardized data collection tools to provide for obtaining early information about novel disease progression and management. Countries increasingly will need to integrate with regional partners, such as ECDC, and through global exchanges of information and novel pathogens, such as with WHO collaborating centers. To support this type of cooperation, agreements are required at the global and regional levels on data and specimen sharing and, where relevant, shared intellectual property. The latter issue is particularly important when specimens originating in LMICs are used to develop diagnostics, vaccines, and therapeutics that are then distributed and sold globally through the private sector (Fidler, 2008).

As many countries move toward more privatized provision of diagnostic services (Corti, Passini, Lanzavecchia, & Zambon, 2016), steps are needed to ensure that reference services receive adequate and representative samples of pathogens. One way to ensure this access is to develop a mechanism whereby provision of appropriate samples leads to diagnostic and therapeutic development, leading to local deployment of novel tests or drugs. Integrated disease surveillance, including a One Health approach including animal health and laboratory infrastructure investment, is key to "rapid identification and containment of . . . emerging and re-emerging infectious diseases" (Houlihan, Youkee, & Brown, 2017).

Data Sharing

There is a growing consensus among stakeholders about the importance of data sharing in advancing health (Wellcome Trust, 2011). Sharing public health surveillance data enables regional collaborations, capacity strengthening, and insight into public health system performance. This, in turn, leads to improvements in risk management, and enhances public health responsiveness (Chatham House, 2017). Seven principles have been proposed to help create an environment conducive to data sharing (**FIGURE 14-5**). They are intended to facilitate good practice and encourage ethical sharing to the highest achievable standards, while also helping to identify opportunities for capacity building (Chatham House, 2017).

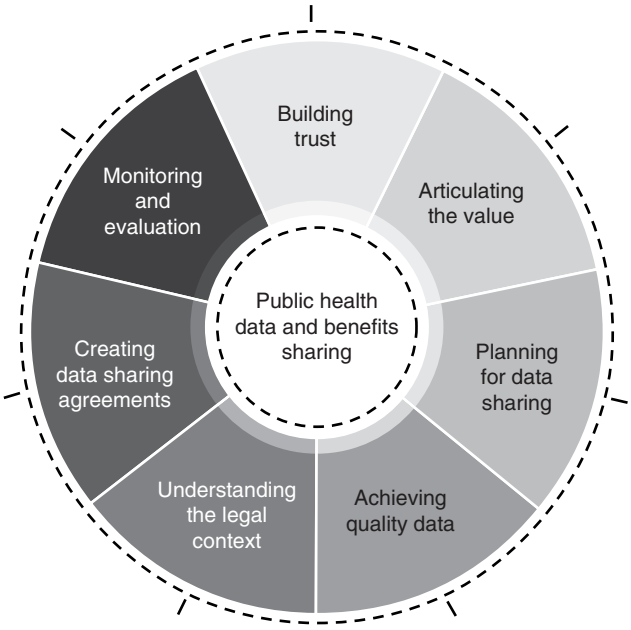

FIGURE 14-5 Data sharing principles for public health surveillance.

Reproduced from Chatham House, Royal Institute of International Affairs. (2017). *A guide to sharing the data and benefits of public health surveillance.* London, UK: Author. Copyright © The Royal Institute of International Affairs, 2017. With permission of RIIA through PLSclear.

Data sharing is particularly pertinent during a public health emergency, where it is critical to ensure the timely dissemination of information that might have value in combating the crisis. The ability to mobilize data-sharing networks enables researchers to more quickly develop and test hypotheses, provide evidence to inform the public health response, and thereby facilitate a prompt and effective global response (GloPID-R Data Sharing Working Group, 2017). Further, sharing data between stakeholders helps prevent the duplication of work, and pooling efforts both extends the value of limited resources and reduces the lag time between the identification of a public health emergency and the mounting of a response.

Many different types of data, ranging from clinical, epidemiologic, and pathogen genome data to information on experimental diagnostics, therapeutics, and vaccines, may contribute to the research response. The increasing depth and breadth of international collaborations, coupled with technological advancements including informatics, rapid whole-genome sequencing of pathogens, and novel methods to collect and analyze clinical and epidemiological data, present a huge potential to advance public health and transform responses to outbreaks (Wellcome Trust, 2011; Yozwiak, Schaffner, & Sabeti, 2015). However, the power of these "big data" to aid such responses can be realized only if the data are shared widely and promptly (Yozwiak et al., 2015).

Despite this necessity, in practice, the timely and transparent sharing of data remains a challenge. The shortcomings of existing data-sharing mechanisms were highlighted during the Ebola outbreak in West Africa (Whitty et al., 2015). In the early stages of the epidemic, individuals and organizations, including WHO, were reluctant to share data in real time. In these type of situations, the main reason given for withholding information is the perceived disincentives to share data, including concerns that data sharing may jeopardize subsequent publication, would allow other researchers to use the data for their own publications, and might violate confidentiality agreements. Additional reasons given for lack of sharing include the lack of incentives and the absence of a mechanism to enable information dissemination. This unwillingness to share data had implications for the effectiveness of the early response and put the lives of those HCWs on the frontline at risk, many of whom had provided the data in the first place. Further, the particularities of outbreaks can present additional barriers to data sharing. Outbreaks often bring together people and communities from all over the world, and who often have different norms and values. This "culture clash" can create uncertainties regarding ownership of data (Yozwiak et al., 2015). Further, in emergencies it can be difficult to obtain patient consent for data sharing, especially in situations, such as in the Ebola outbreak, where patients and their families are vulnerable to stigmatization and exploitation.

Thus, there is an obvious need to develop clear guidelines and initiatives to encourage and enable data sharing. In 2015, an agreement was reached on the need for data sharing, particularly during public health emergencies (WHO, 2015b). In this meeting, a consensus was reached that the risks and potential harms of nondisclosure of important information provide a strong ethical rationale for the rapid sharing of data. Among other things, it was recognized that while epidemiologic data belong to the country of origin, the default option is that data should be shared (i.e., opt-out policy) to ensure that knowledge generated becomes a global public good. It was also agreed that the disclosure of information should not be delayed by publication timelines, and that prepublication disclosure must not prejudice journal publication. Prepublication information sharing should become the global norm in the context of public health emergencies, with the exception of some conflict settings (Karunakara, 2013).

In implementing data-sharing initiatives, a number of issues need to be considered. First, incentives and safeguards should be created to encourage researchers to disclose their data (Yozwiak et al., 2015). Ethical, legal, and governance issues also need to be addressed to safeguard participants and communities, overcome regulatory hurdles, and mitigate challenges associated with benefit sharing and reciprocity. A data-sharing infrastructure needs to be developed to facilitate prompt dissemination of information, including the creation of networks and norms for repositories and best practices.

The Global Research Collaboration for Infectious Disease Preparedness (GloPID-R) is a platform that brings together research funding organizations on a global scale to facilitate an effective research response to a significant infectious disease outbreak (GloPID-R, 2015). Data sharing is a key priority of GloPID-R, and a working group has been established to develop systems for data sharing during public health emergencies (Littler, 2016). The data-sharing working group has also drafted a set of seven core principles to underpin and support the development of systems for data sharing in public health emergencies (GloPID-R Data Sharing Working Group, 2017); these principles are described in **TABLE 14-1**.

Another initiative is the Infectious Diseases Data Observatory (IDDO, 2017), which acts as a "central repository for evidence of optimal management and treatment efficacy for selected infectious diseases." This platform for collaboration facilitates the investigation of key scientific questions and rapid response to public health emergencies. It offers a variety of disease-specific data-sharing platforms where data can be collated, standardized, and stored securely.

ISARIC provides a collaborative platform for clinical researchers to share data and access protocols needed to facilitate a rapid response to outbreaks of emerging diseases (ISARIC, 2017a). ISARIC can be described as a network of networks having gathered in one place more than 70 networks and individuals. This organization also promotes the standardization and harmonization of definitions, endpoints, and data collection methods to streamline the aggregation, tabulation, and analysis of data across many different settings.

As in other responses to public health emergencies, preparedness is key to ensure successful data sharing during a public health crisis. The systems, standards, and principles of data sharing should already be in place as part of standard data-sharing practices. These mechanisms can then be scaled up or extended to address the specific challenges associated with data dissemination during public health emergencies (Littler, 2016). Not only does this expedite the process of data sharing in an emergency,

TABLE 14-1 GloPID-R Data Sharing Principles

Principles	Description
Timely	Data must be shared promptly with few access limitations. This may include the use of harmonized study protocols and the development of clear guidelines.
Ethical	Data sharing must abide by applicable ethical and legal standards. Informed consent models that allow for secondary use of data (broad consent) should be utilized.
Accessible	Data sharing should be subject to as few restrictions as possible. Data providers should clearly indicate which conditions are in place.
Transparent	Information outlining how data can be requested and how requests are considered should be provided, including timelines and conditions governing use and access.
Equitable	To ensure equal access, data should be made available to all parties at no cost, or at a cost-recovery level only.
Fairness	The provision and use of data must be done in such a way that ensures fair treatment of all parties involved and recognition of their contributions.
Quality	While speed is of the essence in public health emergencies, a minimum quality standard of data must be ensured by the provider.

Modified from GloPID-R Data Sharing Working Group. (2017). Principles for data sharing in public health emergencies. Version 1. GloPID-R. Retrieved from https://s3-eu-west-1.amazonaws.com/pstorage-wellcome-4792389547823904/7897831/20170330PrinciplesforDataSharinginPublicHealthEmergenciesAdobe.pdf

but it also builds advance confidence in the system. It is difficult to rapidly cultivate trust in the context of an emergency; therefore, it is crucial that such relationships are already in place to facilitate data sharing (GloPID-R Data Sharing Working Group, 2017). Further, implicit in the principle of fairness mentioned earlier is a need for a circular model of data collection, in which the benefits derived from the sharing of data feed back to the community from which the data are derived. This also fosters trust and confidence in the system, in turn facilitating the future collection and sharing of data as people and communities are more likely to be willing to engage with researchers.

Conclusion

While population health has improved greatly in the past few decades, major health disparities persist around the world. In the majority of countries, the underlying cause of these disparities is an inadequate health system. Public health infrastructure remains the poor relation of healthcare services within the health systems of LMICs. It tends to be less visible than the curative services, and so often does not garner much political support, despite some clear examples of the popularity among the electorate of an improved health system and strong economic arguments for investing in public health initiatives (Jamison et al., 2013). While there have been promising advances in strengthening essential public health, most of the recent attention has focused on enhancing health security. While this approach to public health has a long history, it has been stimulated recently by a series of serious epidemics that have amply demonstrated how unprepared is the world to respond to major outbreaks and crises. While these health security initiatives are welcome, they are by their nature more limited in scope than a human rights–derived public health agenda. There is an urgent need to work to align and consolidate these two public health approaches to provide a comprehensive strengthening of public health infrastructure for the future.

Acknowledgments

We wish to thank Ala Alwan, Colin Brown, Emmeline Buckley, Katie Carmichael, Supamit Chunsuttiwat, Mishal Khan, Annette Luker, Rishma Maini, Brian McCloskey, and Monica Sethi for their contributions and insights into the writing of this chapter.

Discussion Questions

1. How valid are concerns that public health has received inadequate attention and resources relative to healthcare, and that this bias in favor of healthcare has limited the potential for population health gains? Give examples to support your position.
2. Which evidence-based arguments might you make to show that strengthening public health infrastructure is an essential component for achieving the Sustainable Development Goals?
3. Discuss the challenges to strengthening public health systems at the district and community levels. Which approaches can be used to address these challenges?
4. Which policies and actions could support the creation of a resilient public health system in a LMIC?
5. Discuss ways in which the reformed International Health Regulations' monitoring and evaluation process can improve national public health systems. Outline gaps in the process that could be addressed for comprehensive strengthening of essential public health functions.

CHAPTER 15

Management and Planning for Global Health

Tolib Mirzoev, Andrew Green, and Marsha Orgill[1]

What Is Management and Planning?

This chapter focuses on an area essential within global health for all parts of public health—management and planning. We focus particularly on application of these concepts at the national level and below, and management primarily within and by the public sector. Although we occasionally refer solely to either management or planning, the key issues discussed in this chapter—such as the wider contextual influences and key themes—apply to both management and planning.

The importance of health management and planning for strengthening national health systems has been increasingly recognized. However, management and planning in the health field still have an unfortunate reputation. They are often regarded as unnecessary and cumbersome activities that at best divert resources from the real frontline activities of providing health care or preventing ill health. At worst, health management and planning are seen as interfering in these activities in an unhelpful and bureaucratic manner. When they are working well, their presence is not always noticed; when they are malfunctioning, they are likely scapegoats for the health system's problems. In this chapter, a more balanced perspective on management and planning is sought, beginning by asking what management really is, and subsequently discussing health planning.

The key to understanding management and planning is the relationship between resources and objectives. Management is a process of making decisions about how resources will be generated, developed, allocated, combined, and used in pursuit of particular organizational objectives. It is difficult to deny the need for such decisions, given that resources—including, for example, financial, staff, medical supplies, physical space, and transport—are limited. Health planning is a "method of trying to attain explicit objectives for the future through the efficient and appropriate use of resources, available now and in the future" (Green, 2007, p. 3).

Planning and management are related, yet different activities. Both management and planning are concerned with ensuring the best possible use of resources to achieve the intended objectives. An important distinction between the two relates to their time frame and the balance between strategic and

[1] Acknowledgment is given to Charles Collins, who co-authored the previous editions of this chapter.

operational perspectives in their foci. Management is primarily concerned with shorter-term, operational decisions regarding resource use, whereas planning focuses on linking resource requirements to achievement of projected objectives in the future. Planning can be both strategic (i.e., longer term) and operational (i.e., shorter term). Health planning has also been described as a bridge between longer-term strategic policies and shorter-term operational management (Collins & Green, 2014). Drawing on this conceptualization, we interpret policy, planning, and management as a continuum. The policy end of this continuum is primarily about defining the strategic vision and longer-term direction; the management end is mostly about the day-to-day decision making; and health planning serves as the connecting process.

How limited resources within the health system are deployed is critical. Decisions are needed at a macro level within a health system regarding how resources are to be allocated among different areas of activity, and at a more operational level among different approaches to the delivery of health services. Management and planning are concerned with improving the allocation of such resources. For example, there may be an imbalance between the resources targeted at curative activities versus public health, between levels of care (primary versus secondary versus tertiary), between disease control programs, between geographic areas, between social or ethnic groups, between spending on different items such as personnel versus medicines, and between allocations of different personnel such as physicians versus nurses.

How such decisions are made is critical, and this process in part relates to the question of *who* manages. Management and planning functions are best carried out as a shared responsibility between staff whose only or primary activity is management or planning (i.e., managers or planners) and those whose primary function is working as health workers. One important role of specialist managers is to provide health workers with the space and resources they require to carry out their roles (see the *Public Health Infrastructure* chapter for more on the public health workforce and leadership).

Although the discussion presented here so far has focused on the limited resources available within health systems and the key role of managers and planners in responding to this major constraint, it is important to recognize other constraints that they face, including political (in the widest sense) limitations. These healthcare personnel may respond in different ways to such constraints—that is, by accepting, challenging, or looking for ways of maneuvering around them. Indeed, the success of management is often a function of the ability of a manager to work creatively with, rather than passively accept, constraints. At an operational level, this key attribute of management is one way in which this role differs from administration, which is more related to routine implementation of existing rules and procedures.

The definition of management presented earlier in this chapter may suggest it comprises a technocratic mechanical process. In reality, effective management is as much an art as a science, and the same description also applies to planning. One particular aspect of management that is often forgotten is its role in dealing with contradictions (discussed later in this chapter). To be effective, managers must recognize the context within which they operate and adapt their approach accordingly. Such contextual factors include the health situation, the degree of political stability, the general attitude toward public-sector reforms, the level of the country's economic growth, and international influences. Solutions that are appropriate in one situation may not work in another. One key message of this chapter, therefore, is to exercise caution when called upon to adopt blueprint approaches to management.

Management and planning occur at different levels of a country's health system, including at the organizational (e.g., within a ministry of health or district), sectoral (health sector), and health system (across the social sectors) levels. Health managers and planners are therefore staff within organizations at each level of a country's health system. Health managers can work within a specific health program or area (e.g., tuberculosis control program manager), work within a specific component of a health system (e.g., human resources manager), or focus on the whole health system (e.g., district medical officer). Similarly, health planners, and the resultant health plans, can focus on a particular program, a health systems component, or a health system as a whole. Given that both management and planning are concerned with the best possible use of available resources, there are inevitable overlaps between the work of planners and managers. For example, planners are expected to work closely with finance managers in projecting the budget for implementing health-related plans.

Management and planning at sectoral and system levels can also be interpreted as a reflection of approaches to, and principles of, wider governance within the health system such as participation, accountability, and use of information to support decisions (Mikkelsen-Lopez, Wyss, & de Savigny, 2011; Siddiqi et al., 2009). Earlier we outlined the relationships among policy, planning, and management. An important distinction between the concepts

of governance and management and planning is the following: Health systems governance is defined by the World Health Organization (WHO) as "ensuring strategic policy frameworks exist and are combined with effective oversight, coalition-building, the provision of appropriate regulations and incentives, attention to system-design, and accountability" (WHO, 2007a). This is a much broader concept that frames the earlier-mentioned continuum of policy–planning–management. In the last decade, there has been a substantial proliferation of studies exploring governance or its individual elements, such as regulation, and proposing frameworks and principles of good governance and detailed variables for measuring governance within health systems (Lehmann & Gilson, 2015; Mikkelsen-Lopez et al., 2011; Ramesh, Wu, & He, 2014; Siddiqi et al., 2009; Vian & Bicknell, 2014; Vian, Brinkerhoff, Feeley, Salomon, & Vien, 2012; WHO, 2010a). A recent systematic review has identified as many as 16 frameworks for understanding governance that stem from various disciplines, including institutional economics, political science, public management, and development studies (Pyone, Smith, & van den Broek, 2017). Siddiqi et al.'s (2009) 10 principles of good governance (strategic vision, participation and consensus orientation, rule of law, transparency, responsiveness, equity and inclusiveness, effectiveness and efficiency, accountability, intelligence and information, and ethics) underpin one of the most comprehensive frameworks for understanding and assessing health systems governance. A recent framework for good governance, proposed by Collins and Green (2014), emphasized eight similar criteria: a proactive state, effective accountability, decentralization of decision making, intersectoral action, inclusive involvement, ethical conduct, effective regulation, and transparency and democratizing information.

The political character of management and planning also needs to be emphasized. Although management and planning require certain technical skills, they inevitably deal with change, which can be threatening to affected groups and, therefore, stimulates opposition. Thus, for management and planning to succeed, their practitioners must have capabilities in political analysis as well as technical skills. Various techniques have been developed to map attitudes to particular interventions, of which the best known is stakeholder analysis (Brugha & Varvasovszky, 2000). How different groups are involved in management is likely to affect the quality of the process, the speed of decision making, and the ownership of the resultant decisions and action. For example, consultation may occur at different points in the management and planning process—with different aims and implications. It can be seen as the following types of engagement:

- Seeking views as to priorities and strategies at the beginning of decision making
- Seeking views on alternative options once these choices have been formulated
- Seeking views on a formulated plan of action

If consultation takes place later in the process, the more it may be viewed as a formal and even tokenistic process. The earlier consulation takes place, the more likely it is to influence the thinking behind the development of management actions and plans. Consultation can take place in a variety of ways, including directly with the stakeholders (e.g., through surveys or focus groups) or indirectly through representative organizations. It can take place through special one-off mechanisms or through ongoing management processes. Each approach has both advantages and disadvantages in terms of the resources and time required and the robustness of the information gathered.

A fundamental point regarding both management and planning is this: These processes are not and cannot be value-free. One determinant affecting the particular choice of management and planning approach is the values underpinning the health system (Collins & Green, 2014), which could include some of the following:

- Equity, including its different interpretations
- Efficiency
- Choice
- Gender sensitivity
- Transparency and accountability of decision processes
- Market values, including the pursuit of profits
- Participative and accountable decision making
- Solidarity
- Long-term perspective

Some values may be inconsistent with and perhaps even contradict others, most notably market values and equity. The choice, pursuit, and realization of these values through management processes is political in that it affects the interests and views of different groups in society. Furthermore, managers themselves are not value-neutral, but rather bring to the job their own political perspectives and positions.

A health sector committed to the pursuit of accountability and transparency is bound to approach its decision-making processes and consultation differently from one that assigns less importance to this value. Closely related to this are differences between approaches to management and planning within the

public and private sectors.[2] Although the main difference between these two sectors is often suggested to be the freedom of maneuvering enjoyed by a manager, a more salient difference stems from the values and principles that underpin the public and private sectors, and in particular their organizational motives. The private (for-profit) sector is aimed at profit generation for its owners. This stance contrasts with the social goals of the public sector, whose formal objectives may be stated as health promotion and protection, equity and accountability, responsiveness to people's medical and nonmedical expectations, and, increasingly, efficiency and cost containment. This difference in motivation suggests that different styles of management will be used in the public and private sectors, with the former usually emphasizing longer-term sustainability, often collaborative as opposed to competitive strategies, and political debate and negotiation regarding social values. This chapter focuses primarily on public-sector management.

FIGURE 15-1 depicts a framework for management and planning, and the approach taken in this chapter. The chapter follows this schema. It first draws out the important aspects of context. This is followed by a discussion of the structures within which health care may be organized. We then look at health planning as a key activity in a health system that determines the pattern of activities and services to be developed to meet an organization's objectives. Next, the chapter examines issues in the management of resources, focusing on finance, staff, transport, and information. It concludes by discussing some cross-cutting themes in management and planning. The reader is cautioned that, because the areas of health management and health planning are broad, the analysis in this chapter cannot be exhaustive and is, in parts, necessarily selective. It is hoped that this introductory chapter will lead the reader on to further reading on specific topics in health management and planning.

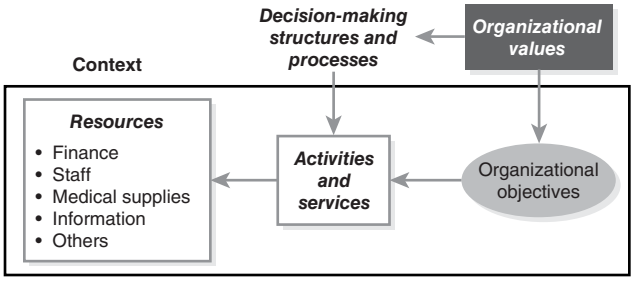

FIGURE 15-1 Key elements in management and planning.

The Context of Management and Planning

Management and planning are social processes of relations that differ according to the social context in which they are found. One would not expect the processes of a public health service in Mali to be the same as those of a multinational corporation based in the United States, for example.

This potential for variation poses dilemmas for the manager and the planner, who need to recognize that the management and planning process does not occur in a vacuum. The way in which managers (and planners) relate resources to objectives needs to be adapted to the environment in which that management takes place. However, the manager faces two difficult issues in ensuring this flexibility. First, he or she must confront universalism—that is, the idea that there is one best way for management to work, irrespective of time, place, or condition. Second, the relationship between the management process and the context is not easy to understand and respond to. On the one hand, the context strongly influences the management process. Management and planning cannot be simply transplanted from one situation to another; rather, the manager must read the current and ever-changing context and determine the most appropriate response given that background. The economic, social, and political context determines the social well-being of communities and the health needs they express, together with the pressures on healthcare organizations. The context affects the feasibility and effectiveness of the options available to managers and planners. On the other hand, the influences do not just flow in a single direction: Managers can (and indeed are expected to) have an impact on the environment.

This section analyzes the complex relationship between the management and planning processes and the context in which they operate. Although much of the discussion refers specifically to the context of management, the same context is also applicable to health planning.

Different definitions of context exist. Dobrow et al. (2004) defined context as including "all factors within an environment where a decision is made" (p. 209). A more detailed approach, introducing a three-tier distinction between macro (systems), meso (organizational), and micro (individual and interpersonal) levels of context, has been used in health

[2] Particular aspects of the analysis in this chapter referring to the public sector and its characteristics and contradictions draw on and develop points raised by Stewart and Ranson (1994).

policy analyses (see, for example, Hudson & Lowe, 2009; Mirzoev et al., 2017; Ricketts, 2010). For organizational purposes, the context in this chapter is broken down into different thematic areas, economic, social, political, and international. These are analytical constructs, however, and do not represent real-life boundaries. In reality, such boundaries are overlapping, permeable, and flexible.

Economic Context

The economic circumstances of a society will influence employment and income and the extent to which individuals and groups can meet their basic needs. These macroeconomic circumstances provide the fundamental backdrop to social well-being—or the lack of it—to which management needs to respond.

The management process is also influenced by the amount and type of resources available to managers. The flow of resources to, and within, the health sector reflects the country's economic circumstances (e.g., economic growth and amount of government taxation) and resource allocation decisions. The flow of resources has important effects on the freedom with which managers are able to work through various options. Furthermore, availability of resources can affect the degree and nature of involvement of different stakeholders in management processes.

Social Context

The broader processes of social change set the scene for the health context in which managers work. For example, unemployment, aging of the population, and migration all raise social and health issues, placing new demands on the health sector. At the same time, social factors influence the feasibility and effectiveness of options. For example, although managers may seek to develop community participation, the feasibility of this endeavor will depend on factors such as past experiences with community participation, geographic settlement patterns, and the degree of social homogeneity. **EXHIBIT 15-1** provides an example from Brazil that illustrates the contextual impact on health management.

EXHIBIT 15-1 Social Context and Health Management: Local Context and Decentralized Health Management in Brazil

Research analyzed the factors that influence the effectiveness of decentralized health management in three Brazilian municipalities. The study identified a variety of contextual factors, including political patronage, different ethical notions of acceptable practices, and differing commitments of staff to the localities. While showing the effects of context on the management process, the study also highlighted the role of managers in influencing that context by referring to the "space for the formal health system to influence local social organisation and political culture and offer a potential for change" (Atkinson, Medeiros, Oliveira, & de Almeida, 2000, p. 632).

Political Context and Public Sector

Four issues in the political environment in which the public sector operates are also contextually important.

Public Service Orientation, Corruption, and Patronage

The management process should be concerned with health and healthcare objectives for the public. Defining these objectives is difficult enough given the contradictory interests of social and political groups in society. Public-sector managers, however, constantly face a further challenge, related to the contradiction between this public service role and the opportunities for private gain through the public sector that arise in four interrelated ways (Green & Collins, 2003):

- *Corporate gain*: Private companies often profit from the public sector. Obvious examples include pharmaceutical, construction, and information technology companies. Tax concessions or public-sector training for the private sector may subsidize the private medical industry. The private sector may also be able to capture those public agencies designed to regulate it.
- *Corruption*: Illegal and unethical use of public resources for private gain can take many forms, ranging from bribes to theft, and can have an adverse effect on government activities (Gaitonde, Oxman, Okebukola, & Rada, 2016). It is important to note that corruption is not solely the preserve of low- and middle-income countries (LMICs).
- *Patronage*: Public resources may be used to strengthen the political position of a patron or political leader. Complex networks of patronage can emerge and sustain themselves, particularly through the manipulation of employment (Collins, Omar, & Hurst, 2000).
- *Professionalism*: Although its contribution to standards and the quality of care can be positive, professionalism can also lead to factionalism and the manipulation of public resources to favor the interests of particular professional groups to the detriment of the public interest.

Integrity and Cohesion of the Public Sector

Public-sector management takes place within a system that is not always cohesive. Such discontinuities are particularly problematic in some LMICs. The impact of neocolonial domination, economic crises, political conflict, famine, and national disasters can lead to disintegration and fragmentation of state authority.

Structural Change of the Public Sector

The public sector in many countries is undergoing significant change. Health-sector management and planning has been part of that change, as witnessed by the three major waves of international health reform affecting LMICs—the Alma Ata primary health care (PHC) movement, subsequent market-based reforms (discussed in the *Design of Health Systems* chapter), and more recent efforts to apply more integrated approaches to health systems development in achieving universal health coverage, signaling the revival of the PHC agenda. **TABLE 15-1** identifies the potential implications of these broader changes for the role and operation of health-sector management in LMICs.

The management changes outlined in Table 15-1 have been mediated by other factors and have had different impacts both between and within country health systems. First, alternative health-sector approaches, drawing their inspiration from the PHC approach, have continued to emphasize, for example, the importance of citizenship, equity, and social justice, and have focused on community participation in health systems decision making. This multiplicity of aims can generate contradictions for management

TABLE 15-1 Health-Sector Change and Management

Management Change	Examples
New management responsibilities	The introduction of competitive relationships, contracting, voucher systems for service users, and market research to assess customer responses generates new responsibilities for managers.
New management skills	The introduction of the above responsibilities can require new skills in areas such as contracting, customer relations, and quality assurance techniques.
New management boundaries	The introduction of public–private joint ventures, contracting out to the private sector, and the use of competitive markets have blurred the distinction between the public and private sectors. This evolution suggests new boundaries for public-sector managers, with implications for management values and relations.
Changing management actors	Reforms can lead to greater diversity within the health system, as public-sector facilities gain semiautonomous status and private-sector facilities (both nonprofit and for profit) become involved in health care. Managers need to take note of this diversity in developing a range of relations, from collaboration to competition.
Changing management objectives	Efficiency and health facility financial survival and growth can eclipse objectives and values based more on social justice and equity. For some, the generation of profit or financial surplus becomes an accepted objective of management action.
Changing management structures, systems, and processes	Management structures, processes, and systems associated with the private sector have been introduced into the public sector—for example, performance-based incentives in pay structures and competition between health facilities.
New management options	Reforms in many countries have opened up the option of contracting out service provision to the private sector, as opposed to relying on internal service provision.
Dealing with new challenges and contradictions	Decentralization has been associated in some countries with the requirement that health facilities be financially self-sufficient. Managers face the challenge of simultaneously ensuring the continuity of healthcare services provision, meeting equity objectives, and generating resources for institutional survival.

(Flynn, 1997). For example, market-based strategies of service delivery emphasizing individual customer choice may clash with more citizen-based strategies based on community participation and collaborative relations within the public sector.

Second, the capacity for making the type of management changes outlined in Table 15-1 is constrained in many LMICs by the prevalence of informal arrangements in the economy and public sector, and the scarcity of general administrative and managerial skills and systems (Schick, 1998). Corruption and patronage frequently maintain a stranglehold on health management and planning, thereby limiting systems' capacity for change. The result is often a changing blend of different approaches, leading to a muddled, confused, and contradictory character for public-sector management. At times, a thin veneer of reform fails to disguise a cumbersome bureaucracy bent on corruption and patronage. At other times, purposive action by dedicated health staff overcomes strong constraints to provide health care to communities.

Increasing Role of the Private Sector

The private sector consists of both for-profit and not-for-profit institutions, each with a different set of objectives. The primary objective of the for-profit private sector is to benefit financially, whereas the objectives of the not-for-profit private health sector are closer to the social objectives of the public sector. The private sector can include in-country institutions (e.g., private hospitals or private insurance companies), international agencies (e.g., international pharmaceutical companies) and global institutions (e.g., Global Fund to Fight AIDS, Tuberculosis and Malaria). The distinction between the private and public sectors is often blurred—for example, many public-sector health staff may have private practices in addition to fulfilling their public-sector jobs.

The role of the private sector, which is discussed in more detail in the *Design of Health Systems* chapter, differs across countries. Nevertheless, it typically includes engagement in the areas of policy making, financing, provision of services (often contracted out from the public sector), and regulation.

Outsourcing of public services through contracts with the private sector (e.g., cleaning or transport services) is seen as a way of benefiting from economies of scale and the technical expertise of specialist contractors in areas generally removed from the central responsibilities of healthcare organizations. Some also argue that the private sector's perceived efficiency and the control and accountability conferred by contracts are other advantages associated with this model. Concerns raised by outsourcing of these responsibilities include the transaction costs of contracting out; questions about whether lower costs are merely the result of lower salary costs; the lack of sustainability and management learning in contracts; potential problems with poor quality, collusion, and corruption; and the lack of contracting skills in purchasing organizations (Mills, 1998).

The public and private sectors can engage in different types of interrelationships, referred to by many as the public–private mix (PPM) or public–private partnerships (PPPs). The underlying assumptions for the PPM model are its perceived greater efficiency in service delivery; a recognition that the public sector alone may be unable to ensure comprehensive coverage of, and access to, health services; and the complementary nature of the public and private sectors in achieving this aim.

The role of the private health sector (both the for-profit and nonprofit segments) was widely promoted in the mid-1990s through, for example, incentives to the private sector (e.g., tax concessions on capital invested or on private health insurance), public-sector contracting with the private sector (e.g., in Brazil), outright privatization, and outsourcing in the private sector (e.g., support services in a public-sector hospital). There are examples of successful PPPs, such as in tuberculosis control (Karki, Mirzoev, Green, Newell, & Baral, 2007). Nevertheless, the uncontrolled growth of the private sector in many countries has raised concerns about the quality and coverage of many health services delivered through private-sector companies (Mills, Brugha, Hanson, & McPake, 2002), leading to further health inequalities and calls for better regulation (Lê, Ha, Mirzoev, & Nguyen, 2015; Sheikh, Saligram, & Hort, 2015), as discussed in the *Design of Health Systems* chapter. Examples of challenges for public-sector managers include understanding the new range of providers and negotiating new relationships through, for example, contracts, leasing, and concessions; the need for public-sector managers to devise strategies to retain staff in the public sector; and pressures to incorporate the style and techniques of private-sector management into the workings of public agencies.

International Context

The international economic and political context has an important effect on the national and local economic, social, and political processes of a country through investment, interest rates on debt repayments, trade, and technical advice and support, among other mechanisms. For example, significant funding is provided

by the Bill and Melinda Gates Foundation and other philanthropic institutions for health systems development in LMICs. These initiatives, which are known as global public–private partnerships (GPPPs), inevitably affect management and planning practices at country and local levels. For example, while providing increased funding, the GPPPs may be

> depriving specific stakeholders a voice in decision-making; . . . [contributing to] misguided assumptions of the efficiency of the public and private sectors; . . . wasting resources through inadequate use of recipient country systems and poor harmonisation; and inappropriate incentives for staff engaging in partnerships. (Buse & Harmer, 2007, p. 259)

The growth of the international policy presence of the World Bank during the 1980s and 1990s had an important impact on health management reform in LMICs. The powerful financial presence of such international donors can leave health ministries in a dependent relationship. Moreover, the development of budget support, Poverty Reduction Strategy Papers (PRSPs), and health sector-wide approaches (SWAps) throughout the 1990s influenced changes in the relationship between national governments and international agencies. More recently, the global financial crisis in 2008 affected the availability of resources for health sectors at both the national and international levels (Bednarz, 2010). The general concern that underfunded and weak health systems had hindered the achievement of health-related Millennium Development Goals (MDGs) also spurred an exploration of alternative health financing mechanisms, as shown by the establishment of a High-Level Taskforce on Innovative International Financing for Health Systems (Fryatt, Mills, & Nordstrom, 2010).

More recent changes in international context include large-scale population displacements, increasingly frequent and severe conflicts and emergencies, disease outbreaks (e.g., Ebola and Zika viruses), and political commitments and targets related to the Sustainable Development Goals (SDGs) that replaced the MDGs. Many of these changes highlight the growing number of fragile states on a worldwide basis, and call for integrated, cross-sectoral management approaches to help ensure health system resilience and responsiveness as well as more sustainable health systems development (O'Hare, 2015; Roome, Raven, & Martineau, 2014; Schmidt, Gostin, & Emanuel, 2015).

The general point raised by the discussion in this section is the importance of understanding the interrelationship between context and health management and planning. Managers need to interpret the wide range of changing and complex contextual factors that influence the way in which management is actually conducted in the health system. At the same time, managers can be proactive; they are not powerless (Atkinson et al., 2000; Grindle, 1997). There is a margin of maneuverability in which they can operate, which varies in time but allows purposive action to be developed. One example of this flexibility can be seen in the different forms of sector-wide approaches that have emerged in response to different country contexts (WHO, 2006a).

Organizing

An important management function is developing the organizational structure—that is, the way that work is assigned, both vertically and horizontally, together with the formal framework of links with other organizations and groups. Managers usually inherit an established structure. Recognizing this fact of life, this section takes the form of a review of organizational structure, indicating key issues and options available to managers to address those issues.

In reviewing this organizing function, several points need to be emphasized. First, health managers need to consider the full range of structural changes open to the organization. For this purpose, this section presents a framework setting out the dimensions of a review of the organizational structure. For purposes of illustration, it refers to ministries of health, although the framework could be adapted to decentralized health authorities or health facilities. The role of managers in structuring an organization will depend on their authority within the organization and the significance of the structural issue to the organization.

Second, in deciding on organizational structure, managers need to take into account contextual factors, such as the staff capacity, the health policy, and the overall government structure.

Third, there is a need to secure a balance between two key factors. On the one hand, managers have to keep the organizational structure under review and implement necessary changes. Structural changes are not the only component of change, however; they are just one factor to be considered and balanced against changes in resources, systems, values, and skills. On the other hand, managers need to recognize that structural changes can be both expensive in terms of resource use and disruptive to staff motivation and service delivery. Change should also not be used to mask more difficult and controversial issues of resource availability or health policy content.

Three overlapping dimensions of the organizational structure are reviewed here:

- Center–periphery relations
- Relationships with other organizations and groups
- Internal structure

These dimensions relate system-level issues to more micro-level issues. Reference may be made to the *Design of Health Systems* chapter to understand some these issues in greater depth.

Center–Periphery Relations

A ministry of health (MOH) is organized based on relations that link the center to the periphery. This raises important dimensions of geographic decentralization, purchaser–provider relations, and delegated semi-autonomy.

Decentralization

Decentralization is "a transfer of authority to make decisions, to carry out management functions and use resources. Focusing on the public sector, it means the passing of these from central government authorities to such bodies in the periphery as local government, field administration, subordinate units of government, specialised authorities and semiautonomous public corporations" (Collins, 1994). An assumption, or perhaps a value-driven judgment, here is that greater local decision space within the decentralized context can help ensure greater accountability at local levels. Conversely, an argument can be made that in a decentralized health system where each regional government is sufficiently autonomous, there is a clear danger of losing an inter-regional equity perspective.

Purchaser–Provider Relations

As explained in the *Design of Health Systems* chapter, health-sector reforms have encouraged a shift from organizationally integrated and hierarchically structured systems to a separation between the purchaser organization, which has the financial resources and interprets the needs, and the provider, which is responsible for services provision. Purchasing involves identifying interventions or services to be purchased (based on need, priority, and cost-effectiveness), choosing service providers (based on quality, equity, and efficiency), and determining how services will be purchased, including contractual arrangements and provider payment mechanisms (RESYST, 2014). "Passive purchasing implies following a predetermined budget or simply paying bills when presented. Strategic purchasing involves a continuous search for the best ways to maximize health system performance by deciding which interventions should be purchased, how, and from whom" (WHO, 2000).

Delegated Semi-Autonomy

Delegated semi-autonomy, as a form of decentralization, involves the transfer of semi-autonomous authority to manage an organization. In health care, a common form involves hospitals organizationally attached to a health ministry. These facilities may be managed by a board that is only partly appointed by the ministry; staff may be hospital (not ministry) employees, while the hospital has powers of staff appointment, revenue generation, determination of salaries, and purchasing authority. This delegation can take the form of a purchaser–provider separation and be executed through a contract that formalizes the hospital's responsibilities and the ministry budget allocations to the hospital.

Another form in which purchaser–provider separation is combined with delegated semi-autonomy occurs when the whole operational side of health care is taken out of the MOH and located in a separate health services structure. This arrangement is found in Ghana, for example. Within the Ghanaian health sector, the MOH wields power over public policy decision-making processes, while the Ghana Health Service (GHS) is a semi-autonomous agency responsible for service delivery at regional, subdistrict, and community levels. Other service delivery agencies also include teaching hospitals and national ambulance services (Couttolenc, 2012; Koduah, 2016). Metropolitan, municipal, and district assemblies do not run or manage facilities, but rather provide certain health-related services, mostly involving support to MOH and GHS activities (Couttolenc, 2012).

Managers should have a responsibility for developing the center–periphery relations, or at least be consulted as important stakeholders in the process of organizational change.

Relationships with Other Organizations and Groups

The public sector—in our example, the MOH—needs to have clear and defined relations with a variety of external organizations and groups. Private-sector growth requires organizational links with government such as joint ventures, contracting out, and policy consultation. Community participation raises issues of how the community will be organizationally integrated into the health system. Many LMICs depend on international organizations, both bilateral and

multilateral, for significant financing of the health sector and develop important relations around health policy formulation and implementation. This organizational relation can take the form of aid agencies developing links with parts of the healthcare system when they take responsibility for financing particular disease-control programs or healthcare services for particular geographic zones. Notably, the development of health SWAps in the 1990s led to organizational linkages between international donors and MOHs to develop health policy frameworks.

The MOH also relates to other government agencies—an interaction typically required as part of the cross-governmental process of management via ministries such as finance, social affairs, and labor. An important aspect of this interagency cooperation is the development of an intersectoral approach to health development. Structuring relationships with special interests, such as the private, for-profit healthcare sector, forms an important part of consultation. At the same time, the MOH is required to exercise regulatory powers over the same special interests.

Internal Structure[3]

Related to the two dimensions of center–periphery and external relations is the organization's own internal relations and assignment of roles. These aspects of internal structure encompass four interrelated factors:

- Hierarchy and span of control
- Relations of authority
- Horizontal divisions
- Internal linking

Hierarchy and Span of Control

Organizations usually adopt some form of hierarchical shape consisting of different levels of management. These recognized levels of authority have a specific depth of authority and span of vision over the organization; the higher up the hierarchy, the greater the authority and the broader the vision. An organization can adopt different hierarchical shapes, although it is often thought that a flatter organizational shape is more appropriate for effective communication and inclusive decision making.

Health ministries often suffer from overextended and overly tall hierarchies. This structure can result from bloated bureaucracies and the tendency to confuse public-service grading systems with management levels (the number of management levels increases to accommodate new grades). Hierarchies can be made flatter by allowing several grades to occupy the same management levels, or by reducing the number of management levels. However desirable it might seem to widen the span of control for entities within the hierarchy, this endeavor can be difficult. Attention has to be paid, for example, to the capacity of both managers and subordinates to deal with a widened span of control, the changed nature of the work, and the wider organizational and systems context in which the managers and planners operate.

Relations of Authority

Relations of authority are important in binding the organization together. Healthcare organizations, depending on the type of decentralization, typically exhibit different forms of overlapping authority, such as strategic, main line managerial, technical, professional, and supervisory. Strategic authority is fundamental to a MOH and involves decision making with implications for the direction in which the whole or a significant part of the organization is working.

One notable feature of healthcare organizations is the existence of dual authority relations in which staff have more than one relation of authority In **FIGURE 15-2**, for example, the district tuberculosis (TB) officer is under the managerial authority of the district health officer but under the technical authority of the regional TB officer.

Dual authority relations can be used to widen spans of control. **FIGURE 15-3** shows how a health manager can increase his or her span of control by appointing a supervisor or support staff to help in the management of staff. The supervisor falls under the main line management control of the health manager, as do the subordinates. Each subordinate, however, is

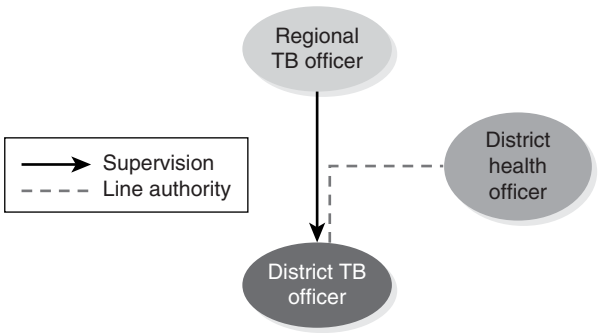

FIGURE 15-2 Dual authority relations.

[3] This section draws on the work of Collins (1994).

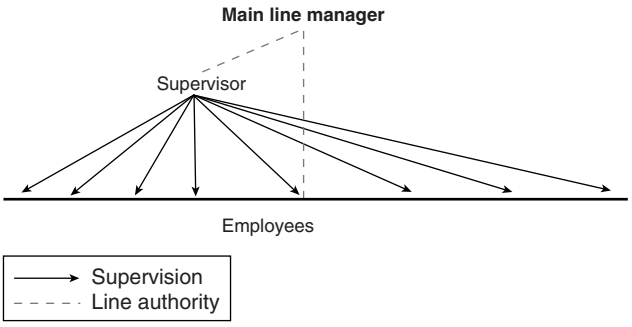

FIGURE 15-3 Reducing the burden of a wide span of control on a main line manager through the creation of supervisory staff.

Modified with permission from Rowbottom, R., & Billis, D. (1987). *Organisational design: The work level approach.* Aldershot, UK: Gower.

under the joint authority of both the supervisor and the main line manager. Because the pressure of direct supervision has been taken off the main line manager, the span of control can be widened.

Although dual authority relations may appear strange and confusing, they are commonplace in health systems. Increasing health system decentralization through devolution to local government presents challenges for authority relations, however. Technical and hierarchical relations with the center need to be balanced with the strengthened horizontal relations within the local government authority.

Managers need to design authority relations in such a way as to avoid potential confusion. There are two complementary ways of clarifying dual authority situations. First, the different forms of authority in operation should be clarified and explained to the staff. For example, the relationships in Figure 15-2 among the regional TB officer, the district TB officer, and the district health officer might be clarified by identifying one superior, the district health officer, as possessing main line managerial authority and the other as holding another form of authority, such as technical supervisory, monitoring, coordinating, or prescribing authority. Second, the dual authority structure could be clarified by specifying the areas of management for the exercise of authority. Key areas of authority to be allocated among the authority holders can include combinations of issues related to staff appointments, induction and training, performance review, supervision and development, development and implementation of policies and programs, introduction of standards and methods, and control over budgets. Both methods of dual authority relations require a clear specification of authority and responsibilities and a culture of understanding between the persons involved.

Horizontal Grouping

At each managerial level, work has to be assigned to staff within different groupings, such as divisions, departments, and units. This division of work may be based on different combinations of geography (e.g., in a decentralized system), functions (e.g., in planning or national disease control programs), or staff cadre (e.g., in a nursing department). The MOH could be based on a simple logic of planning, doing, and supporting, with directorates of planning (including aid coordination and information systems), health services (including primary healthcare services, national health programs, and hospital services), and support services (including human resources and financial administration) (Collins, 1994). This sort of arrangement has some drawbacks, however: Notably, it can lead to a lack of horizontal links between the directorates and to imbalances in power, such that one directorate becomes the most powerful.

Internal Linking

The previous discussion focused on the application of internal structures to divide work, which runs the risk of fragmenting the organization. The health organization needs to be brought together and act as an integrated whole. One way to ensure such cohesiveness is through the operation of strategic authority. Strategic policy authority and resource allocation flow downward, maintaining vertical integration. At the same time, horizontal collaborative links are developed between the various divisions, departments, and units in the organization. Several structural arrangements may be employed to accomplish this goal:

- Job descriptions to specify lines of authority in the particular job in addition to job liaison responsibilities and membership of teams
- Organizational devices, such as interdepartmental committees and task groups, in addition to specific linking responsibilities assigned to staff
- Matrix systems (e.g., staff may belong to the basic departments in the organization in addition to specific task units and projects)

Planning[4]

Like the management function, planning does not have a good reputation in many parts of the health sector. Its record is not good, with plans often not being implemented or implemented ineffectively. The

[4] This section draws on the work of Green (2007).

reasons for this failure vary, but frequently include top-down, rigid, and often bureaucratic centralist processes; a failure to integrate planning processes with other decision-making processes such as budgeting; a failure to fully understand and take account of changing context; and a failure to involve key groups, including health services managers, professional groups, and users in planning. These criticisms should not, however, be interpreted as pointing to the inevitable failure of planning, but rather as recognizing the need to develop systems appropriate to the particular healthcare needs and context of a country. This section looks at various background planning issues and provides an overview of the planning cycle.

Why Plan?

Planning is an essential element of health systems governance that is concerned with making decisions today to influence the future. It is a response to the dilemma that faces these organizations, which must deal with an inevitable shortfall in resources compared with increasing health needs and hence the need to make choices between competing uses for the resources—that is, to set priorities.

Four other critical issues underpin the importance of planning. First is the changing nature of health and health care. Decisions on resource usage need to take account of likely future changes to health needs, resources, and potential health service strategies and technologies. Health need changes include both new diseases—such as human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) or, more recently, Ebola and Zika viruses—and changes in the relative prevalence of particular problems as a result of epidemiologic or demographic transition. Variations on this theme include, for example, the growth of multidrug-resistant strains of TB. Resource changes that require consideration include both financial forecasts and the availability of key resources—in particular, health workers. In many countries, the large population displacements and international migration of key staff such as doctors and nurses may lead to critical future shortages unless appropriate policies are developed now. The last area of forecasting relates to future technology developments and their impact on the health sector.

Second, as noted earlier in this chapter, decisions about priorities take place within economic, social, and political contexts that will vary between countries and within countries over time. Health planning, therefore, can be seen as means of identifying and responding to the context-specificity of different health systems. Closely linked to these priority decisions are questions as to both what the underpinning values of the health system are and who determines these priorities.

The third issue is the recognition that the current allocation of resources within the health sector is not optimal, as discussed earlier. As a consequence, planning is concerned not just with dealing with changes in the future, but also with addressing current problems in a way that will have effects in the future (e.g., effects of distribution of human resources on availability and quality of services and, ultimately, on health status). Shifts in resources could lead to a more effective and efficient use of resources.

Last, health planning is a way of avoiding decisions driven by status quo, taken by a small elite group(s) of decision-makers such as policy makers, external agencies, or health workers without consulting other relevant stakeholders.

What Is Planning?

Health planning has been defined by Green (2007, p. 3) as follows:

> A systematic method of trying to attain explicit objectives for the future through the efficient and appropriate use of resources, available now and in the future.

The important components of this and other similar definitions are as follows:

- Where one is going (objectives)
- With what (resources)
- How (efficient and appropriate implementation)
- When (future)
- With what degree of formalization (explicitness, systematic, and method) about the process

There are, however, different approaches to, and types of, planning. In particular, we can contrast strategic (or allocative) and operational planning. *Strategic planning*, which closely resembles policy making, aims to provide an open and formalized process for making these difficult decisions as to which health needs will be met by the limited resources and how. Thus it attempts to provide a broad direction of travel for the health sector. In contrast, *operational planning* (also known as activity planning) focuses on the detail of implementation by setting out time frames for activities in the short term. In practice, the two types of planning should be linked, and often there will be elements of both within any particular plan document. Highlighting the conceptual difference between the two is helpful, however.

Health planning also involves a chain of interrelated processes at different levels of a country's health

TABLE 15-2 Misperceptions About Planning

Misperception: Planning Is . . .	But . . .
About the production of plans	Planning is concerned with change, not documents; these may be necessary but are not a sufficient part of the planning process
About capital budgets	Planning should also focus on recurrent budgets
Only concerned with projects	Projects are simply one way of achieving change
A highly technical and specialist activity	Much planning is common sense
Carried out by specialist planners	Planning needs to be shared by a wide group of actors
An objective and neutral activity	Planning involves value judgments

Reproduced with permission from Green, A. (2007). *An introduction to health planning in developing health systems* (3rd ed.). Oxford, UK: Oxford University Press.

system. The following levels of planning can be distinguished: country (e.g., PRSPs), sector (e.g., SWAps, policy, and strategy), and program and project (e.g., maternal and child health [MCH]) (Mirzoev & Green, 2017).

One criticism of planning is that it is seen as being unfeasible during periods of uncertainty or instability. However, the reverse can also be argued—that planning is itself a means of dealing with uncertainty, while retaining a strategic direction. However, it needs to be sufficiently flexible to achieve this aim.

Several common misperceptions about planning need to be addressed. **TABLE 15-2** sets out these sources of misunderstanding, along with the counter-views.

Planning for Health and the Health Sector

The arguments for a government lead in planning hinge on whether health care is viewed as a special good for which the normal market mechanisms are not appropriate (e.g., because of equity implications or because of their public-good nature). The following discussion takes the widely held position that (1) at a minimum the state has a responsibility to set and regulate policies, and (2) the state will continue to provide certain key healthcare services for the foreseeable future.

Historically, planning in the public sector has tended to focus on the state's own healthcare services. More recently, it has become more widely recognized that planning by government needs to recognize the actual and potential inputs (both positive and negative) of other healthcare agencies, such as those in the private for-profit sector and nongovernmental organizations (NGOs). This expanded reach calls for the development of new policy and planning tools to implement such strategies, and will be needed for developing strategic long-term plans and policies to achieve universal health coverage (WHO, 2017).

In addition, although we tend to label plans in the health sector as "health plans," in reality they tend to focus on health care, with little recognition of the positive and negative effects of other (non-healthcare) agencies on health. Genuine health plans need to broaden their scope and incorporate appropriate actions related to other sectors.

The changes in the structure and roles of government that have been taking place in many health sectors in recent years often require corresponding changes in the government planning approach. In particular, the increasing number of healthcare providers that are not directly managed or controlled by one government agency and the decentralization of authority mean that governments need to develop new ways of achieving change in providers other than those whom they directly manage. New forms of incentives and regulatory powers are needed, in contrast to the traditional managerial command-and-control approaches. This trend also implies that a greater onus is placed on the lead government agency to provide overall policy frameworks for the health sector that specify appropriate roles for other agencies.

Approaches to Planning and Their Relationship to the Context in Which Planning Occurs

Various approaches to planning are possible. Following are descriptions of two continua of approaches,

although it is important to note that they are not mutually exclusive:

- *Problem-solving reactive approaches versus longer-term needs assessment*. Planning can focus on, and try to identify solutions to, existing problems. A variety of techniques have been developed to assist planners and managers in problem identification and solving, including problem tree and fish-bone analysis. One danger with such an approach is that its focus on current problems may detract from longer-term needs assessment and timely responses to emerging needs (Green, 2007; Mirzoev & Green, 2017).
- *Structured logical frameworks versus looser strategic directional approaches*. During the 1990s and early 2000s, a number of organizations, and in particular donor agencies, adopted an approach to planning (generally projects) using logical frameworks (logframes) that set out in a structured manner a hierarchy of objectives and activities, together with means of identifying whether they have been achieved, and the potential future risks or assumptions (Nancholas, 1998). Such an approach can be contrasted with a looser narrative strategic plan.

Plans can also have a different focus. Plans may focus on any of the following:

- An organization such as a hospital
- An administrative geographical level such as a district and its population
- Particular health programs (such as reproductive health or TB) or time-bound projects
- Health systems components (such as human resources or information systems)

The appropriate approach to and focus of planning will depend on the context in which the planning occurs. As an extreme example, the presence of a conflict or an emergency situation will affect planning. For example, in Sierra Leone during the civil war, quarterly plans were set, in recognition of the inability to take a longer-term strategic view during this period.

Planning and Organizational Levels

Planning occurs—or should occur—at all levels in the health system, as illustrated in **FIGURE 15-4**. As decentralization policies are increasingly implemented within health sectors, it is important that they incorporate a clear expression of the relative planning responsibilities of the different levels of the health system. **TABLE 15-3** gives an example of the division of responsibilities in a two-level system.

Types of Planning Time Scales

Planning, as we have seen, focuses on actions related to the future. However, decisions have to be made as to the time scale. For many planning systems, a period of five years has been taken as the standard time frame.

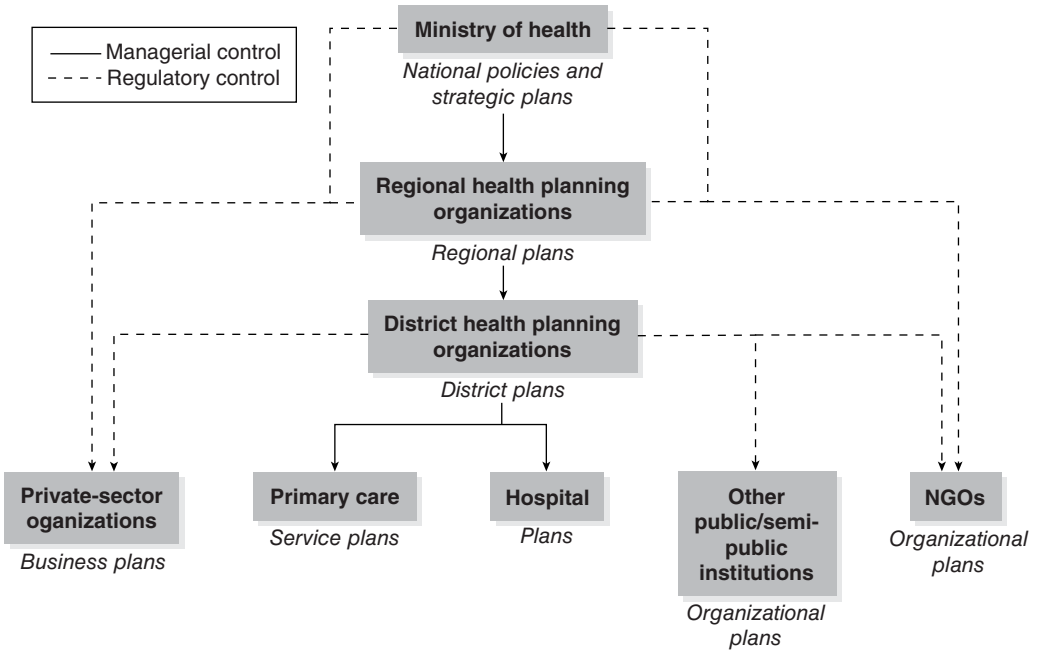

FIGURE 15-4 Examples of planning at different organizational levels within a deconcentrated system.

TABLE 15-3 Example of the Division of Responsibilities Between Center and Periphery

Central Functions	Joint Activities	Local Functions
Broad policy leadership	Monitoring and evaluation	Local needs assessment
Resource generation and allocation		Development of local plans, and local generation of resources in decentralized contexts
Donor coordination		Implementation of local plans
Liaison with central ministries		Liaison with local government authorities
Coordination of local plans		Provision of primary and secondary health services
Planning of central specialist services		Human resources performance appraisal and support
Human resources planning		
Technical planning support		
Legislation		Local operational policies

Modified from Green, A. (2007). *An introduction to health planning in developing health systems* (3rd ed.). Oxford, UK: Oxford University Press.

Other health systems have found this practice too rigid and have adopted a rolling process of planning, as exemplified in **FIGURE 15-5**, where each year the plan period (in this example, three years) is rolled on by a year. To maintain an overall set of strategic direction, this type of plan is often combined with a long-term perspective plan that sets out a broad set of policies or direction of strategic travel. Such an approach underlines the importance of ensuring consistency and full integration between the wider policies, strategic plans and operational plans.

Planning timetables need to take account of both the need for wide consultation at different stages of planning and the fact that planning at each level (e.g., district) must link to planning both at higher and lower levels and other parts of the overall system (e.g., local government plans).

Elements of Planning

FIGURE 15-6 sets out diagrammatically the health planning spiral, which shows the various stages involved in planning. Two general points need to be made. First, conceptually, this process is a spiral rather than a cycle—suggesting movement in a direction rather than a repetitive cycle. Second, planning refers to a process rather than a chronological sequence. Several activities may be occurring at the same time, together with various iterations within, and across, the six stages of the planning process. Each of these stages in planning is briefly introduced here.

Situational Analysis

In the situational analysis stage, planners assess the current situation (in other words, the current context) and project future changes to it. This stage also represents a useful mechanism for getting a planning team working well together early in the planning process and for opening up the process to a wider group of organizations and individuals. Examples of key information needs for situational analysis, covering both the current situation and likely future trends, include population characteristics (e.g., demographic data, morbidity and mortality), area characteristics (e.g., geography, infrastructure, resources), the policy environment, the functioning of the health system (e.g., existing policies, and availability and quality of

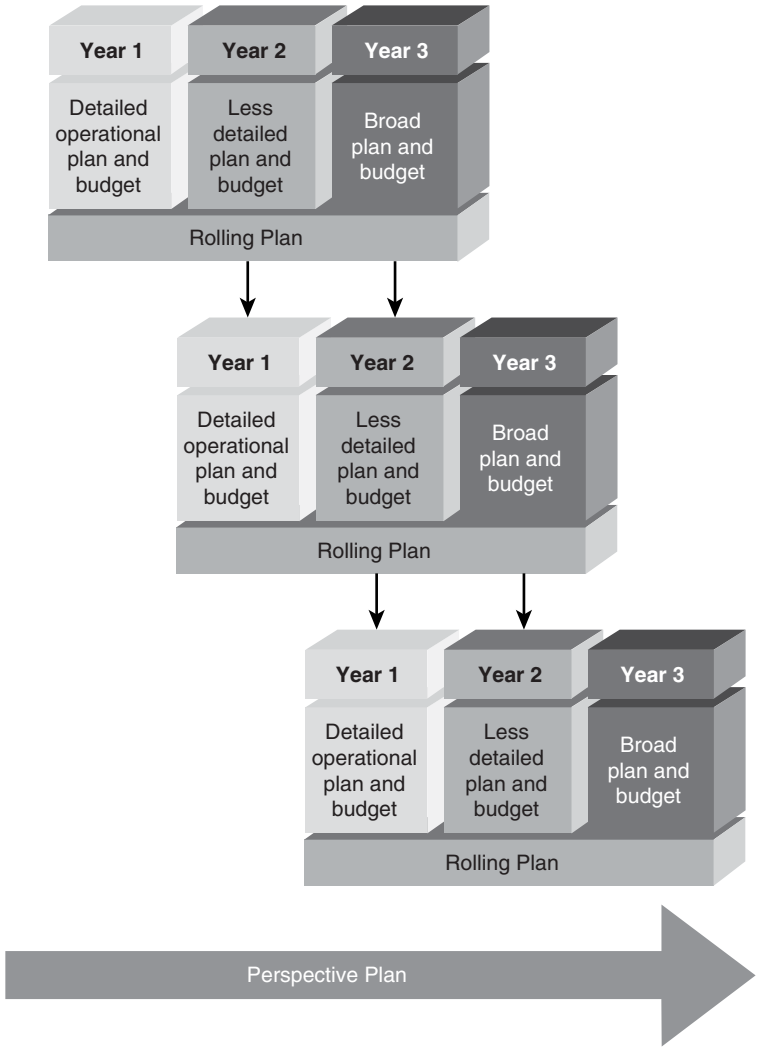

FIGURE 15-5 Three-year rolling plan and long-term perspective plan.

services provided), and health needs (as perceived by health staff and communities) (Green, 2007).

A SWOT (strengths, weaknesses, opportunities, and threats) analysis may also be used during situational analysis (**FIGURE 15-7**). This technique directs attention toward internal and external aspects of institutions and is generally better suited to assessing an institution such as a commercial firm, but there may be occasions when it provides a useful format for health-sector organizations.

The end product of the situational analysis stage is usually a focused overview of the current situation with identification of specific areas requiring actions.

Priority Setting

In the second stage, planners set priorities for the organization, in the light of competing needs and limited resources. Setting priorities is perhaps the most critical and most difficult planning stage—but a part of

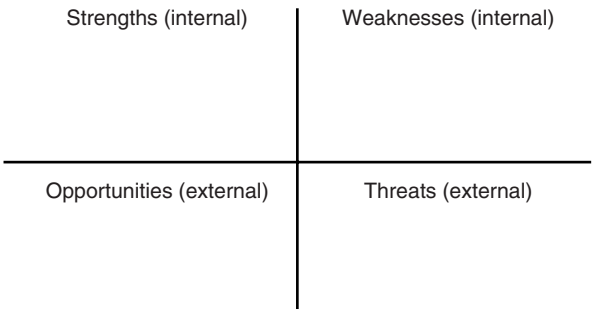

FIGURE 15-7 SWOT analysis framework.

the planning process that cannot be avoided. Priority setting is also a key contributor to health systems performance (Barasa, Molyneux, English, & Cleary, 2015).

For the state providing an overall strategic plan, its priorities need to be sufficiently broad to allow for local variations as a result of differing needs. Underpinning all of the issues regarding how priorities are set is a tension between attempts to make decisions evidence driven and recognition of the essentially political or value-laden nature of such decisions.

What Should Priorities Be Based On? At one level, the most obvious answer to the question of the basis for prioritization is that priorities should be set on the basis of greatest health need. However, this response in itself raises various further questions, such as how health need is perceived. In particular, is a broad or a narrow view of health taken, how is health need measured, and should priorities focus on health needs or healthcare needs? It also (and related to the preceding discussion) is affected by whose perception of health is taken.

Clear criteria are needed so that the process of priority setting can be as open as possible. These criteria should be derived from overall policy and could include the following:

- The maximum health gain given the available resources (efficiency)
- The effects on equity
- Public demands for change

These criteria may sometimes work against one another. For example, there may be a tradeoff between equity and efficiency, unless efficiency is seen as a means to achieve objectives that include the distributional aspects of the health gain.

Who Should Set Priorities? A critical issue within the planning process relates to who has the right or responsibility to set priorities at which level in the national health system. For example, good arguments may be made for any of the following groups to be involved in priority setting: health workers, administrators and managers, users of services, and, more widely, communities or politicians. The priorities set will depend significantly on who makes them. Therefore, adequate engagement, empowerment, and satisfaction of key stakeholders in relation to the process of priority setting are important (Barasa et al., 2015).

Stakeholders' power is an important consideration in understanding the broader political environment of priority setting. For example, a study in Ghana found that interventions that targeted breast cancer, spearheaded by the country's First Lady, received greater attention despite the epidemiologic and economic evidence suggesting that cervical cancer should be prioritized (Reichenbach, 2002). Stakeholder analysis (Brugha & Varvasovszky, 2000) can be a useful technique in assessing the strengths of different groups in society.

Establishing Priorities Within a Planning Framework. It is important that the planners make explicit how priorities are to be set. This process needs to allow a broad view of health, rather than health care alone; find an appropriate balance between decision making at the national and local levels; be transparent; and end up with feasible objectives. A common flaw in the priority-setting process is that everything is viewed as a high priority, meaning effectively that no real priorities have been set. A good test of a robust priority-setting system is whether it clarifies those areas that are not viewed as high priorities.

Various processes and techniques can be used to set priorities, including economic appraisal (e.g., using cost per disability-adjusted life year [DALY] as the basis for measurement), multivariable decision matrices, and Delphi techniques. The resource allocation processes from the center to lower health services levels are also an important vehicle for ensuring that broad priorities (and particularly those of equity) are reflected in the budgets allocated for service delivery. However, there is a danger in assuming that priority-setting is value-free, when it actually incorporates a number of implicit values. **FIGURE 15-8** provides examples of value-driven judgments exercised in conducting economic appraisal of health programs.

Multivariable decision matrices offer another approach in which any number of criteria can be incorporated and the information used either quantitatively or qualitatively. **FIGURE 15-9** provides an example. Caution is needed when such tools are used, however, because they can easily mask implicit value judgments such as relative weightings between the criteria.

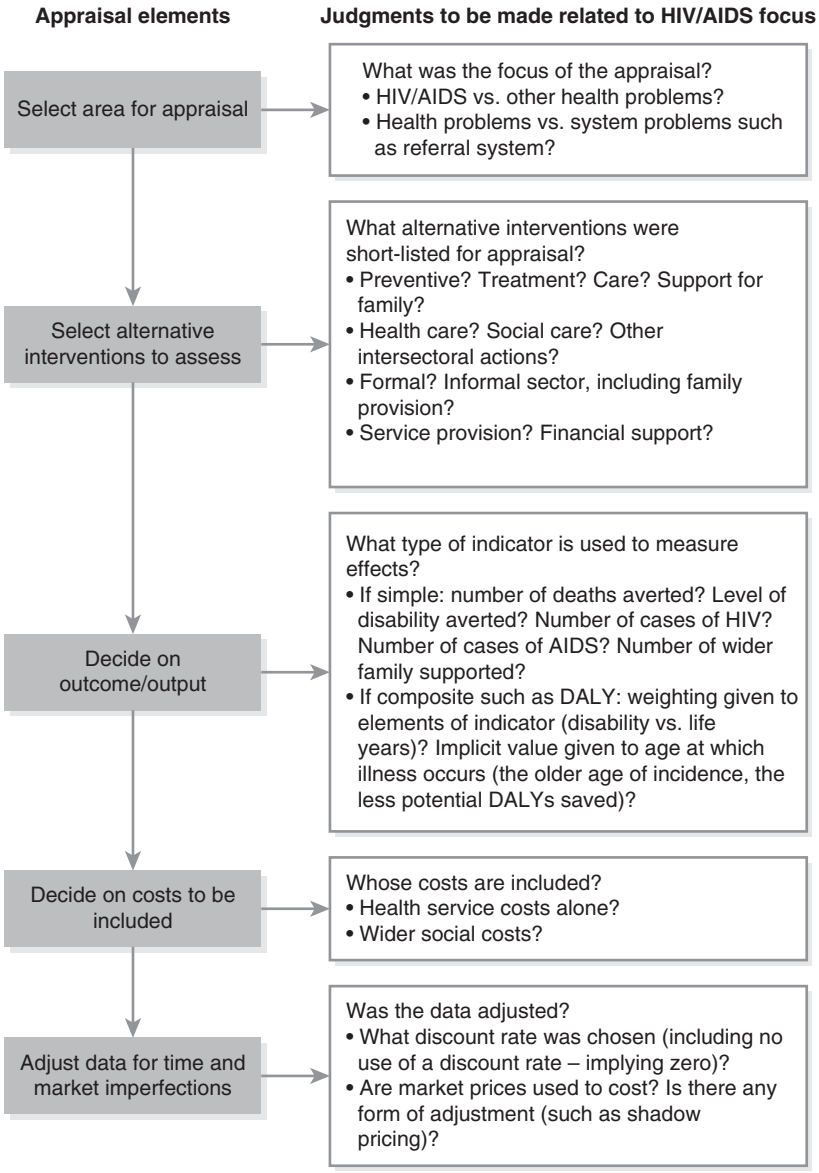

FIGURE 15-8 Examples of value judgments required in economic appraisal using an HIV/AIDS program example.

	Polio	4
	Gastroenteritis	1

FIGURE 15-9 Hypothetical example of a multivariable decision matrix.

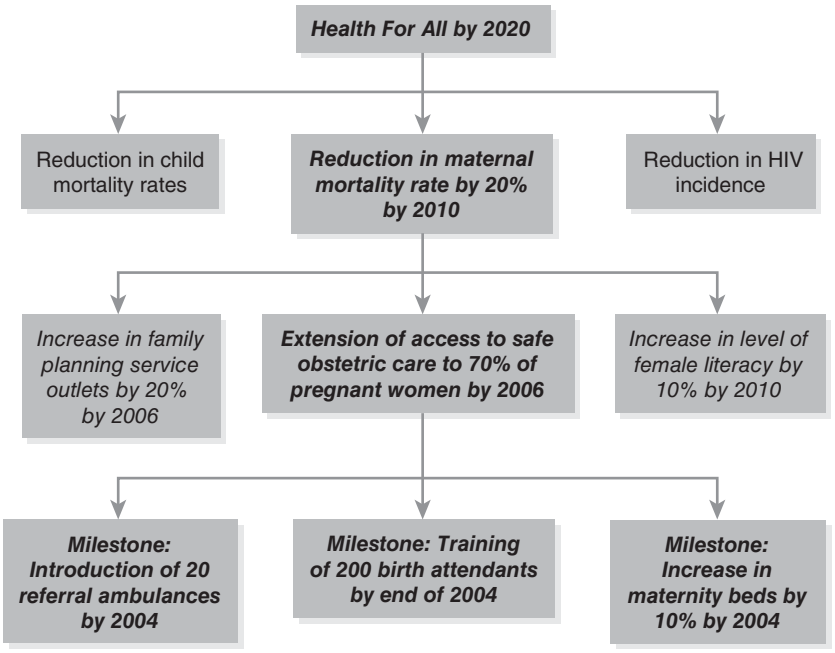

FIGURE 15-10 Example of the hierarchy of objectives.

Courtesy of Dr. Nancy Gerein.

The end result of a priority-setting stage should be a set of clear objectives for an organization. Although different terms are often used by different organizations for objectives (e.g., goals, purpose, aims, objectives, and targets), the important feature is that they are structured in a hierarchy. For example:

- Broad overall health goals achieved through *x*
- Specific health aims related to particular health problems to be achieved by *x*
- Health-sector activity objectives to be monitored by *x*
- Targets that are milestones along the way to achieving aims and objectives

FIGURE 15-10 sets out an example of a hierarchy of objectives. The mnemonic SMART is often applied to objectives to suggest that they should be Specific, Measurable, Attainable, Relevant, and Time bound.

Option Appraisal

For each priority area, there may be various strategies that can be followed to achieve those aims. In the third stage of planning, planners appraise each alternative to determine which is most appropriate according to various criteria. These criteria should include those that underpin economic appraisal techniques (cost and effectiveness) as well as others such as equity, feasibility, and acceptability.

A variety of options are available to any organization, but are particularly feasible for use by the state, which has multiple "carrots and sticks" that it can deploy to encourage or require action by other organizations. In traditional command-and-control planning systems, plans were expected to be implemented through managerial commands and compliance, rather than through incentives and creation of an enabling environment for better performance. With the recognition of the importance of other sectors and providers, a wider range of tools has become necessary. Thus the state may see, as one of its options to be appraised, the contracting out of services to other, nonstate organizations. The end product of the option appraisal stage should usually be a detailed record of alternative options considered, along with a clear framework for assessment and justifications for the chosen planning option.

Programming

The next stage in planning encompasses programming for services and projects. The aims of and agreed-upon approaches for meeting the organization's objectives are brought together in a document that sets out mechanisms to achieve these objectives, along with a time frame and financial plan. The level of detail, particularly regarding the budget and time frame, will depend on whether the plan is primarily strategic or more operational. **EXHIBIT 15-2** outlines the components of a typical plan document.

Logframes (logical frameworks) are often advocated as a means of both ensuring that a logical

approach to project design is followed and providing a means of monitoring progress. **FIGURE 15-11** gives an example of a logframe layout.

The end product of the programming stage should be a detailed plan of action identifying clearly the resource implications, time frame, and distribution of responsibilities.

Implementation and Monitoring

Planning is useful only if it culminates in implementable action. Unfortunately, planning has a poor implementation record, with failure being possible for a variety of reasons—for example, lack of funds, lack of relevant resources, poor timing of inputs, resistance to change, neglect of institutional or legal requirements, unexpected results, poor coordination, and unforeseen circumstances. Frequently, the root cause is poor planning design, often as a result of a failure to recognize the political nature of planning at the design stage and the development of overly optimistic and infeasible objectives.

A key activity that can improve implementation is monitoring. It requires an explicit time frame for well-specified activities and a clear understanding of who is responsible both for implementation and for monitoring of the activities. Monitoring techniques such as Gantt charts set out, in tabular form, activities by their expected dates of completion. In addition, planners must ensure that monitoring does not end up being viewed as an end in itself, but rather as a means of facilitating the achievement of the set objectives. As such, it is important that only the minimum number of monitoring indicators are chosen and *used*, and that monitoring is seen as a supportive (rather than punitive) activity. This understanding is closely linked to the concept of performance management of an organization, which seeks to identify the progress toward the organization's objectives and any barriers to this advancement.

The end product of this stage should be a record of implementation (e.g., services provided) including the challenges faced and any deviations from, or changes to, the original plan.

EXHIBIT 15-2 Possible Outline for a Plan

- Situational analysis, including the health needs or problem being tackled
- Objectives of the plan
- Strategies to meet these objectives, and specific activities as appropriate
- Resources required, including funding to provide the services and sources of these resources
- Timetable with identification of specific roles and responsibilities
- Foreseeable constraints or risks

Objectives	Objectively verifiable indicators	Means of verification	Assumptions/risks
Goal			
Purpose/objectives			
Outputs			
Activities	Inputs		

FIGURE 15-11 Example of a logframe layout.

Note: See Nancholas (1998) for a description of the process.

Evaluation

The final stage of planning involves the evaluation of the plan. Similar to monitoring, evaluation seeks to establish whether and to what degree the objectives have been achieved. Evaluations may be formative (process evaluation) or summative (end evaluation). While monitoring is primarily seen as an in-house activity, evaluation can often be outsourced to an "external" (i.e., not involved in the implementation) person or a group. Evaluation is also regarded by many as a separate activity in itself, involving a series of stages that are similar to those occurring in research (i.e., identification of questions to answer, methodology design, data collection, analysis of findings, and report writing). The key areas that an evaluation is likely to focus on are the following:

- Inputs: Did the resources planned arrive? Were they sufficient for the services provided?
- Processes: How were resources allocated, and by whom? How were services provided, and how was quality assurance performed?
- Outputs: Were the services provided? Were the services appropriate, relevant, and adequate?
- Outcomes: What were the objectives of the activity being evaluated? Were they appropriate? Were the objectives set achieved? If not, why not? Were there any other effects of the activity?
- Impact: Did any health improvements occur as the direct result of the activity? What are the other benefits or unintended consequences of the implemented activity?

The results of the evaluations should be fed into the next round of the situational analysis, thereby completing one round of the planning spiral.

Political Aspects of Planning

The preceding discussion outlined different stages and techniques used in developing plans. It is important to recognize that during all of these stages, there is a need to consider the political dimension of planning, which is inevitable in a process that is designed to determine who gets what in the health sector (**EXHIBIT 15-3**). There are two levels at which planners need to be aware of the political nature of planning as a process. First, they need to recognize that techniques and decisions are rarely value free. Second, they need to understand that techniques such as stakeholder analysis and political mapping may use priorities set at different points in the planning cycle to analyze levels of support for different strategies.

EXHIBIT 15-3 Examples of Political Decisions in Planning

Situational Analysis

- Who chooses the information (e.g., in determining health needs)?
- Whose view is taken? What emphasis is placed on the different information?

Priority Setting

- Whose views are taken?
- Which view of health is chosen, and by whom?
- Which criteria for priorities are chosen (e.g., equity versus efficiency)?

Option Appraisal

- Who chooses, and how, the original options that are appraised?
- Which criteria are chosen, and by whom, for the option appraisal?

Programming

- How are resources distributed, and by whom?
- Who is responsible for the different tasks?

Implementation and Monitoring

- Who is coordinating the implementation, and how it is done?
- Who is using the information from monitoring and how?

Evaluation

- Who is involved in the evaluation?
- What are the criteria for evaluation?

Management of Resources

Management, as we argued earlier, is about resources—how they are generated and developed; allocated; and combined and used with a view toward achieving objectives. Management of resources can be either direct by public-sector managers or indirect (e.g., through contracting out this function to the private sector or other agencies within the public sector), and may be informed, and driven, by the managers' underlying values such as equity, efficiency, and participative and accountable decision making (Collins & Green, 2014). Resources of particular importance to the health sector include those in the financial, human, information, supplies (including pharmaceuticals), and transport categories.

This section first presents an overview of the main issues related to resource generation, allocation, and use; it is followed by a more detailed discussion of how the principal resources—money and staff—are managed. This is followed by brief comments on the management of supplies, transport, and information. In most countries, management of specific resources is undertaken by separate subsystems (e.g., the health management information system) that have their own staff, organizational rules, and objectives. Although much of the discussion in this section refers specifically to management or managers, in reality many issues (e.g., related to resource generation and allocation) apply to planning as well, so they should be of relevance to health planners.

Resource generation and development relates to the different processes for production and enhancement of various types of health resources. Examples of these processes include preservice training of health staff, manufacturing of pharmaceuticals and medical supplies, different types of health financing (e.g., taxation, insurance, user fees), and procurement of transport and technology. Given the complementarity of such resources in their eventual use, it is important that the generation of these resources is planned in a coordinated way. Unfortunately, this is not always the case: There may, for example, be an imbalance between the number of health workers trained and the health facilities in which they are to work.

A broad interpretation of the concept of resource allocation defines it as "the process by which available resources are distributed between competing uses" (Pearson, 2002, p. 7), highlighting the links between resource allocation and priority setting or rationing (Martin & Singer, 2003). A well-known example of the result of prioritization of resources within the health sector is a minimum or essential package of healthcare services. Although some systems of resource allocation focus on nonfinancial resources, such as the distribution of staff, the most common interpretation of the term "resource allocation" relates to financial resources.

Different classifications of *approaches to resource allocation* exist, including a distinction between normative and empirical approaches (Martin & Singer, 2003), as well as negotiation and political compromise, incremental budgeting, and allocation according to health needs (Pearson, 2002). Approaches to resource allocation rarely exist in isolation. For example, the allocation of financial resources for health in Mexico, Nicaragua, and Peru is done through a combination of legal, political, and technical approaches (Arredondo, Orozco, & De Icaza, 2005). Any approach to resource allocation is linked with (i.e., driven by, and likely to affect) the underlying health system values. For example, a true needs-based system of resource allocation will address equity, whereas an incremental approach is likely to reinforce existing inequities.

The *types of resource allocation* can be described using two continua: (1) the allocation of resources across different levels (e.g., between the center and decentralized levels) and (2) the allocation of resources within a single level (e.g., within a district health system). The types of resource allocation also reflect the underlying *methods for allocating health resources*. Resource allocation may include different combinations of (1) *input-based models* (e.g., based on numbers of facilities or staff) and (2) *needs-based models* (e.g., based on identified health needs requiring specific types of health services). Other principles in allocating resources include continuation of historical trends and patterns in utilization of health services.

Different economic tools and techniques are available to support allocation of resources, with the most commonly used tools including cost-effectiveness, cost-utility, and cost–benefit analyses (Arnesen & Kapiriri, 2004; Hutubessy Chisholm, Edejer, & WHO, 2003; Kapiriri, Norheim, & Heggenhougen, 2003). An important caveat here is that, irrespective of which tools and techniques are used, there is a need to ensure consistency between the overall strategic direction identified within the health policy or plan, the underlying values, and the allocation of resources.

From a management perspective, the use of different resources refers to the most efficient and effective combination of available resources to achieve intended objectives such as providing high-quality services. Where different management subsystems are set up to manage different resources, a particular challenge is ensuring the coordinated and complementary deployment of these resources.

Financial Management

A key resource for any organization is, self-evidently, finance. This section looks at the main elements of good financial management.[5] Finance is, of course, important in that it allows human and physical resources to be obtained, such as by hiring health worker and administrative staff, purchasing equipment, and investing in infrastructure. Good financial management supports the health organization in

[5] Acknowledgment is given to Jane Shaw for her input into this section.

the achievement of its objectives. As such, it must be closely linked to other key decision-making processes and, in particular, to planning. Financial management, like general management, is not value-free, and must be viewed as a means rather than an end in itself. The elements of financial management are described next.

Resource Generation

Various sources of financial support are available to a health services organization, and it is important to recognize the interrelationships between these different sources and consider them as a whole in planning. These sources are explored in the *Design of Health Systems* chapter.

Financial Resource Allocation and Budgeting

Financial resource allocation refers to the distribution of block financial resources from a higher level to a lower level in an organization (a vertical process). Budgeting refers to the allocation of financial resources within an organization.

Within the public health sector, financial resource allocation from the center is a common feature. Its importance will depend on the health financing system and the degree of decentralization of resource generation within the health system (Green, Ali, Naeem, & Ross, 2000).

Frequently, financial resource allocation is based (explicitly or implicitly) on one or more of the following factors:

- Previous allocations
- Service or facility patterns and norms
- Capital developments and associated recurrent implications
- Political profile and compromise

These approaches, although potentially nonthreatening to existing budget holders, fail to address issues of efficiency and equity. In contrast, an equity-focused strategy bases its resource allocation on an assessment of the needs of particular areas or population groups. **FIGURE 15-12** sets out a conceptual model for such a process. The potential components for allocation are as follows:

- The population's size, composition, and health needs
- The costs of providing services
- Variations in costs between different areas
- The costs of activities other than health care, such as research or teaching
- Flows of patients across administrative boundaries

FAIR: Formula for Allocation of Internal Resources

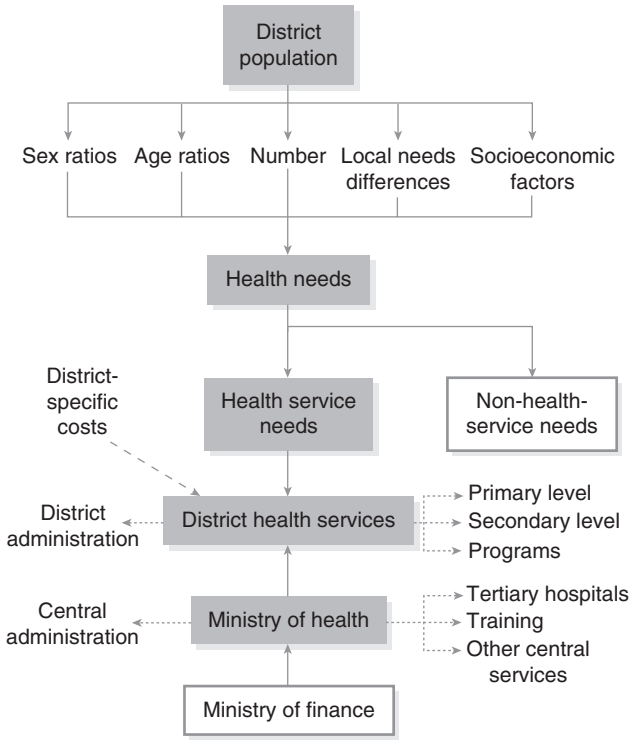

FIGURE 15-12 Conceptual model for needs-based resource allocation.

Data from Green, A. (2007). *An introduction to health planning in developing health systems* (3rd ed.). Oxford, UK: Oxford University Press.

"Health need" is the most significant and most difficult element to measure, as its ingredients include demographic factors; morbidity, mortality, and disability; and indicators of deprivation.

Formulae to allocate resources on the basis of needs have been developed in a number of health systems. The historical U.K. RAWP (Resources Allocation Working Party) model is a well-known example, with similar approaches that target specific groups such as the poor being the subject of resource allocation experiments in other countries such as Cambodia, South Africa, and Uganda (Pearson, 2002). A number of issues arise regarding the implementation of such a formula, however—most importantly, the choice of indicators, and the availability of information. Other issues affecting the introduction and implementation of resource allocation a formula include the absorptive capacity of areas receiving significant additional funding and the political resistance of areas that are "losing" funding. In many countries, it may be necessary to start with a basic allocative a formula based on the size of population being served before developing more sophisticated approaches. One particular challenge that managers often face is balancing allocated funding for local health priorities with the

management of donor funds earmarked for particular disease priorities. Besides potentially distorting local priorities, donor funding can create some unique tensions: New donor-linked incentives and targets can change the behavior of actors within the health service, and potentially result in an overall reduction of local funding to the health sector if the funding is seen as a subsidy rather than as a supplement to the government budget.

Budgets specify the allocation of financial resources within an organization. These statements of intended expenditure are required in the implementation of planned activities, and should reflect the plans of an institution or service. Thus, budgets are vital management tools. Two major forms of budgets are distinguished:

- *Capital/development:* for buildings, large equipment, and vehicles
- *Recurrent/revenue:* for expenses necessary to run the organization, including salaries and supplies

In addition, an organization may develop separate project budgets, which may combine both of these forms.

A budget consists of three components: what it is spent on (line items such as personnel, medicines, and equipment), for what purpose (service or institution or geographic area), and when. Within health organizations, budgets may also be set up on the basis of programs (such as maternal health) that cover all aspects of care irrespective of where it takes place. Such program budgets are better aids in planning because they allow for programs to have different priorities; however, they are much more difficult to manage.

Budgets may be established in various ways. The most commonly used practice is historical incrementalism, whereby the previous period budget is increased across the board. Such an approach is easy to administer and nonthreatening, but it does not reflect major changes in priorities or new developments. A common variant on this approach involves additional increases to a budget (over and above the historical increment) arising from capital developments such as a new building and its associated service.

A contrasting method is activity-based budgeting, whereby the budget is set based on predicted activity levels. This technique allows for a clear link between the budget and the service objectives. An extreme example is zero-based budgeting, in which no prior assumptions are made, and every item in the budget for each year has to be fully justified.

Zero-based budgeting is more time-consuming and generally more politically sensitive compared to historical incrementalism, as it requires information on both the level of activity and the costs of a unit of activity. These costs may, of course, change depending on the level of activity and on the relationship between fixed and variable costs.

A possible timetable for budgeting is given in **TABLE 15-4**.

Expenditure Drawing and Disbursement

The next element is that of expenditure against a set budget. Each financial management system will have mechanisms to authorize named officials to incur expenditures, within certain predefined limits and conditions, that reflect the level of decentralized authority.

Expenditure Monitoring and Control

Monitoring of expenditures against the budget throughout the year is an important management function. Critical to this process is a good information system. Each management system will have its own set of accounting methods. Such a system needs to be able to give the manager up-to-date information not only on past expenditures, but also on any commitments already made. For managers to understand the real implications of such information, they need to have an indication of the likely expected profile of expenditures throughout the year; that will allow them to discover any variance from the budget early enough that they can take the necessary remedial action. Needs for some resources (such as staff salaries) may be evenly spread out over the course of the year; others, such as medicine purchases, may occur more sporadically (in batches) and may reflect within-year differences in usage due, for example, to seasonal disease incidence. Capital equipment is even more lumpy in terms of expenditure patterns.

A manager needs to be able to compare actual expenditures against the expected expenditure profiles and understand the likely reasons for possible differences. An example of a simple monitoring tool appears in **TABLE 15-5**. It shows a monthly management statement after nine months of the year. The "Budget to Date" column shows what might be expected to have been spent three-fourths of the way through the year. It is assumed here that spending will be equal each month (which is unlikely, of course); more sophisticated estimates could be made. The variance columns show the relative (not actual) over- or underspending.

TABLE 15-4 Annual Budget Cycle for a Three-Level Decentralized Health System

Month	Activity
1	The financial year begins.
5	The ministry of health receives its provisional annual allocation from the central government, together with any special constraints or conditions.
6	The ministry of health issues broad resource allocation guidance to regions on the basis of the provisional allocation.
7	Regions issue broad allocations to districts on a similar basis.
8	Budget holders develop and return proposals showing the following: ■ Review of service targets in line with the plan ■ Estimated expenditures for the previous year ■ Estimated expenditures for the current year ■ Reasons for under- or overspending ■ Budget proposals for the following year, costed and showing how they will meet planned service targets
8	Budgets are totaled and reconciled first at the regional level and then at the ministry of health.
9	Adjustments are made for the following reasons: ■ To reflect national policy ■ To reconcile with other budget proposals ■ To reflect constraints ■ To reconcile with central government allocations
9	Discussions are held with the central government.
10	Adjustments are made with the input of service managers.
11	Informal approval of the budget is granted.
12	The government approves the budget.
1	Budgets are issued to budget holders.

Modified with permission of Oxford University Press from Green, A. (2007). *An introduction to health planning in developing health systems* (3rd ed.). Oxford, UK: Oxford University Press.

Once managers have identified a projected over-expenditure (or under-expenditure), they need to consider the various options open to them to prevent this departure from the budget. Potential actions include the following:

- Seeking additional funds
- Instituting cost-control mechanisms, such as freezing expenditures
- Revising service objectives
- Reallocating funds from one budget (line item) to another

To select the appropriate option, managers need to have a clear understanding of the reasons for the overspending or underspending, so they can suggest the best remedial strategy. It is also important that the implications of any remedial actions be weighed against their effects on the organization's objectives. Cost-control mechanisms, for example, will affect services in terms of either the quantity deliverable, the quality, or the efficiency with which the services are delivered. The first two of these factors will, in turn, affect the ability to achieve the service objectives.

TABLE 15-5 Monitoring Tool Example

				Variance from Budget to Date (+, under-expenditure; −, over-expenditure)		Projected Year-End Expenditure	
Month: 9	Full-Year Budget ($000)	Expenditure to Date ($000)	Budget to Date ($000)	Amount ($000)	Percentage	Projected to Estimated ($000)	Comment
Personnel	600	400	450	+50	+11.1	500	Underspending is due to recruitment difficulties
Medical supplies	150	140	112.5	−28	−24.4	160	Earlier epidemic, likely to result in final overspending
Transport	80	75	60	−15	−25.0	95	Earlier epidemic
Utilities	50	10	37.5	+28	+73.3	50	Delays in invoicing
Other	120	100	90	−10	−11.1	100	
Total	1,000	725	750	+25	+3.3	905	Overall underspending projected

Auditing

The last elements of the financial management process are internal and external auditing. An internal audit is a process of testing and validating the financial control and accountability systems to ensure that they are working correctly. This task is performed by a special department of the organization, which is separate from the normal accountancy group. In external auditing, the accounts of an organization are subjected to independent external scrutiny to confirm that they do not contain errors or hide fraud. For any organization, auditing is an important part of its governance.

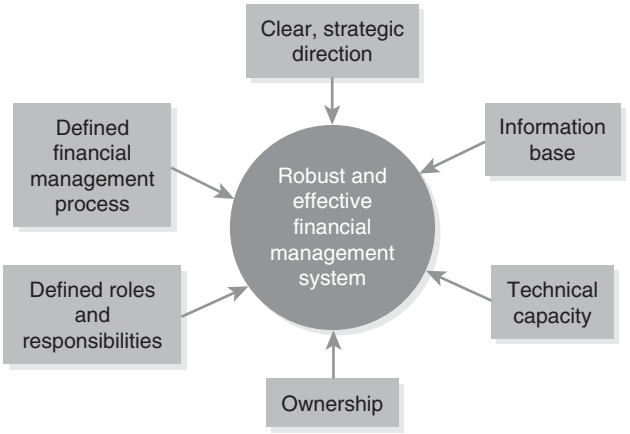

FIGURE 15-13 Requirements for an effective financial management system.

Requirements for an Effective Financial Management System

FIGURE 15-13 identifies a number of critical features of an effective financial management system. If these aspects are lacking, there is a real danger that the system will not perform its expected task—that is, ensuring that the desired strategic direction is followed.

Management of Staff [6]

The management of health staff was for some time a somewhat neglected issue. Indeed, only since the mid-2000s have international policy makers explicitly refocused their attention on human resources for health (WHO, 2006b). In the past, policies largely sought to reform health systems through new financing arrangements or organizational changes, such as decentralization. Yet staff costs are a major part of the health budget, and the quality of staff is vital to ensure the effectiveness of health care (Buchan, 2004; Rondeau & Wager, 2001). Furthermore, the development of staff management systems and skills throughout the health system increases in importance as decentralization and hospital autonomy spread out the management responsibility throughout the health system.

In developing staff management capabilities, several factors must be considered. First, the inequitable distribution of health staff must be addressed. It is often difficult to persuade health staff to work in poorer areas, where incentives such as good living conditions and the possibility of supplementing income through private practice are lacking. Second, some health systems are undergoing important changes such as decentralization, or facing contextual changes such as conflicts, that are affecting how health staff are managed and how their capacity is enhanced (Kolehmainen-Aitken, 2004; Prashanth et al., 2014; Rockers Peter & Bärnighausen, 2013; Roome et al., 2014). This kind of transformation can mean important changes in civil service arrangements, for example (as shown in **TABLE 15-6**). Two other influences on how staff are managed are professional authority and power, and corruption and patronage.

There are many systems and approaches for managing staff, ranging from defining staffing needs and jobs to employing people and developing their performance. The discussion here focuses on a number of key issues and functions.[7]

Staffing Review

An important issue is how the workforce can be used to improve performance in meeting health needs. A review may be undertaken, with key questions focusing on the number of staff employed, possible substitution by technology, and changes in the skill mix and grades currently employed (Strike, 1995). A simple technique for defining staffing needs of a healthcare unit is provided

TABLE 15-6 Decentralization and Options for Civil Service Structure

Civil Service Option	Commentary
Centrally controlled system	Terms for the civil service are centrally controlled and staff are seconded or transferred to local units.
Health-sector centrally controlled system	Health-sector staff are taken out of the national civil service and included in a national system exclusively for health staff.
A national local government system	All local government units operate under the terms and conditions of a national system that is specifically designed for local government staff.
Local public service commissions	A public service commission can be tasked with and empowered to investigate, monitor, and evaluate the organization and administration of the public service, as well as tasked with promoting measures to ensure effectiveness and efficiency.
Decentralized unit	The decentralized unit determines the terms and conditions and employs its own staff.
Mixed system	Following decentralization, existing staff are kept as part of the national civil service, while new staff are employed under the new decentralized system.

Data from Collins, C. (1994). *Management and organisation of developing health systems*. Oxford, UK: Oxford University Press; Kolehmainen-Aitken, R.-L. (2004). Decentralisation's impact on the health workforce: Perspectives of managers, workers and national leaders. *Human Resources for Health*, 2, 5.

[6] Acknowledgment is given to Tim Martineau for his input into this section.

[7] A more comprehensive and in-depth analysis would cover issues such as employee relations, change management, staff communication, and conflict management.

by Kolehmainen-Aitken and Shipp (1990); it involves the definition of job responsibilities and calculation of a "standard workload" for each person (e.g., number of outpatients attended per day). This value is compared with projected workloads in the health facility to estimate staff required. The possibility of using such planning tools is restricted by the degree of autonomy local managers are given, the existence of patronage, the availability of information, the capacity of managers to use the tools, and the willingness of staff to move.

At a facility level, WHO (2010b, p. 2) has developed human resources management tools and guidelines that (1) determine how many health workers of a particular type are required to cope with the workload of a given health facility and (2) assess the workload pressure endured by the health workers in the facility. The tools take into account multiple services that need to be delivered in a facility.

Defining Jobs and Employment

The defining of jobs and staff employment may be viewed as a set of the following logical steps:

1. Job analysis: assessment of which tasks are required and which category and level of staff are required
2. Development of a clear job description: a detailed description of the planed duties and responsibilities, as well as personal specifications (both essential and desirable) for the anticipated candidate
3. Advertising: inviting potential candidates to apply for the position(s)
4. Selection and recruitment: processing of applications and selecting (typically following an interview, test, or another method to assess the candidate's appropriateness) the most suitable candidate(s) for the position against the personal specifications
5. Posting: assigning the recruited candidate to a workspace
6. Induction: initial training and discussions to help candidate understand the organization and start performing the duties

The definition and use of clear principles and rules and an open and transparent process can facilitate an effective and fair employment process.

Staff Payment

The issue of payment is related to the staff grading system and form of public service system (see the earlier discussion). Changes in health systems, such as decentralization, can lead to corresponding changes in the source and level of pay. The form of payment may be based on time spent working, physical results produced, individually assessed performance, or a combination of these factors. Payment by time is simple, whereas performance-related pay is both complicated and controversial (Alimo-Metcalfe, 1994; Kessler, 1994). The latter approach assumes that staff will work more, and will perform better, if their earnings are related to their performance. In addition to practical difficulties in measuring performance, drawbacks of this strategy include its potential to introduce conflict between staff members and to counteract a teamwork approach.

Reliance on material incentives downplays the important motivation that public health staff may derive from the inherent usefulness of their jobs and public service (Perry, Hondeghem, & Wise, 2010; Vandenabeele, 2007). In fact, the extent to which pay actually acts as a motivator will vary according to the context and the type of staff concerned.

Delegation

Delegation involves transfer, trust, responsibility, tasks, and authority. Delegation is a transfer of authority and tasks between two people or groups of people. It entails entrusting part of your own authority to someone else (French & Saward, 1983). Although the person receiving the delegation has the responsibility or obligation to satisfactorily perform his or her duties, the person doing the delegating does not relinquish responsibility for that task. Rather, that individual retains "responsibility for that person's exercise of authority" (French & Saward, 1983, p. 122). This responsibility can also involve authority over resources—an issue that is important to recognize in the act of delegation.

The purpose behind the delegation is likely to affect its form and should be clear. For example, delegation might be used to address work overload or underload, to motivate staff, to bring decisions nearer the point of service delivery, or to gain a better understanding of service needs and achieve more timely decisions and increased flexibility and adaptability. Greater ownership may also be achieved with a more participative management style.

Delegation is not easy, particularly where there are constraints on its effectiveness. In a setting of limited resources, for example, delegation may not transfer authority over those resources. Managers may resist losing authority and control; staff may lack the knowledge, skills, and values to practice delegation. They may also lack motivation where the delegation has no additional incentives and a culture of blame exists in the organization that is not conducive to delegation.

It is important to identify the objectives involved to communicate them to staff, monitor the effectiveness of the delegation, and design the means of delegation. The delegation needs to be clearly identifiable in terms of tasks, authority, control over resources, and its limits. A particular issue is the capacity (e.g., skills and experience), support, and motivation of the person receiving the delegation. Is that person equipped to receive the delegation? A useful concept in making this determination is staff "maturity" (Hersey, Blanchard, & LaMonica, 1978), which encompasses the skills, experience, and willingness to take on new responsibility.

Performance Management

In the field of staff management, performance management is frequently associated with annual confidential reviews or appraisals that are bureaucratic and routine, and that do little to develop performance. Effective performance management requires not only reinvigoration of such yearly events, but also a broader approach of continuous performance management (**TABLE 15-7**).

Performance can be improved by focusing on its various aspects. Grindle (1997), for example, has examined organizational culture and identified which aspects of an organization lead to good performance. These elements include an organizational mission and a strong sense of attachment to it among staff; good management relations, such as fairness and teamwork; positive expectations concerning staff performance; and institutional autonomy in staff management.

Incentives and Motivation

Incentives and motivation represent an area in which there has been considerable theoretical debate and that has provided useful indications about possible causes of staff motivation. Unfortunately, theories on motivation often fall short of providing health managers with a comprehensive framework that would allow them to understand fully the wide range of factors that can motivate or demotivate staff. Furthermore, the list of such factors can be so long as to render it useless as a managerial guide.

Another problem associated with attempts to explain motivation is that different individuals and

TABLE 15-7 Steps in Performance Management

Steps	Commentary
1. Explain and reinforce the logic of performance management.	Managers explain to staff the organization's performance management and supervision practice.
2. Understand job context, content, and relations.	Performance management needs to be based on appreciation of the job content and the often complex relations of authority it involves. When they understand the job context, managers and staff should recognize the various factors that affect performance.
3. Agree on performance criteria.	Managers and staff develop a joint understanding about the meaning of "effective work." This agreed-upon standard accompanies an understanding of the conditions that need to be in place (e.g., logistics support, flow of funds, skills) for actual performance to meet these standards.
4. Compare actual performance with standards.	Managers and staff monitor performance using the agreed-upon performance indicators (both quantitative and qualitative).
5. Discuss and agree on action.	This step involves both feedback on performance with dialogue and agreement on the causes of this performance and possible changes required (including agreement on training needs).
6. Take action and monitor.	Action may need to be taken in areas, such as job context, content, and support. The effects of this action need to be monitored.

Data from Bacal, R. (1999). *Performance management*. New York: McGraw-Hill; McMahon, R., Barton, E., & Piot, M. (1992). *On being in charge: A guide to management in primary health care* (2nd ed.). Geneva, Switzerland: World Health Organization; Weightman, J. (1996). *Managing people in the health service*. London, UK: Institute of Personnel and Development.

groups of health staff respond to different factors (Weightman, 1996). Attempts to generalize across groups are not easy, although a general distinction may be made between "satisfiers" and "dissatisfiers" (Herzberg, Mausner, & Snyderman, 1959).[8] Dissatisfiers are those factors that in themselves do not necessarily motivate workers, but whose absence can demotivate individuals; they are related primarily to attracting people into jobs and ensuring their retention. Typical examples are pay and security. In contrast, the presence of satisfiers does lead to improved motivation and performance; typical examples are career development and job achievement. Notably, the following factors can have a bearing on staff motivation (Henderson & Tulloch, 2008; Ogundeji, Jackson, Sheldon, Olubajo, & Ihebuzor, 2016; Willis-Shattuck et al., 2008):

- Career development
- Job characteristics
- Working and living conditions
- Managerial style and organizational culture
- Job rewards (financial and nonfinancial)

In using such a checklist of motivational factors, managers need to distinguish between the satisfiers and the dissatisfiers. Job characteristics, for example, can be the cause of demotivation for staff if too many duties are imposed on the job holder; if the job lacks variety, scope, and delegated authority; and if the job is badly defined and, therefore, the object of conflict. Even so, job holders may feel that the job is meaningful and contributes to social welfare and solidarity. Staff working in the poorer areas of a country may perceive that they have inadequate working conditions (e.g., office accommodation, information technology) and living conditions (e.g., schools), which are also dissatisfiers.

In contrast, transparent and open management, showing an interest in good supervision and communication, staff involvement in policy making and problem solving, good teamwork, and reinforcement of ethical standards can be positive forces (satisfiers). The pattern of rewards and incentives is important as well, and can include the extent to which the basic needs of health workers are met and are considered equitable, the regularity and security of payment, and nonfinancial rewards such as stability and status of employment. Likewise, the possibility of career development can be important. Building workplace trust relationships, through supervisory support, appreciation and recognition, communication, and feedback are important for promoting and sustaining intrinsic motivation—that is, working because the work is inherently enjoyable, rather than just for a tangible reward (Okello & Gilson, 2015).

Supervising

Like the other management functions, supervision is a process, rather than an end in itself. Supervision supports staff through a process of continuous professional improvement, includes all levels of the organization, and uses information from the staff, service users, and the community. It is defined as "[a] range of measures to ensure that personnel carry out their activities effectively through direct, personal supervisory contact on a regular basis to guide, support, and assist designated staff to become more competent in their work" (Management Sciences for Health [MSH], 2003, p. 3).

Among the roles of the supervisor are the following (Bosch-Capblanch, Liaqat, & Garner, 2011; Collins, 1994):

- Defining tasks to be carried out and planning their implementation
- Providing professional and technical advice
- Problem solving and decision making
- Ensuring performance standards (technical, ethical, and legal) and providing feedback
- Personal counseling and employee motivation
- Providing referral, broker, and advocate services
- Ensuring appropriate support for the job
- Providing training and development support

A distinction may be made between line management authority and supervisory authority (see Figure 15-2). In particular, the two types of authority may be separated to allow the line manager to widen his or her span of control (Rowbottom & Billis, 1987). Depending on the relation between supervisor and line manager, the supervisor can also be involved in disciplinary actions and career development.

Despite its importance, the value of good supervision is often overlooked. Pressures on time and the demoralizing lack of incentives and overall support to managers and health workers may shunt supervision aside, such that it is perceived as a peripheral activity. Yet the importance of effective supervision is well recognized. For example, Trap and associates (2001) evaluated the effect of supervision on pharmaceutical management in Zimbabwe and concluded that it had a positive impact, emphasizing the importance of training in supervision.

[8] For a brief description of Herzberg's approach and its application to a LMIC context, see Dieleman et al. (2003).

Managers have a variety of options at their disposal with which to improve the supervisory process. Both individual and group supervisory techniques may be considered, and a combination of formal and informal methods may be implemented (Collins, 1994).

The style of supervision is also important. The concept of supportive supervision was emphasized by Management Sciences for Health as one of the most effective ways of supporting improvements in staff performance (MSH, 2003). A distinction can be made between supervision that focuses on the supervisee's performance and supervision that focuses on the more personal relationship factors. The style of supervision employed may be contingent on a variety of contextual factors, some of which are discussed in this chapter.

Finally, the supervisory process may be formalized. A three-stage plan for such a process can consist of preparation, supervision, and follow-up.

Teamwork

Teams are widely recognized as a positive influence in the health sector and can improve decision making, problem solving, and innovation; motivate team members; improve communication, collaboration, and support; and allow for training. Teams are used in a variety of health-sector settings and for a variety of reasons (**EXHIBIT 15-4**).

EXHIBIT 15-4 The Importance of Teams for Health and Health Care

Teams can operate at senior management levels within a district health system (DHS). Sometimes referred to as a district health management team (DHMT), such a team is made up of staff with a range of competencies and capabilities who manage under conditions of complexity. Teams can also be used to work throughout the DHS. In South Africa, district clinical specialist teams (nurse–physician dyads working in three key disciplines) were introduced to support clinical governance through clinical supervision and mentorship at the facility level as well as to support the DHMT by supporting organizational collaboration and communication. Teams can also be developed to deliver preventive health services at the interface between the community and the health services platform, such as ward-based outreach teams as well as more specifically in primary care to promote holistic patient care, known as interprofessional teamworking.

Data from Doherty & Gilson, 2015; Kwamie, Agyepong, Dijk, 2015; Mampe, Schneider, & Reagon, 2016; Oborien et al., 2015; Voce et al., 2014; Xyrchis & Lowton, 2008.

Although Exhibit 15-4 suggests some reasons for developing health teams, such groups do have the potential to be associated with problems. Accountability within the team may be dispersed and lost, and team meetings can put pressure on time.

Ultimately, the effectiveness of teams will depend on factors such as definition of the objectives and tasks of the team, team members' willingness to modify their working styles to fit the team, good motivation among team members and leadership, effective team meeting skills, getting team size and members' characteristics right, understanding the changing nature of teams, good team action planning, and achieving a balance between team cohesion and diversity (Noakes, 1992). An increasing body of knowledge is available on how to build better teams. In addition, interventions that focus on team design, training and development, and team leadership can be applied to improve team effectiveness (Katzenbach & Smith, 2005; Kozlowski & Ilgen, 2006).

Managing Staff Development

Staff development is an important aspect of individual-level capacity development and a factor that affects the motivation and performance of staff members. It can be done through various combinations of training, delegation of tasks, and supportive supervision. Although training is often associated with off-work courses, there is scope for incorporating staff development into the management process. We have already noted the importance of induction for new recruits. **TABLE 15-8** looks beyond this step, suggesting informal processes that allow training to become an integral part of the management process. Many of these mechanisms avoid taking workers out of their environment and disrupting service delivery. Moreover, learning in the workplace can be more relevant and realistic.

Unfortunately, interest in these training mechanisms may arise for the wrong reasons, such as cost cutting or the ineffectiveness of poorly managed training courses. Learning environments are not easily created at work, especially where employees face strong pressures to ensure service delivery. Furthermore, when carried out properly, on-the-job training is not an inexpensive option.

It is not enough to think about the development of individual management competencies in isolation from the broader complex contextualized settings within which managers work. Indeed, managers will be able to put acquired individual knowledge and skills into practice only given the right conditions. WHO (2007a) considers three other dimensions to be critical to leadership and management capacity development:

TABLE 15-8 Forms of Training Within Management

Form of Training	Commentary
Self-development	A learning agreement may be used in which the conditions are provided for staff to take the initiative in planning their own training. This experience can be isolating, however, and those workers who are less able and more in need of training may be less successful in self-development. Also, there is no guarantee that the staff view of self-development will coincide with the interests of the service.
Shadowing	In shadowing, a worker learns from another employee through observation. Potential drawbacks are that the "shadower" may be exploited as a "free helper," observations may not be systematically recorded, and the "shadowed" individual may be unconvinced of the usefulness of the procedure. Care needs to be taken that the experience is relevant.
Mentoring	Mentoring may involve an experienced colleague (not the worker's manager or supervisor) taking on roles such as providing advice, setting specific learning tasks, and suggesting new work options. Recognizing the problems that can occur within the context of this relationship, mentoring should be voluntary and parties' roles should be clear.
Supervision	Although there is a danger of overloading this important relationship, there are opportunities for supervisor and supervisee to agree upon and implement plans for skills development and problem solving.
Delegation	Delegation may provide an opportunity for developing staff, although the worker receiving the delegated task should have sufficient capacity to perform it. Good supervision is necessary to take full advantage of the possibilities inherent in delegation.
Secondment	Staff can gain from the experience of temporarily working in another unit or organization. Care needs to be taken to ensure that the secondment experience is relevant to the responsibilities of the original job and that opportunities are given for learning.
Job rotation	Staff may undergo planned movements throughout the organization to develop new knowledge and experience.
Action learning	Learning through participation in completing tasks in a challenging environment may be useful. Such learning must be carefully planned and should not disrupt service delivery. This strategy is particularly useful to ensure a deep and engaging approach to learning.
Group-based work	Such work can involve a range of activities, such as study circles, support groups, professional and occupational groups for developing quality standards, and specific group meetings.
Reflective practice and journaling	This form of staff development involves thinking and writing about what has happened during the day. The purpose is for managers to pause and reflect on how they have coped during the day, how they have behaved, and what they have learned from the day—a practice that promotes reflection and learning.
e-Learning	There are multiple ways in which managers can learn online, ranging from access to readings in shared online folders, to modular or full coursework online, to highly interactive web sessions with multiple participants.

Data from Kerrigan, J. E., & Luke, J. S. (1987). *Management training strategies for developing countries*. Boulder, CO: Lynne Rienner Publishers; Storey, J. (1994). Management development. In K. Sisson (Ed.), *Personnel management: A comprehensive guide to theory and practice in Britain* (pp. 365–396). Oxford, UK: Blackwell Business.

an adequate number and deployment of managers throughout the health system, the existence of functional critical support systems to help in decision making (e.g., information and financial services), and the creation of an enabling working environment (e.g., delegation, stakeholder management, cultural, and economic context). Collins and Green (2014) argue that the values of the health system can be found in these broader dimensions for capacity development. For example, a health system with equity as its value base will regulate the migration of health workers from LMICs, will promote an organizational culture that incorporates a public-sector ethos, and will ensure that managers are treated in a fair and empowering fashion to support self and team development.

Personnel Administration

Most staff management functions outlined previously may be performed by either line managers (and supervisors), personnel specialists, or administrators. Personnel specialists can take on strategic, advisory, and operational roles (Cole, 1988). The administrator category encompasses the mostly routine administrative and procedural activities associated with functions such as recruitment, selection, pay administration, staff contracts, staff grading, promotion, transfer, staff communication, health, safety, and welfare in addition to maintaining a human resources information system (Strike, 1995).

Supplies Management[9]

The management of supplies includes those resources related to health technologies, such as medicines and diagnostics, and nonmedical items (such as food, fuel, and cleaning materials). This section focuses mainly on medicines, although many of the principles apply to other supplies.

As much as one-third of a country's budget for health care can be spent on medicines. Thus, as one would expect, this is an area of political interest (see the *Pharmaceuticals* chapter). It is also a complex area requiring, among other things, the choice of new health technologies at global, national, and local levels (Frost & Reich, 2008), and a process of procurement (including international and national tendering) characterized by complicated technical specifications and strict quality assurance throughout the process.

Effective management of pharmaceuticals requires international-, national-, and local-level management processes. At the international level, standards of quality, safety, and efficacy need to be set and monitored. An example of such a system is the WHO prequalification project, which since 2001 has monitored the compliance of selected HIV/AIDS, tuberculosis, and malaria medicines with unified standards of quality, safety, and efficacy (WHO, 2010c). Another important global public health task is the control of counterfeit medicines in international trade (International Medical Products Anti-Counterfeiting Taskforce [IMPACT], 2010). At the national level, in addition to robust systems for ensuring quality, safety, and efficacy of medicines, the appropriate mechanisms for licensing of medicines and regulating costs are important. Local challenges concern the storage and distribution of medicines in often inhospitable climatic and inaccessible geographic conditions with limited resources.

Problems with the availability of medicines in many services can be a major source of community complaints and irritation for health staff. In part, this issue arises because of the scarcity of material resources and the economic context. Other challenges relate to the existence of an underpaid and insufficient workforce with inadequate training, which may lead to poor management and corrupt practices. Poor management, for example, may include inadequate determination of need and demand, inappropriate selection, long delays in procurement, weak distribution systems, inadequate systems for medicine storage, and unsuitable use.

Supplies management is sensitive to changes in health systems and health policies. Reorganization of this system, for example, may result in separation of the regulator, purchaser, and provider functions. Decentralization requires new definitions of responsibilities in supplies management. Potential economies of scale in central purchasing must be reconciled with the forms of local supplies management and accountability and their associated responses to local needs and flexibility. National medicine policies should include key issues such as the pricing and taxing of essential medicines, the development of legislation and regulatory capacity, the training of health workers and education of the public, and implementation of international policy initiatives such as those developed by the Global Fund to Fight AIDS, Tuberculosis and Malaria (Anderson, Huss, Summers, & Wiedenmayer, 2004).

The supplies management system for pharmaceuticals can be seen as comprising four basic stages:

[9] Acknowledgment is given to Mayeh Omar and Reinhard Huss for their inputs in this section.

selection, procurement, distribution, and use (MSH & WHO, 1997). These four stages, which are linked and cyclical, need to be made operational to ensure that the right quantity and quality of medicines are located and used at the right time and right place. **EXHIBIT 15-5** outlines each of the stages and identifies some of the key issues and techniques involved in this process. A more detailed description of management of medicines is provided in the *Pharmaceuticals* chapter.

An important feature of supplies management is the coordination of the various resources such as health technologies, information, money, staff, transport, and nonmedical items. Several functional subsystems are required for good supplies management, such as health management information, regulation, financial/budget management, and transport management. For example, the supplies process must be linked to budget profiling. Also, efficient supplies management relies on a good management information system to monitor items such as stocks and treatment supplies. Furthermore, an effective supplies system is contingent on appropriate staff training and supervision, as was shown in a study conducted in Zimbabwe (Trap et al., 2001).

Transport Management

The importance of managing for an effective transport system should not be underestimated. Transport is central to ensuring access of patients to health services and the effective working of the referral system through both the emergency ambulance service and the transport of nonemergency patients. Health policies based on improved access and the principle of equity should

EXHIBIT 15-5 Stages of the Supplies Management System

Selection

Selection should consider the needs of the health units and programs, in addition to understanding the health situation of the particular communities concerned, their unmet needs, and the way in which these factors affect medicine requirements. Among the key considerations are the medicine requirements of the different levels of health care, priorities set, targeting of specific groups (e.g., children younger than 5 years), the use of an essential medicines list and generic medicines, and the design and implementation of quality assurance specifications.

The quantities required need to be estimated. Such estimates can be constructed via methods that use (1) population-based data on morbidity and mortality complemented by norms, (2) service-based data on diagnoses (and frequency) complemented by standard treatment norms, or (3) historical consumption data. Each of these methods has both pros and cons. For example, the second method fails to take into account unmet demand; the third method may be the easiest to use, but fails to account for changes that have occurred since the data were collected or are now occurring. Adequate supplies have to be maintained over time, so attention needs to be paid to issues such as consumption patterns over time, lead time for procurement, safety stocks, and reconciliation of medicine needs with available resources.

Procurement

Medicines are obtained through a procurement process, which involves actions such as following purchase procedures (e.g., tendering, negotiating), selecting the supplier (based on criteria such as price and quality through inspections), clarifying the terms of supply and supply periods (fixed or variable intervals), monitoring order status, and receiving and checking the medicines.

Distribution

Distribution can be based on either a "push" (kits) system or a "pull" (inventory) system. In the former type of system, quantities of medicines are sent at regular intervals, based on estimates of anticipated usage. The latter type of system requires the health unit to order medicines according to need. Use of this approach assumes, for example, the existence of an adequate stock control system and good communications for ordering and delivering. Among the issues to be considered are the simplicity, regularity, and reliability of the push system, in addition to how it compares with the greater sophistication and adaptability of a pull system.

Use

The use stage involves "diagnosis," "prescribing," "dispensing," and "patient compliance." A variety of indicators can be developed to monitor and evaluate medicine use.

take full note of the role of transport systems in reducing the direct costs of accessing health care, as those costs can impose economic consequences on households (McIntyre, Thiede, Dahlgreen, & Whitehead, 2006; Thiede, Akweongo, & McIntyre, 2007).

The management and operation of primary healthcare units and the implementation of community health programs require transport. Community work that involves nonresident health workers also relies heavily on good transport. Likewise, mobility and transport are vital for effective management such as supervision and operation of a supplies system. Finally, transport consumes a significant portion of the health services budget.

Although there are undoubtedly good transport practices that can be applied, problems in transport management are also commonplace, including lack of management skills and systems. For example, there may be an insufficient number of drivers, inappropriate or poorly maintained vehicles, no supervision, no vehicle scheduling or usage information, or poor maintenance. A tendency to treat transport as a free good may be one cause of a lack of cost-consciousness. Donor involvement may lead to a multiplicity of vehicle makes, making it difficult to maintain an effective store of spare parts and capacity to perform repairs. Corruption and the appropriation of transport for private use may also diminish the effectiveness of the transport function. **EXHIBIT 15-6** outlines measures to improve transport management and planning.

EXHIBIT 15-6 Measures to Improve Transport Management

- Include consideration of transport in the health policy, planning, and programming process.
- Determine the organizational arrangements and responsibilities for transport management and planning.
- Ensure financial management arrangements for transport.
- Develop vehicle programming.
- Develop fleet management, including vehicle maintenance and repair and operational norms for transport use.
- Manage and develop human resources for transport.
- Use information for improving transport performance.
- Clarify the contributions made by donors to transport management and planning.

Data from Collins, C. D., Myers, G., & Nicholson, N. (1992). A successful transport scenario for the health sector in developing countries. *World Hospitals, 28*(3), 9–14; Transaid. (2001). *Transport management manual*. London: Transaid Worldwide.

Attempts to develop a comprehensive policy for transport management have been made in countries such as South Africa (Department of Health and Developmental Social Welfare, 1999). Transaid, a transport international NGO working in the health sector in LMICs, has developed a transport management system geared toward service delivery organizations that includes detailed tools for transport management. Two key elements within its system are operational vehicle planning and using information (Transaid, 2008, 2017),

Ideally, the operational planning of transport will be coordinated by a dedicated transport officer, though in many cases this function can be centralized to ensure efficiency of operations. The discussion here assumes that transport in the organization is pooled and that appropriate decisions are made on how to use it best. Users of transport, such as health programs and units, first identify their transport needs. Subsequent decisions are then made based on, for example, service delivery and urgency. Vehicles are programmed, with every effort being made to meet needs and priorities, effectively monitor the process, and ensure the transparency of the process.

The use of information for improving performance is a theme throughout resource management and is particularly evident in transport. Managers responsible for transport need to pay attention to developing—among other documentation—log sheets, vehicle maintenance records, fuel consumption reports, budget management instruments, and reports on accidents and incidents. Key indicators of performance need to be developed relating to the distance traveled (per vehicle), utilization of fuel, vehicle running costs, vehicle availability, and utilization, together with information on the safety of each vehicle and the extent to which the vehicle meets service needs.

Information for Management and Management of Information

One resource that the manager is both responsible for and relies heavily on is information. This section looks at issues related to the management of information, including the development of an organizational culture of evidence-informed management. Information systems provide "information support to the decision-making process at each level of an organization" (WHO, 2004, p. 3). A health management information system (HMIS) is "an information system specially designed to assist in the management and planning of health programmes, as opposed to delivery of care" (WHO, 2004, p. 3).

Types of Information

Managers are constantly bombarded with, and attempting to make sense of, information. Most tend to consider information for use in management as that which is explicit, and often the information gold standard is seen as quantified data. In practice, however, most managers continuously use a considerable amount of information without being aware of it—often information derived from their own experience and frequently of a qualitative nature (Scott, Dinginto, & Xapile, 2015). It is important to recognize and value this type of input, while at the same time being aware that such information may be difficult to validate, in part because of its implicit nature. Managers need to identify points at which decisions are sensitive to critical information and, where necessary, triangulate the information. Data collection and analysis also carry substantial costs; thus, a good manager is able to request and use only the minimal amount of information at the minimal level of accuracy required for that decision.

Information may be of many types and describe a wide range of issues of importance to a manager. Indeed, several types of information systems were described in the preceding sections, including those dealing with budgetary information, information on transport usage, and personnel information. Within these health information systems, three domains of information can be distinguished: information on determinants of health (e.g., socioeconomic factors), information on a population's health status (e.g., mortality, morbidity, well-being), and information related to the functioning of a health system (inputs, processes, and outputs—for example, health services) (Health Metrics Network [HMN], 2008).

Sources of Information

The sources of health-related information can be classified into six broad categories (HMN, 2008; Stanfield, Walsh, Prata, & Evans, 2006):

- National census
- Population surveys
- Public health surveillance
- Vital events monitoring (civil registration)
- Health service records (statistics)
- Resource tracking subsystem

The following four categories are particularly important from the management perspective:

- Routine ongoing data collection (such as immunization records or resource tracking)
- Specific periodic or one-off surveys (such as community health surveys)
- Documented experiences and tacit knowledge of managers
- Comparative information from other health systems

Each source has both strengths and weaknesses in terms of accuracy, costs, and relevance to decision processes. A weakness of some management information systems (MISs) is that too much emphasis is placed on routine data collection systems when less frequent data collection would suffice. There is a temptation to institutionalize all data requirements, which can lead to an unwieldy formal MIS and perhaps a devaluing of the overall system.

Users and Providers of Information

Information systems include a number of components, with the information process being the central element. It comprises the following stages (HMN, 2008; Lippeveld, Sauerborn, & Bodart, 2000):

1. Identification of information needs
2. Collection of relevant data
3. Analysis of data to provide information
4. Use of information
5. Timely feedback to providers of information

Other important elements of information systems include the organizational and systems procedures and rules (e.g., the frequency of reporting) and the availability of resources (e.g., human resources, software and hardware, consumables).

Weaknesses can occur in an MIS at any stage of the information process. In some cases, data collected may not be relevant. For example, a manager seeking to understand why there is low utilization of health care is unlikely to get answers from service-based information, which cannot provide data on access barriers that prospective users may be facing in communities and which may underestimate the prevalence of unreported conditions. One frequent failing in information systems is a lack of feedback to data providers, which can lead to a downward information spiral in which the accuracy of data collected declines due to poor motivation and, as a result, the data are used even less.

Sometimes, inappropriate amounts and types of information may be found at different levels in the management system. **FIGURE 15-14** illustrates a common failing in which a similar amount of data flows up all levels of the system; ideally, the higher management levels should operate on increasingly selective amounts of key data.

Analysis of data and its transformation into information also raise issues in terms of the level at

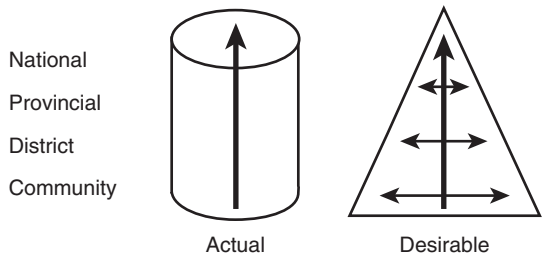

FIGURE 15-14 Data flow.

which these tasks are best done and by whom. A general rule of thumb is the closer the person doing the analysis/transformation to the collection of the data, the better.

Typically, HMIS represents the mainstream information system, covering all services. However, individual programs and projects (e.g., maternal–child health or mental health) may establish their own information systems, which may contribute to fragmentation of the health information system.

Information Technology

The rapid development of information technology provides both opportunities and challenges for health systems. Information technology can significantly increase efficiency of data collection, processing, analysis, and presentation—all of which may potentially contribute to improved quality and utilization of information in management and planning decisions. Information technology has developed rapidly, and organizations must be ready to adapt to these changes. For example, more than a decade ago Ash et al. (2004) reported that in the United States, the Netherlands, and Australia, the implementation of patient care information systems (PCIS) had the potential to foster errors related to the entry and retrieval of information, and to hinder the communication and coordination process that the PCIS aims to support. Nowadays, an increasing number of studies report the opposite effects. The positive effects that followed the introduction of the "SMS for life" plan in Tanzania offer a case in point. Through weekly mobile text messages and electronic mapping technology, this program helped improve accuracy of stock counts and timely replenishments of antimalarial medicines. The plan, which was implemented through a collaborative partnership of public and private institutions, contributed to greater visibility of antimalarial stock levels and supported more efficient stock management (Barrington, Wereko-Brobby, Ward, Mwafongo, & Kungulwe, 2010).

Furthermore, mobile technology provides opportunities to improve the range and quality of health services due to its increasing accessibility at the grassroots level. For example, a recent systematic review identified that, in addition to collecting health data, community health workers have increasingly used mobile technology to receive alerts and reminders, facilitate health education, and conduct person-to-person communication across various programs, including those dealing with maternal and child health, HIV/AIDS, and sexual and reproductive health (Braun, Catalani, Wimbush, & Israelski, 2013). This is consistent with a more general point, reported in an earlier systematic review, that health information technology can facilitate improvements in quality (through increased adherence to guidelines, decreased medication errors, and enhanced disease surveillance) and efficiency benefits (decreased utilization of care) (Chaudhry et al., 2006). The *Innovation, Technology, and Design* chapter provides more information on health and technology.

Key Themes in Management and Planning

The previous sections reviewed two key management and planning activities: organizing and resources management. Permeating these activities are various cross-cutting issues that are brought together and directly addressed in this section. How these cross-cutting issues are approached will have an impact on the way management functions are carried out within the health system. This section focuses on the following issues, which in many respects apply to both health management and health planning:

- Styles of leadership
- Accountability
- Evidence-informed approach
- Systems approach
- Linking and working together
- Sustainability
- Contradictions, tensions, and change

Styles of Leadership

Many of the issues related to leadership have been mentioned earlier in connection with supervision. Leadership is understood as a process of "providing direction to, and gaining commitment from, partners and staff, facilitating change and achieving better health services through efficient, creative and responsible deployment of people and other resources" (WHO, 2007b, p. 1). Effective leadership is concerned

with setting and maintaining an appropriate organizational culture and values that all (or at least a majority) of the organization's members will accept and subscribe to and that will help the organization achieve its organizational vision and mission. More than 400 definitions of leadership exist in the literature (Aarons, 2006; Edmonstone & Western, 2002; King & Cunningham, 1995; WHO, 2007b), and numerous frameworks have been developed for understanding leadership styles and approaches. Examples include a four-way typology of leadership styles denoting the distinction between high and low degrees of political and business orientations (Goodwin, 2000) as well as the various underlying theories of leadership (King & Cunningham, 1995). One framework of particular relevance to management is based on the distinction between the two broad leadership styles: *transformational leadership*, which inspires and motivates followers, and *transactional leadership*, which tends to rely on reinforcement and exchanges (Aarons, 2006; Stordeur, Vandenberghe, & D'hoore, 2000).

EXHIBIT 15-7 presents a number of functions of a leader. How managers practice effective leadership while carrying out these functions will depend on various factors. Personal qualities are certainly important—for example, one would expect a good leader to show personal understanding, confidence, and principled conduct. Nevertheless, these personal qualities are difficult to define precisely and measure. The style of leadership is also important. These styles can be viewed as varying, for example, from authoritarian to democratic, and from technically based to more personal-based leadership. However, leadership style needs to be adapted to the circumstances in which it is practiced, including the nature of the task. For example, problems with open-ended solutions may require a more flexible leadership style than more closed or finite problems; problems requiring an immediate solution may lead to a tighter style of leadership.

The category of staff over which leadership is exercised is also important. As noted earlier in this chapter, Hersey, Blanchard, and LaMonica (1978) highlighted task and relationship behavior as key variables of leadership activities. They highlighted that the maturity of staff is influenced by different combinations of four variables: capacity to set ambitious but realistic goals, willingness to take responsibility, and staff education and experience as both individuals or as a group. Managers adapt their style of supervision according to the level of maturity of their staff. For example, staff with a low level of maturity need the manager to demonstrate a high level of task leadership. As the maturity of the staff increases, the level of task leadership can decrease and the level of relationship behavior can increase.

The various styles of leadership in management are outlined in the following subsections. Note that these styles are not mutually exclusive, but rather can coexist within a single organization.

EXHIBIT 15-7 Functions of a Leader

- Scanning for changes and new developments
- Structuring and focusing the situation: determining what is a key priority, making it clear where the group is going and which action has to be taken
- Controlling group behavior: creating and enforcing appropriate rules for guiding the behavior of group members
- Speaking for the group: sensing and articulating (both internally and externally) the objectives and feelings of the group
- Uniting the group to achieve its goals and potential: mobilizing and coordinating group resources and decision making toward a common goal
- Inspiring: being a role model who serves and encourages

Coleman (1969), as quoted in Smith et al., 1982.

Proactive

A proactive approach reflects a key difference between management and administration and lies at the heart of the pursuit of objectives. When this style is applied, management performance should not be measured based on adherence to rules and regulations, as in administration, but rather on the extent of movement toward objectives. Such movement requires a proactive approach and reflects the ability to predict constraints and new opportunities, influence the environment, develop coalitions of support, foresee future problems and take early preventive action, and monitor performance so as to take corrective action.

There is a potential danger that managers' performance may be (perceived to be) judged on the mere appearance of proactivity. This circumstance can lead to shows of being proactive, such as displays of haste, workaholic behavior, and constant change. In some contexts, the necessity to demonstrate a proactive approach may lead to "change for change's sake," with little consideration of the underlying rationale. This is not good management.

Risk Taking

Risk taking reflects another important difference between administration and management. It expresses the inventiveness of managers, meaning their use of an

approach that does not accept existing ways of doing things are the only way. New methods and approaches involve an element of risk, however, so they represent a source of danger for managers. There are necessary limits to the extent to which managers should take risks; this point is particularly evident in the field of health. The notion of reasonable and acceptable risk needs to be understood.

How staff performance is managed also reflects the organization's attitude toward risk taking. For example, if staff are routinely criticized for failure and not praised or rewarded for success, then few staff will be willing to take reasonable and acceptable risks. Effective and supportive communication and supervision, together with the existence of clear and agreed-upon ethical and technical work standards, can create a more conducive environment of acceptable risk taking.

Problem Solving

One function of management is to seek solutions to problems arising from unforeseen changes in circumstances either within the organization or externally. An attribute of good management is the ability to deal creatively with new issues. One danger of paying too much attention to "problems," however, is neglect of future emerging issues at the expense of current firefighting. Problem-solving management needs to be balanced with a more long-term set of considerations.

Accountability

Accountability is defined as "the obligation of individuals or agencies to provide information about, and/or justification for, their actions to other actors, along with the imposition of sanctions for failure to comply and/or to engage in appropriate action" (Brinkerhoff, 2004, p. 372). It can be interpreted as a health system value as well as a principle of good governance (Collins & Green, 2014; Siddiqi et al., 2009; Travis, Egger, Davies, & Mechbal, 2002), and its importance permeates the health system. Accountability is essential to performance management, underlines the seriousness of health and health care and the concern for people's lives, and is crucial to exercising checks and balances on the use of resources. Networks of different (but overlapping) and changing forms of accountability run through the management of the health system, as summarized in **TABLE 15-9**.

Managers need to recognize and respond to each form of accountability. In some cases, they are

TABLE 15-9 Different and Changing Forms of Accountability

Form of Accountability	Commentary
Managerial	Managerial authority sees subordinates as accountable to the hierarchically superior manager. This perspective is typically expressed in the main line managerial relations in the organizational chart.
Professional	Professions are hierarchically structured, so that junior staff are technically accountable to those higher up on the professional ladder. Members of the profession may also be accountable to a professional body for their actions and behavior.
Political	Political representatives can hold staff accountable for their actions and behavior—for example, under devolution, where health staff are accountable to an elected local council.
Community	Health staff may be formally accountable to the community through mechanisms that monitor areas such as availability of medicines, personal relations with health staff, and punctuality of staff. Community accountability mechanisms in LMICs include health center and clinic committees, village health committees, patients' rights charters, and citizen report cards (McCoy, Hall, & Ridge, 2012; Molyneux, Atela, Angwenyi, & Goodman, 2012).
User	User accountability differs from the community form in that health staff are accountable to users of a particular service.
Market	Users are viewed as consumers of a particular service, for which they pay. Health staff are accountable to the consumers of the service through the market. Consumers who are dissatisfied with the service may go elsewhere.

reporting to authorities; in others, they are themselves the authority. Each form of accountability imposes rights and obligations on the management process. At the same time, individuals involved in management take part in the design of accountability relations and need to balance the various aspects of the network of complex, changing, and overlapping relations. In so doing, they are influenced by the values of the health system and by demands for new forms of accountability. The PHC approach, for example, puts the onus on community-based accountability, whereas the contemporary reform of health systems toward devolution emphasizes politically devolved forms of accountability.

Managers need to strike a balance between bureaucratic accountability (at different levels of the health system) and external accountability (to the community) to promote responsiveness to patients (Cleary, Molyneux, & Gilson, 2013). **EXHIBIT 15-8** identifies the key determinants of accountability of health services providers to the public. Note that this exhibit uses the term "user" rather than "consumer" to reflect that these determinants of accountability can be considered in both the public service and the private market context.

Evidence-Informed Approach

As stressed earlier in this chapter, management differs from administration in that it requires individual initiative rather than reliance on rules and regulations. The success of a manager in exercising such initiative is based on a combination of factors, including his or her technical skills and judgment. Both of these also rely on the manager's ability to draw on existing evidence (from HMIS, research, and other sources) when making managerial decisions. Different models have been proposed for utilization of evidence in decision-making processes, including knowledge-driven, problem-solving, interactive, political, tactical, and enlightenment models (Bowen & Zwi, 2005; Hanney, Gonzalez-Block, Buxton, & Kogan, 2003). Most health systems apply a combination of those models.

For the use of evidence to occur, various preconditions need to be met. First, the organizational culture needs to seek, generate, and accept the use of evidence in its decision making. Earlier we mentioned the importance of the values that underpin management and planning decisions; evidence-informed decision making itself can be seen as both a value and a process emanating from other values such as equity. A major criticism of many organizations relates to their failure to use evidence. This omission may result from either a genuine lack of evidence or a resistance to research-generated evidence that is not perceived as relevant—a phenomenon called the "know–do" gap (Campbell et al., 2009; Hanney et al., 2003; Mirzoev et al., 2017). In addition, some of this resistance may be generated by stakeholders with a vested interest in maintaining a particular position that evidence might

EXHIBIT 15-8 Key Determinants of Accountability of Service Providers

While there are many types of accountability, accountability by providers to communities and users is gaining significant traction in international discourse. Managers are stewards of the health system and must ensure that health providers are accountable within the health system and are responsive to community needs. Drawing on Berlan and Shiffman (2012), factors that may shape health provider accountability to users can include the following:

Health System Factors

- Appropriate oversight mechanisms are needed: The actors who supervise health providers may influence whose preferences and needs are prioritized.
- The source of revenue within the healthcare financing system can influence whose needs are prioritized (the rich versus the poor; the funder versus the community).
- The nature of competition between providers may lead to greater focus on user preferences to obtain patients, although this needs to be considered within a broader context of the public–private mix of providers in a country.

Social Factors

- Users often lack information and power to influence provider behavior. For this reason, a focus on empowering users through information provision and access to a broader collective can assist them in holding providers accountable.
- Professional and societal norms can influence the level of accountability that providers feel toward users. Such norms can include provider gender bias, class bias, and professional norms.

Data from Berlan, D., & Shiffman, J. (2012). Holding health providers in developing countries accountable to consumers: A synthesis of relevant scholarship. *Health Policy and Planning. 27*, 271–280.

challenge. Managers have a responsibility to generate an organizational culture that respects evidence-based approaches.

Second, a degree of "user-friendliness" of evidence is needed that is appropriate to the decisions being made (Hanney et al., 2003; Mirzoev et al., 2017; Oxman, Lavis, Fretheim, & Lewin, 2009). Facility managers and even district health planners are unlikely to find the time to read lengthy reports of monitoring and evaluation data sets. Instead, such individuals are more likely to read, understand, and eventually use succinct summaries in their planning and management decisions—that is, brief synopses that are written in nontechnical language and that clearly highlight key facts or issues that need addressing or consideration in the plans or management decisions. Although they certainly offer benefits in terms of their brevity, the level of accuracy may be compromised in such summaries. As noted earlier, there are clearly costs involved in seeking evidence, and these costs are directly related to the level of validity and accuracy of generated evidence as well as "packaging of the evidence" in an easy-to-use format to inform planning and management decisions. In turn, a decision maker needs to request only the minimum set of evidence necessary for any particular decision without compromising the quality of the overall evidence.

In the end, we return to the theme of the manager and the planner as practitioners of a value-driven art rather than a purely technical science. An indefinable quality of a good manager, which in part results from experience, is the ability to sift through information, select the appropriate information, and act appropriately on it. While management information systems, as a source of evidence, are an important source of inputs into the decision-making process for managers, Collins and Green (2014) note that decisions and activities decided upon by managers are, in fact, premised on an intersection of evidence, values, and judgment. Managers must combine the evidence (scientific and nonscientific) with which they are presented with their personal and health system values that they seek to uphold and achieve in the future. Management judgment is then applied to weigh tradeoffs and potential conflicts in decisions and activities. Policy, planning, and management decisions often require the agreement of many stakeholders, all with their own personal and collective value sets. Managers and planners should be aware that these stakeholders may or may not share their own values base, and should be aware of their own value sets, which shape their practices and management decisions.

Systems Approach

The advantages of the division of labor often prompt organizations and health staff to parse broader functions into specialized tasks. Although understandable, this approach runs the danger of producing fragmentation, narrow perspectives, and inflexible working patterns. In the management process, staff need to complement their own specialized responsibilities with a broader, more flexible approach—that is, with a *systems approach*.

Embrace of the systems approach means that staff, in addition to handling their own specialized tasks in management (such as human resources or logistics management), need to acquire a broad range of knowledge, skills, and aptitudes. This wide scope is important for the management process because managers need to combine and use different resources. It is also important in that it allows for more flexible working patterns, allowing staff to be more multifunctional and deal more effectively with short-term changes in the organization's work.

In addition, adoption of the systems approach means that staff are clear in relating their own positions in the organization to the overall organizational objectives. Thus, the manager of the TB program is not just concerned with a reduction in TB morbidity and mortality, but also with how overall community morbidity and mortality can be reduced. In this case, staff appreciate how their own actions relate to the work performed by other parts of the organization. Perhaps extra resources for one department or program are taking resources away from an area of greater priority. Or maybe having extra staff at a health center located in a high-income area may means staff are not assigned to health centers in poorer areas. Thus, the systems approach means appreciating the opportunity costs of managerial action.

The concept of systems thinking was recognized by the WHO Alliance for Health Policy and Systems Research in its flagship publication that identified the 10 steps in this process (De Savigny & Adam, 2009). The application of systems thinking in LMICs is deepening our knowledge of managing and leading in complex health systems (Adam, 2014; Gilson, Elloker, Olckers, & Lehmann, 2014; Kwamie, van Dijk, & Agyepong, 2014; Prashanth et al., 2014).

Linking and Working Together

The call for more collaboration is a frequent recommendation in management reports and guidance documents for health planners. Collaboration, however,

remains an elusive feature of management and planning, although attempts have been made to define its different manifestations, such as coordination and cooperation (e.g., Wang, Collins, Vergis, Gerein, & Macq, 2007). The forces behind individualism, exclusive group interests, and group interorganizational and intraorganizational conflicts are difficult to overcome. Yet the health system, if it is to function effectively and efficiently, needs to push collaborative strategies to the forefront of managerial action. Health staff, in their various organizations, need to work together. This includes the development of integrated management of patient care, team approaches within an organization, interdepartmental cooperation, public–private partnerships, and interorganizational and intersectoral linkages (Elloker, Olckers, Gilson, & Lehmann, 2012–2013; Langlios, Montekio, Young, Song, & Alcalde-Rabanal, 2016).

Working together through an intersectoral approach has long been advocated. Health depends on a wide range of factors located outside the healthcare system, including those known as social determinants of health (see the *Understanding and Acting on Social Determinants of Health and Health Equity* chapter). The challenge for management and planning is to devise effective approaches, actions, mechanisms, structures, and attitudes that can lead to greater ability of healthcare personnel to work together and coordinate their activities with their counterparts from other sectors such as education or housing. Ways of working across boundaries include the following:

- *Coordinating*. Two or more units agree on joint objectives, dedicate resources, and develop a joint plan, organization, and program (Rogers & Whetten, 1982).
- *Cooperating*. Two or more organizations keep their own separate but compatible objectives and agree to help—or at the least avoid hindering—each other (Rogers & Whetten, 1982). For example, health and agricultural organizations might agree to support the cultivation of subsistence crops and to protect fish-bearing rivers to ensure adequate nutrition of rural communities.
- *Community supporting*. Communities, which can view needs from a more integrated perspective than can the public sector, might support policies designed to strengthen community involvement in decision making and planning, so as to encourage more community demands and support for integrated action by the public sector.
- *Nesting*. Resources or activities are located in other organizations that support an intersectoral approach (Wang et al., 2007). For example, the MOH might strategically support initiatives of an intersectoral character in local governments, community associations, and NGOs by locating or nesting support in strategic points in these organizations. In return for action of an intersectoral nature, these bodies would receive resources and technical support.
- *Advocating*. The MOH often takes on the role of advocating for a health perspective to be used across the various sectors of the public sector—for example, through control over tobacco consumption, the use of car seat belts and motorcycle helmets, and elimination of fire hazards. Ideally a Health in All Policies approach should be adopted to minimize unintended impacts of public policy (WHO, 2014).
- *Regulating*. As discussed in more detail in the *Design of Health Systems* chapter, the MOH has authority to ensure compliance from other individuals and organizations. A particular challenge has arisen from the growth of the private sector in many LMICs (Lê et al., 2015; Sheikh et al., 2015). The MOH and other health-related organizations may be vested with legitimate regulatory authority to demand certain behaviors leading to health improvement. This role requires the development of legal expertise within the MOH, the focus of regulatory action on health objectives, the creation of regulatory mechanisms to require certain behavior, and the development of a sustainable administrative structure to implement regulations. In turn, political commitment is needed to back up regulatory legitimacy, while proactively initiating dialogue as well as taking intellectual leadership on the part of the MOH. Constraints on regulation might include a lack of state legitimacy, a shortage of financial and human resources to enforce the regulations, and regulatory capture by vested interests.
- *Shifting Authority Upward or Downward*. Authority for setting a cross-cutting strategic direction can be shifted upward in the hierarchy of government, moving above the organizational and sectoral divisions. A powerful cross-governmental commission for social development involving related ministries, for example, could provide intersectoral decision making as well as national planning and resource allocation. Authority can also be shifted downward to multifunctional devolved units at the local level. As discussed in more detail in the *Design of Health Systems* chapter, devolution, as a form of decentralization, opens up the potential for an intersectoral approach that links healthcare systems and other departments such as education and social services, although

the divisions between departments within local government can still constitute strong constraints.

- *Intersectoral collaboration*. This type of collaboration is defined as "the joint action taken by health and other government sectors, as well as representatives from private, voluntary, and nonprofit groups, to improve the health of populations" (Public Health Agency of Canada, 2016). In addition to requiring political commitment and support for the integrated system, successful intersectoral collaboration can be facilitated by engaging with partners early and establishing shared values and purpose. This includes deciding on concrete objectives and results as well as making clear the resource implications (personnel and money) for each party. It is also important to invest in the alliance-building process and to identify relevant champions who can support and drive the collaboration forward. Leadership, accountability, and rewards should be shared fairly among all parties (Public Health Agency of Canada, 2016).

Management Systems

Collaboration can be built into the management systems of organizations based on how they use resources. Agreements on consultation and use of information, for example, could be integrated into the system of district health planning and other sector planning. Information systems can also take on an intersectoral character (de Kadt, 1988).

Contracting

Contracts between organizations can be a useful means for developing collaboration. As shown in **FIGURE 15-15**, this relationship involves a commissioning body or purchaser, the contract, and the provider. The existence of a contract assumes some form of separation between the purchaser or commissioner (who has the funds and is the primary agent for determining the needs to be met by the contract) and the provider. The contract itself can include issues relating to services, object, and payment, and can be executed in a competitive or noncompetitive environment.

The elements involved in the contracting process suggest that variations in these components can lead to numerous contractual forms (**TABLE 15-10**). The different types of contracting may be appropriate for different environments.

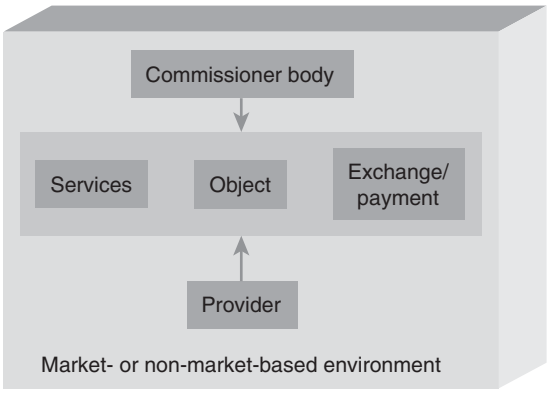

FIGURE 15-15 Elements in contracting.

TABLE 15-10 Variables in the Analysis of Contracting Primary Care Services

Variable	Comment
Object of the contract	Ranging from type of service to geographic coverage
Type of contracting	Ranging from formal and legalistic to more flexible contracting
Type of commissioner	Could include centralized or decentralized agencies with different degrees of organizational autonomy and financing (e.g., taxes, insurance systems, fee based)
Type of provider	Public-sector organization, NGO, or private for-profit organization, each with its own variations
Type of exchange or payment	Based on a definition of services and payment system, which could be, for example, performance based
Market or nonmarket based	Contracts can be based on competitive tendering, with services provided in a market environment, or without competitive tendering, with service providers operating in a noncompetitive environment

One can distinguish between a time-based versus a lump-sum nature of the payments in contracts. As an alternative means of classifying contracts, Palmer (2000, p. 823) distinguishes between classical contracts ("discrete transactions between people who will never see each other again"), neoclassical contracts ("less discrete and therefore contain techniques for flexibility within the terms of the contract, such as third-party determination of performance"), and relational contracts (the terms of the contract are not the key element; rather, the whole relationship between the parties over time is key, and importance is put on harmony and keeping the relationship). Palmer suggests that LMICs often rely on classical and neoclassical contracting, despite the possibility that relational contracting might well be more promising in that environment.

Sustainability

An important theme in management is that of the sustainability of services. Lafond (1995, p. 63) sees sustainability as "the capacity of the health sector to function effectively over time, with a minimum of external input." The mention of "external input" is of particular relevance to poor countries that are heavily reliant on funds from international agencies. Olsen's (1998) definition emphasizes the longer term: "A health service is sustainable when operated by an organisational system with the long-term ability to mobilize and allocate sufficient and appropriate resources (manpower, technology, information, and finance) for activities that meet individual or public health needs/demands" (p. 289).

The relevance of sustainability to health management and planning rests on two key points. First, health care is rarely time limited. Disease control, for example, requires continued interventions over time. As one case in point, the continuity of action in TB control is important to limit the spread of disease. In particular, continued medicine supply and continued treatment are important to avoid the development of drug-resistant TB.

Second, the importance of sustainability draws on four problematic and interrelated features of the public sector, particularly in LMICs:

- The extremely limited resource base of poor societies, coupled with the limited authority of national governments, leads to intense resource scarcity in the public sector. This limitation, in turn, underlies the problem of maintaining a secure and constant flow of resources to finance government programs and produces high levels of dependence on international aid.
- The historical focus of international aid to LMICs on capital investment, with less support being given to recurrent expenditure, leads to difficult problems of maintaining programs of action. This issue is compounded by the vertical and cyclical nature of foreign aid projects.
- Corruption has a marked impact on the continuity and effectiveness of government given the high level of resource scarcity.
- High staff turnover may lead to limited effectiveness and reduced sustainability of government programs (Collins et al., 2000).

In practical terms, managers need to develop the appropriate health systems capacity, and in particular the organizational culture based on the chosen values, vision, and mission, and then ensure its sustainability. By "ensuring sustainability," health planners usually mean drawing realistic plans and ensuring consistency between longer-term policies or strategic plans and shorter-term operational plans and management practices (Mirzoev & Green, 2017).

Sustainability is not actually an end in itself, but rather a means to a wider end. It is colored by the policy objectives held by the stakeholders. This influence introduces two possibilities:

- *Appropriate sustainability* occurs when a particular activity has continuity over time and has outputs that maintain their value. For example, policy objectives often specify the achievement of improved and equitable health care, with certain types of action deemed essential to achieve this outcome.
- *Inappropriate sustainability* occurs when programs and activities need to be stopped at a particular point, but instead continue. For example, as the incidence of a particular health problem declines, related interventions may need to be reduced. Smallpox vaccination is a classic example.

Of course, what is seen as appropriate sustainability by one stakeholder may be viewed as inappropriate sustainability by another. Stakeholders in a particular government activity will have different interpretations of a program, largely determined by how it affects their own particular interests. **TABLE 15-11** highlights the possible interests of different stakeholders in sustainability.

To capture the determining features of sustainability, the analysis of the health system needs to recognize the broad-ranging character of sustainability and its multiple determinants. The factors influencing sustainability will also vary in different circumstances.

TABLE 15-11 Stakeholders' Potential Interests in Sustainability

Stakeholder	Potential Interests in Sustainability
Donors	Shifting resource dependence away from donors and increasing local contributions
Ministry of health	Ensuring regularity of donor resources and/or shifting resource dependence away from donors and increasing local contributions
Staff	Ensuring continuity in employment and career progression
Users	Ensuring continuity of improved service delivery
Nonusers	Expansion of services on a regular basis to cover their needs
Private-sector contractors	Shift to public financing and private provision under favorable conditions

Conclusion and Challenges for Managers and Planners

Management and planning are fundamentally concerned with the relationship between resources and objectives. They both deal with scarce resources, operate within various technical and political constraints, are strongly influenced by values, can operate in a political manner, and have a strong interrelationship with the changing social, political, economic, and international context. Two interrelated functions of management and planning have been emphasized in this chapter: Organizing and management of resources. Cross-cutting issues permeating these management activities include styles of leadership; accountability; an evidence-informed approach; a systems approach; linking and working together; and sustainability.

The future direction of health management and planning in LMICs is far from clear. Certainly, the goal of universal health coverage will require significant improvements in health management and planning. However, such improvements cannot be divorced from some challenging questions.

What Is the Future of Public-Sector Management and Planning?

Criticisms of state and public-sector management and planning have ranged from simple market orthodoxy to a more nuanced approach that recognizes their needs and social responsibilities. All too often, the prevailing view of corruption, bureaucratic expansion, administrative fragmentation, and patronage within health systems has made it easy for many to levy criticisms. Nevertheless, two points need to be recognized.

First, public-sector management and planning typically operate in a context of low funding, intense and changing needs, and an unstable environment. Of course, the degree to which the resources are constrained varies across countries. For example, the rapid growth of many Asian economies provides—at least in theory—a platform for increased investments in these countries' public health sectors. Changing health needs (e.g., due to epidemiologic and demographic transitions) and unstable political and economic environments and crises put additional strains on management of the public health sectors in many countries.

Second, there is a need to recognize the specific characteristics of public-sector management and planning. Public-sector and private-sector management have much to learn from each other. The future development of public sector management, and the values that underpin it, need to take into account three considerations:[10]

- The public sector seeks to meet public needs and interests, although different social and political groups have different interpretations of these needs and interests. Resolution of these discrepancies requires open and transparent

[10] These three points draw on the work of Stewart and Ranson (1994).

participation and negotiation regarding the definition of public interest and agreement on the underlying values. Public-sector bodies need to define their objectives in relation to these public needs and interests.

- The multifaceted nature of public needs means that public-sector organizations can achieve their objectives only by engaging in collaborative strategies with other bodies, whether public-sector organizations, NGOs, or private for-profit organizations, and across all health-related sectors, such as education or housing. This also requires collaborative strategies between the public sector and communities.
- Social needs are not ephemeral in nature but rather are long-term issues, and they require public-sector management to recognize and respond to their persistence. Planning, sustainability, continuity of service provision, capacity building, systems development, and planning for professional development are among the key features of public management.

Are Managers Being Asked to Manage the Unmanageable?

That managers in health systems have to deal with contradictions, tensions, and change is not new. However, the immensity of these challenges becomes evident as we consider the paucity of resources available even in middle-income countries and the scale of the health needs stressed elsewhere in this text. In dealing with these challenges, there is a gap, which varies from one country to another in terms of both its size and its nature, between the existing capacity of management to meet those challenges and the potential that exists to do so through management strengthening. It is a matter of concern, however, that an already difficult situation is being made worse through sharpening contradictions and weakened means to respond to populations' needs.

First, the tension between public interests and private gain is increasing as a result of the growth of public–private partnerships and the trend toward self-funding public bodies. Second, the public sector faces threats because of the poor rewards for public servants, the downgrading of the role of the public sector, and a hollowing out of its rationale and process. The culture of individualism, internal markets, and self-funding of health units and programs all stand in opposition to the public sector's perspective of social interests, collaborative strategy, longer-term framework, and public ethos. In the words of Flynn (1997, p. 232):

> What . . . [was] . . . needed is a change in attitude towards the public sector. If spending could be based on need and a realistic assessment of what is affordable rather than a constant state of crisis and if management arrangements could be based less on distrust and fear and more on cooperation, then public services could make a valuable contribution to the economic health and quality of life of society.

Twenty years on, although the narrative of the New Public Management persists, it has become decidedly more nuanced. The initial illusion of possible vast increases in the efficiency of the public sector (through adopting private-sector principles) has since been overshadowed by the recognition of the continuous "firefighting" mode in which the public sector operates, which requires continuous adaptation to multiple crises. The nature of these crises is fundamentally different from the pressures that the private (particularly for-profit) sector faces. For example, while populations in many countries have become more affluent, health inequalities have widened dramatically in rapidly developing countries such as China. Large population displacements across the globe, for various reasons, have put additional strains on the public health systems of the recipient countries. Even as the likelihood of profit generation has increased, the quest to address the social goals of equity and universal health coverage has become more of a challenge. The concept of health systems resilience has emerged in the last several years, signaling the need to prepare health systems (and particularly the public sector) and their managers for both everyday shocks and major crises (Gilson et al., 2017; Kruk et al., 2017).

Perhaps as a consequence of the ever-changing contextual pressures, although the fundamental principle of focusing on social value remains the dominant theme within the public health sector, the role and resultant shape of that sector has changed. The introduction of internal public-sector markets has brought principles of competition to the public health facilities in countries such as Vietnam (Lê et al., 2015) and China, raising questions regarding the balance between the social goals of the public sector and the pressures to remain financially sustainable. In other rapidly developing countries (e.g., Thailand and Brazil), the public sector's role and primary focus on

social goals have been maintained, illustrating the public sector's potential resilience to pressures of marketization and calls for increased efficiency. Such calls can, for example, counterbalance the pursuit of health equity and universal health coverage.

What Are the Challenges Facing Public-Sector Health Managers?

This chapter has provided a brief overview of the key issues that a manager or a planner working in the public health sector needs to address. Management and planning, we have argued, is a key, but often undervalued, component of a health system. As managers and planners seek to establish the structures, resources, and processes necessary for meeting the SDG, which emerging challenges are they likely to face?

First, public health planners and managers will need to grapple with the increasingly diverse structures of the health system and new approaches to funding. The ever-more-intertwined public and private institutional complexity and changing relations between the system center and the local levels, combined with new funding flows and public–private partnerships, suggest that decision makers need to seek new ways to meet these challenges.

Second, although LMICs continue to face major financial resource constraints, the crisis of the health worker gap must be seen, for many countries, as an even greater constraint. This trend, coupled with the low staff morale in many health systems, presents major challenges for planners and managers, who will need to find new ways to cope with shortages of healthcare workers.

Third, managers face an increasingly vocal and empowered citizenry, conscious of the global rights agenda. This trend will increasingly—and rightly so—challenge established values and principles (such as command and control) and will ultimately place greater demands for accountability on the health system. Planners and managers will need to think strategically in meeting this demand.

Fourth, new technology is continually emerging and increasingly being used in various aspects of health systems, including provision of health services, planning, and management. Its utility is often counterbalanced by its high costs, with managers being called upon to respond to and manage the potential of, and access to, the technology.

Fifth, the increasing number of fragile economies in the countries across the world, combined with heightened interest in building resilient health systems that can anticipate and withstand everyday challenges as well as major shocks, create specific challenges for planners and managers. These challenges are manifold: Examples include responding to an ever-changing context including the resource environment, ensuring consistency between short- and longer-term perspectives, and ensuring sustainability.

The nature, and indeed excitement, of management and planning lies in identifying and adequately responding to such emerging and ever-changing challenges. Management as a scientific art must continuously develop new approaches and tools to accomplish this feat.

Discussion Questions

1. Which approaches to health management exist in a country known to you? Which factors affect any differences in approaches to health management at different levels of the country's health system, and why?
2. Consider which kind of health planning takes place in a country known to you. How successful is it? Which major health needs exist that are not met? Can you identify an expenditure that is of lower priority than these unmet identified needs? How could health planning be improved?
3. How are healthcare priorities decided within the health sector of a country known to you? What is the role of the manager in this process? Which values do these priorities and plans reflect?
4. Describe the financial management system of a country known to you. How are resources allocated to lower levels? Are there any differences in allocation between different types of resources? How is resource allocation linked to the planning process?
5. Which system of decentralization exists in your country? What are its strengths and weaknesses for the health sector?
6. Which practical steps could be taken to improve intersectoral collaboration for health in your country?
7. Consider the way in which local-level health staff are managed. Which steps could be taken to improve the way in which these staff are managed?
8. What information is included in the health information system(s) of a country known to you? How effective is it in providing timely, accurate, and relevant information to inform health management and planning decisions?

CHAPTER 16

Pharmaceuticals

Kara Hanson, Stuart Anderson, Henry Lishi Li, Barbara McPake, Benjamin Palafox, Giuliano Russo, and Rima Shretta

Introduction

Pharmaceuticals are a critical element of the health system. They consume, on average, 25% of a health system's total expenditures (Lu, Hernandez, Abegunde, & Edejer, 2011) and are a potent symbol of effective health system functioning: When medicines and vaccines are not available in health facilities, the confidence of both patients and providers is undermined. Their central role in health systems is reflected in the Sustainable Development Goal target for universal health coverage, which highlights the importance of access to safe, effective, quality, and affordable essential medicines and vaccines for all, and captures the need for households to be protected from the impoverishing effects of health expenditures, of which expenditures on medicines represent an important part. Pharmaceutical access is influenced by all the core health system building blocks (see also the *Design of Health Systems* chapter):

- Service delivery, which affects how patients access medicines and whether they are appropriately prescribed and used
- Information systems, which are responsible for monitoring appropriate use and effective supply management
- Financing systems, which need to generate sufficient resources and protect households against out-of-pocket payments
- Effective governance and stewardship, capable of stimulating pharmaceutical research and development and regulating the introduction of new products; ensuring the quality, safety, and appropriate distribution of existing products; and providing transparent procurement

Despite these products' importance, large numbers of people around the world lack access to essential medicines. Improving access to pharmaceuticals is, therefore, a global public health priority, as evidenced by the number of international health movements that have included it as part of their central goals. The first Model Essential Drugs list, created in 1977, coincided with the development of the primary healthcare movement. The 1987 Bamako Initiative committed to improving the availability of essential medicines across sub-Saharan Africa. From 1990 onward, a range of global health initiatives, including the Global Fund to Fight for AIDS, Tuberculosis and Malaria; Stop TB; and GAVI took up the challenge of improving access to essential medicines and vaccines, providing both financing and support in procurement to ensure quality standards. In the present era of universal health coverage, there is renewed focus on securing sufficient funds to meet the healthcare needs of populations through the expansion of public health spending, but also recognition of the need for these resources to be used efficiently. For medicines, meeting that goal requires a focus on these products' selection,

procurement, distribution, and appropriate use. Antimicrobial resistance poses a major challenge to the existing pharmaceutical business model and highlights the tensions between enabling access to vital medicines while simultaneously seeking to restrain their use so as to conserve their effectiveness. Moreover, as the epidemiologic transition unfolds in all parts of the world and the burden of noncommunicable disease increases, new challenges arise. Chronic conditions often require lifelong use of medicines, so incorporating these medications into care benefit packages and ensuring their regular availability is critical for treating such conditions.

Three key components of access are addressed in this chapter: availability (addressing both "upstream" issues of product discovery and development and "downstream" challenges of national pharmaceutical supply systems), affordability, and safe and effective use of medicine. Two current issues in pharmaceutical policy—growing resistance to antimicrobials, and the need to ensure adequate availability, affordability, and use of medicines for chronic conditions—are presented at the end of the chapter as case studies to illustrate these issues.

Throughout the chapter, we strive to maintain consistency in terminology, while recognizing that the preferred names of the products that are discussed have changed over time. Currently, *medicine* is the preferred term over *drug* for any substance that is used to modify physiological systems or pathological states for the benefit of the recipient, as the latter is now widely regarded as referring to illicit substances. *Pharmaceutical* is a broader term that generally encompasses both medicines (prescription and over-the-counter) and vaccines in their finished form. Although *medicine* and *pharmaceutical* are often used interchangeably, the latter may also encompass other products of the pharmaceutical industry—for example, the active pharmaceutical ingredients (API) used in production, other biologicals such as blood products and insulin, veterinary medicines, and diagnostic products such as those used for blood typing and test kits for the human immunodeficiency virus (HIV) and malaria parasites (Anderson & Huss, 2004; World Health Organization [WHO], 2002).

Other important and germane definitions and concepts include *essential medicines*, which are defined as the medicines that satisfy the priority healthcare needs of the population, and that are selected based on public health relevance, evidence on efficacy and safety, and comparative cost-effectiveness. *Generics* are pharmaceutical products that are intended to be interchangeable with the original innovator product and are marketed after the expiry of an original product's patent or other exclusivity rights. Generic products may be marketed either unbranded ("commodity generics") or under a new brand name ("branded generics") (Anderson & Huss, 2004; WHO, 2010b).

Pharmaceutical Availability: Upstream Issues

One of the reasons why many people worldwide do not have access to medicines may be that the right sorts of products have not been developed yet, or that they are marketed at prices unaffordable for many. The following sections present the so-called upstream availability issues, discussing in turn the inherent complexity for the pharmaceutical industry of inventing new medicines, the performance and flaws of the current research and development (R&D) system, and the alternative strategies that have been developed to address these shortcomings.

A starting point for securing access to pharmaceuticals in high-income countries as well as low- and middle-income countries is the development of the right products—that is, products that are safe, effective, and acceptable and that address major causes of disease burden. Pharmaceutical R&D mostly takes place in high-income countries, and is driven by a profit logic. Understanding the incentives operating in the industry is, therefore, essential as an entry point to influencing investment choices.

The Current System for Researching and Developing Pharmaceuticals

Developing a new pharmaceutical product is a long, heavily regulated, and expensive process, estimated to take 5 to 15 years, and to cost in excess of $2.5 billion (DiMasi, Grabowski, & Hansen, 2016). The drug discovery cycle typically goes through seven different phases: prediscovery, discovery, preclinical testing, clinical trials, regulatory agency review, scale-up to marketing, and postmarketing surveillance. This process involves laboratory experimentation, animal testing, three phases of clinical trials on humans, and several regulatory reviews before a drug can be made commercially available (**FIGURE 16-1**). In the United States, the regulatory function for pharmaceuticals is performed by the Food and Drug Administration (FDA).

The probability of identifying a promising molecule is reported to be small in the initial phase of R&D (0.1%): More than 5,000 molecules may have to be

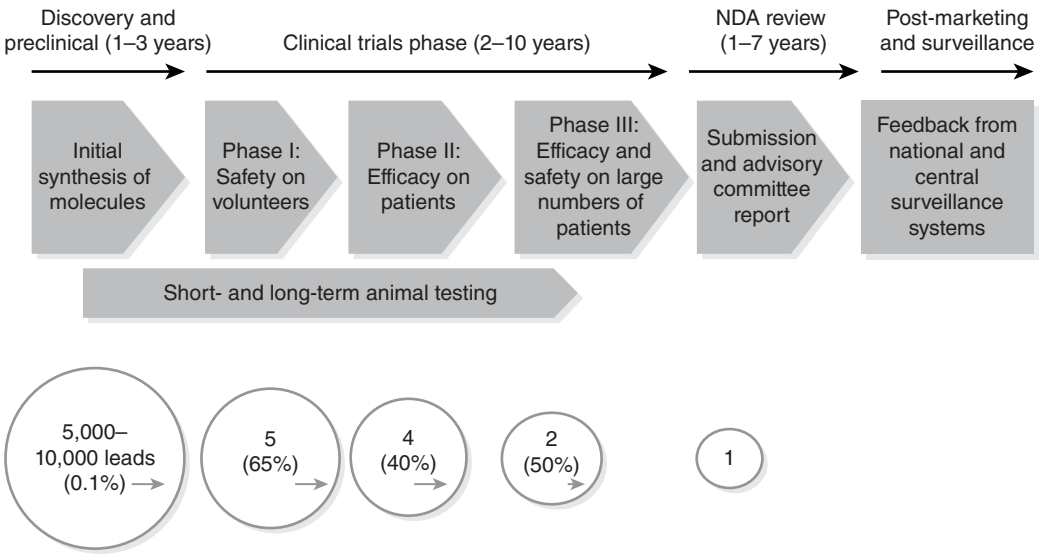

FIGURE 16-1 Overview of the key stages involved in the pharmaceutical R&D process and probabilities of compounds progressing to the next phase.

Modified from DiMasi et al., 2006; Petrova, 2014.

synthesized to identify 5 candidates that are suitable to progress to the next phase. Phase I clinical trials involving small numbers of volunteers are conducted to test the compounds for safety, tolerability, and stability of the active ingredient. Efficacy and dosage are explored in Phase II small trials on tens of patients. Safety and efficacy are then tested in larger trials involving thousands of patients from real-life settings in the final clinical phases (Petrova, 2014). The cumulative probability of success for the three clinical trial phases alone has been estimated to be in the range of 12% to 33%; considerable costs are associated with the preclinical industrial phase (approximately 25% of the total costs), and with the clinical trial phases (60% of the total costs) (DiMasi et al., 2016; Petrova, 2014).

To create incentives for companies to engage in this costly and risky pharmaceutical innovation, governments award inventors with patents, granting the inventors 20 years of exclusive rights to exploit the production of the patented medicine worldwide. Patents are defined as exclusive property rights on intangible creations of the human mind—hence the term "intellectual property rights" (IPR). While several forms of IPR protection are available, the product covered by a patent must be something that has never been previously disclosed anywhere in the world, and that would not be obvious to a person ordinarily skilled in the field involved. This is a crucial point for pharmaceutical entities, as their manufacturing process is often easy to replicate and can be copied with a fraction of the investment required for research and clinical testing (Saha & Bhattacharya, 2011). The appropriateness of 20 years as a patent term has been contested, with some arguing that a long protection period provides a negative incentive for real innovation (Leoni & Sandroni, 2016). In contrast, the industry has sought to extend these terms for medicines for which efforts are being made to conserve their efficacy by limiting their use (see the later discussion on antimicrobials) (Outterson, Samora, & Keller-Cuda, 2007).

Since the vast majority of medicine discovery activities are carried out in high-income countries and patents are awarded by specialized agencies based there (such as the U.S.-based FDA and the European Medicines Agency [EMA]), patents are upheld worldwide through the institution of Trade-Related Intellectual Property Rights (TRIPS), and enforced by the World Trade Organization (WTO) through its member nations. Negotiated between 1986 and 1994, the TRIPS agreement set the minimum standards for intellectual property protection that all WTO member countries—some of which did not provide patent protection for pharmaceuticals prior to the agreement—must respect. It also specified mechanisms for local enforcement and procedures for resolution of conflicts (WHO, 2005). Pharmaceutical patents and TRIPS were originally established as a remedy to the global markets' failure to protect intangible products of intellectual activity; it bans potential manufacturers from free-riding on inventions, thereby creating a financial "pull incentive" for innovation. The TRIPS agreement states that all pharmaceutical patents must be available for at least 20 years from the filing date for all products "invented" after January 1, 1995. To abide

by the agreement, WTO members must modify their intellectual property legislation to align them with the TRIPS standards, although countries at different levels of economic development were given different deadlines to comply with this mandate (e.g., the deadline for the least developed countries is 2033).

Although they are well intentioned, by imposing worldwide legal monopolies, patents prevent price competition and introduce a different market failure in the global market for pharmaceuticals, as the ensuing higher prices restrict consumption of pharmaceuticals (Levy & Rizansky, 2014). Health-sector advocates have also argued that the TRIPS standards should take protection of public health into account, so a provision to allow the patent requirement to be circumvented in the event of "public health emergencies" was included in the agreement (WHO, 2001a). To further clarify this provision, and after much pressure from the international health community, the WTO produced the Declaration on the TRIPS Agreement and Public Health, also known as the Doha Declaration of 2001, and a subsequent Decision on the Interpretation of Paragraph 6 of the TRIPS Agreement was reached in 2003. These clarifications affirmed the flexibilities available to member states seeking to protect public health (Kerry & Lee, 2007) (for further detail, see the *International Trade and Health* chapter).

Some of these measures, such as tiered pricing, aim to create the possibility of charging different sale prices in different countries according to consumers' differential ability to pay (Nicol & Owoeye, 2013). Such practice, however, creates the risk of "parallel imports," in which patented medicines are sold at a lower price in a low-and middle-income country (LMIC), only to be reimported illegally into high-income countries.

Other flexibilities, such as compulsory licenses, limits on data protection, patentability, and parallel imports, aim at allowing national governments to break patents and produce (or outsource production to a third party) generic versions of patented medicines in case of public health emergencies (Musungu & Oh, 2006). Such flexibilities have only rarely been used in LMICs, either owing to a lack of the legal and technical expertise required to take advantage of these complex options, or out of fear of trade retaliation from high-income countries, such as being included in annual watch lists like the Special 301 Report issued annually by the U.S. Trade Representative (Wirtz et al., 2017). Nevertheless, TRIPS flexibilities have proved useful in improving access to medicines in LMICs (see the "Affordability" section later in this chapter).

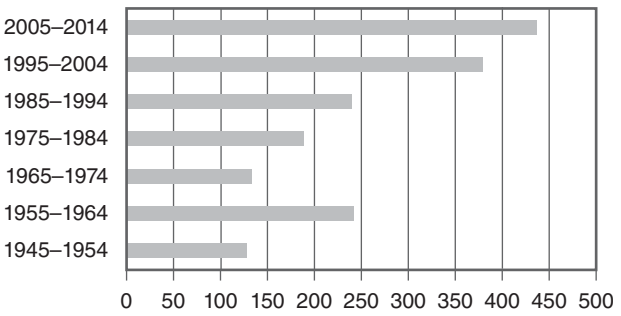

FIGURE 16-2 New molecular entity patents awarded by the FDA in the last seven decades.

Modified from U.S. Food and Drug administration, several years.

Availability Challenges with the Current Pharmaceutical R&D System

The pharmaceutical industry has been criticized for underperforming in terms of discovering new pharmaceutical products, and for being in a productivity crisis (Scannell & Bosley, 2016). Yet in a review looking back at the past 60 years of pharmaceutical discoveries, Munos (2009) showed that the FDA, which is perhaps the world's most important pharmaceutical regulatory agency, has awarded a steady number of patents for new molecular entities (NMEs) each year—45, on average. This number has been increasing in recent years (**FIGURE 16-2**).

Despite the undeniable advances of the last decades in pharmaceutical innovation, certain types of diseases appear to have been neglected by the R&D system. Light and Lexchin (2012) have identified a preponderance of FDA approvals for medicines with few significant therapeutic gains starting from the 1990s, caused by a change in the industry business model from seeking blockbusters to turning out small-variation medicines. This different level of investment in medicines markets is consistent with the distinction drawn by the 2001 Commission for Macroeconomics and Health (WHO, 2001a) between three categories of diseases:

- Type I diseases, which are prevalent in both high-income and LMICs. Their substantial commercial markets in high-income countries drive R&D activity, so there is no product shortfall. Affordability is often an issue, however. Examples include noncommunicable diseases such as diabetes, cardiovascular diseases (CVD), and tobacco-related illnesses, as well as infectious diseases such as pneumonia, hepatitis B, and *Haemophilus influenzae* type b (Hib).

TABLE 16-1 Diseases, Medicines, and R&D Issues

Type of Diseases	Geographical Location of Affected Population	Medicine Examples	Specific R&D Issues
Rare diseases	LMICs, HICs	Orphan drugs; hepatitis G; Fabry disease; hemophilia; cystic fibrosis	Limited sales due to small group of potential patients Need to charge high prices to recoup R&D investment
Tropical diseases	LMICs in the tropics	Dengue; leishmaniosis; leprosy	Limited ability to pay from potential consumers Risk of price controls imposed by authorities
Complex diseases	Mostly HICs, but also LMICs	Specialty medicines; specific cancer types; different type of hepatitis	Complex macromolecules requiring expensive technology Challenge to establish bioequivalence for biosimilar Extended data protection exclusivity granted for biologics
Antimicrobial-resistant infections	HICs and LMICs	Antibiotics for hospital superbugs; rising AMR levels in minimally regulated prescribing settings	Likely delays in wide commercialization due to prescription policies, leading to limited high-price sales during patent coverage

Abbreviations: AMR = antimicrobial resistance; HICs = high-income countries; LMICs = low- and middle-income countries.

- Type II diseases, which are "incident in both rich and poor countries, but with a substantial proportion of the cases in poor countries"—for example, acquired immunodeficiency syndrome (HIV/AIDS) and tuberculosis (TB). These diseases have modest markets in wealthy countries; thus, some R&D activity exists, although it is often targeted at high-income groups rather than LMICs (e.g., short-term courses of antimalarial agents for travelers and members of the military, or complex high-priced antiretroviral medicines).
- Type III diseases, which occur overwhelmingly or exclusively in LMICs and have no commercial market to drive R&D—for example, Chagas disease, dengue fever, Buruli ulcer, and African sleeping sickness (trypanosomiasis). There are often limited or no treatments for these diseases.

It is apparent that products aimed at certain diseases give the pharmaceutical companies access to more lucrative markets than others, and that this factor drives the industry's R&D investment decisions. A taxonomy of diseases and medicines for which the current R&D system does not seem to work adequately is offered in the following paragraphs (**TABLE 16-1**).

Aronson (2006) defines as "orphan drugs" those NMEs not associated with any recognized disease (such as for hepatitis G, a detectable hepatitis virus with as yet unknown implications), and those agents used to treat diseases affecting fewer than 5 to 10 individuals per 10,000 population. Despite the obvious lack of incentive for the industry to invest in such narrow market segments, the patents awarded by the FDA for so-called orphan-designation drugs have increased in recent years, and currently represent approximately 40% of the total number of patent awards (**FIGURE 16-3**).

Neglected tropical diseases (NTDs) is a term used to identify a diverse group of communicable diseases affecting individuals in low- and middle-income tropical and subtropical countries. Unlike the conditions targeted by orphan drugs, large numbers of people are affected by NTDs, but because of their limited disposable income, suppliers' ability to charge high prices for

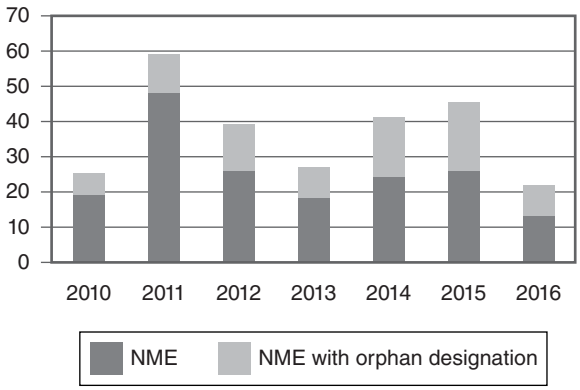

FIGURE 16-3 FDA-awarded patents for NMEs with and without orphan designation, 2010–2016.

related medicines is somewhat limited, and likely to be regulated for equity objectives. As a result, pharmaceutical companies claim that researching and developing medicines for NTDs is risky, as the expected returns would be unlikely to cover the costs in this area (Trouiller et al., 2002). The International Federation of Pharmaceutical Manufacturers Associations (IFPMA) reports that in 2014 multinational pharmaceutical companies were the third largest funders for R&D in NTDs, contributing 13% to the $3.3 trillion global expenditures in this area—up from 7% in 2007; by comparison, 62% of these activities were funded by public sources, and 20% by philanthropic organizations (IFPMA, 2017).

Specialty medicines for complex diseases are often, but not exclusively, complex macromolecules produced through recombinant DNA technology. They are typically used in new forms of treatment for cancer and hepatitis C. The costs involved in discovering and developing such entities are many times higher than those for regular small molecules, because of factors such as the technology involved in the process and the extended data protection exclusivity period granted for biologics. The lack of competitors in this market segment due to the challenge of establishing bioequivalence for biosimilars contributes to the high prices charged for such specialty products (Bigdeli, Peters, & Wagner, 2014).

For new antibiotics, the challenge of the current system of pharmaceutical innovation arises from the need to withhold the launch of new products to the market to delay the emergence of antimicrobial resistance (Power, 2006). The incentives influencing R&D for new antibiotics are addressed later in this chapter.

Alternative Push and Pull Mechanisms to Deliver Pharmaceutical Innovation

In response to the shortcomings of the privately funded R&D system highlighted in the previous subsection, new solutions have been proposed to create incentives for pharmaceutical innovation for specific diseases at affordable prices. Delinking R&D investment from costs and sales is typically the rationale for such strategies (Bigdeli et al., 2014), which have been broadly divided into "push," "pull," and mixed approaches (**TABLE 16-2**). "Push strategies" aim at providing an input at the beginning of the R&D process to help jump-start specific R&D activities, such as new facilities, laboratory capacity, or extra funds.

TABLE 16-2 Innovative R&D Models

Approach	Types	Examples
Push solutions	Product development partnerships (PDPs) between multiple public and private actors	■ GAVI Alliance to improve access to vaccines in LMICs ■ GlaxoSmithKline Diseases of the Developing World initiative ■ Medicines for Malaria Venture ■ International AIDS Vaccine Initiative ■ Global Alliance for TB Drug Development
	Public–private partnerships to generate novel scientific concepts through information and data sharing, and common infrastructure	■ Critical Path Institute ■ Innovative Medicines Initiative ■ Structural Genomics Initiative ■ Open Source Drug Discovery initiative
	Tax credits for R&D spending	■ U.S. tax breaks and differential income tax rates for pharmaceutical companies ■ Drugs for Neglected Diseases initiative
	Targeted research grants programs	

Pull solutions	Prize funds for innovation	■ Currently under study in the United States and by WHO
	Priority review vouchers to fast-track approval process for neglected diseases medicines	■ Priority voucher accorded to Novartis for Coartem antimalarial medicine ■ Priority voucher accorded to Jansen for Sirturo TB medicine ■ Priority review voucher agreed in 2014 in the United States for future Ebola medicines
	Advance market commitments	■ Gates Foundation, World Bank, UNICEF, and U.K. Department for International Development advance market commitment for vaccines ■ GAVI's Pneumococcal advance market Commitment
Mixed (regulatory) solutions	Regulatory measures discriminating positively towards neglected diseases medicines	■ Orphan drugs legislation in the United States and the European Union ■ Mandatory insurance coverage for specialty medicines in Thailand
	Patent pools	■ UNITAID's innovative financing mechanisms to stimulate the market for HIV tests ■ Medicines Patent Pool
	Market-shaping interventions to reduce transaction costs, increase market information, and balance supplier and buyer risk	■ DfID-UNITAID and CHAI's efforts to forecast increased demand for second-line antiretroviral (ARV) medications to reduce their price in 25 countries ■ Global Fund, President's Malaria Initiative, and UNITAID's decisions to make available planned public purchases of artemisinin-based combination therapy drugs to reduce their price volatility
	Strengthening LMICs' capacity to exploit TRIPS flexibilities	■ Incentives for local manufacturing of pharmaceuticals

Conversely, "pull strategies" aim at providing a "reward" at the end of the R&D process to entice participation, be it prize money, or privileged approval conditions for other medicines in a company's portfolio. Mixed approaches can create both inputs and rewards to R&D activity, typically through regulatory interventions.

Product development partnerships (PDPs) are not-for-profit organizational structures enabling entities from the public, private, academic, and philanthropic sectors to aggregate funding and capacity for the development of pharmaceuticals and public goods. Typically, PDPs target neglected diseases whose solutions lack commercial incentives and that disproportionately affect people in LMICs. Each partnership displays different features. In some cases, philanthropic institutions (such as the Bill & Melinda Gates Foundation) or national governments (such as France's support for UNITAID) provide the funds to set up specific laboratory capacity or an institute to mediate between different players, with academics and industry providing the research know-how. In these partnerships, the industry remains responsible for developing and selling the medicines, but commits to an agreed, lower profit margin (as in the case for the new malaria vaccine "RTS,S"—a partnership between GlaxoSmithKline and the Medicines for Malaria Venture).

In most cases, IPR on discoveries made through PDPs are owned by the private pharmaceutical partners that, in exchange for these rights, commit to

cap their profits to ensure wider access to the medicine. Despite some early success, such as Medicines for Malaria Venture's partnership with Novartis to develop a pediatric formulation of an anti-malarial agent, PATH's Meningitis Vaccine Project launch of a meningococcal vaccine for less than $0.50 per dose, and some fixed-dose combinations of malaria medications, no major breakthrough medicines have emerged so far from PDPs, partly because these experiences are quite recent (the oldest dating 15 years back) and the development of new medicines and vaccines is expected to take longer than this. IFPMA (2017) reports that in 2014 there were 17 active PDPs in the pharmaceutical sector.

Since 2012, the government of Brazil has engaged in PDPs with international pharmaceutical manufacturers. In those arrangements, production and technology of patented medicines are transferred to public laboratories for open local production, in exchange for the right to exclusive supply these medicines to the Brazilian national health service at negotiated prices for an agreed time-span—usually 5 years (Viana et al., 2016).

Precompetitive *public–private partnerships* aim to generate novel scientific concepts (e.g., research models) and infrastructures (e.g., databases) by fostering collaboration between multiple public and private entities based on mutual trust, pooling of complementary expertise and knowledge, and sharing of rewards. To avoid potential disputes, activities are limited to the precompetitive space; that is, they stop before the actual development of pharmaceutical products begins (Vrueh & Crommelin, 2017). Examples of such partnerships are the Critical Path Institute, whose mission is to foster the development of new evaluation tools and standards for drug therapy trials to accelerate regulatory qualification and medical product approval and adoption, and the Innovative Medicines Initiative, which aims to speed up the development of, and patient access to, innovative medicines, particularly for neglected diseases.

Advance market commitments (AMCs) are legally binding contracts between donors and R&D companies to subsidize the future purchase of a pharmaceutical (specifically, a vaccine) that is not yet available, if an appropriate vaccine is developed and if it is demanded by LMICs. The product profile and the price are agreed upon prior to the R&D being undertaken. Originally designed in 2005, AMCs have been specifically used to spur the development of vaccines for neglected tropical diseases. In 2010, the launch of an inexpensive vaccine for pneumococcal disease in more than 40 LMICs was made possible by an AMC organized by the GAVI Alliance (Scudellari, 2011).

Patent pools are mechanisms through which patent holders voluntarily exchange the property rights of their inventions for payment of royalties by manufacturers (Bermudez & 't Hoen, 2010). The Medicine Patent Pool is currently the only pool backed by the United Nations; it is supported by specific (innovative financing) taxes channeled through UNITAID. To date, the pool has signed agreements with nine private-sector patent holders for a total of 16 pharmaceutical products: 12 ARV medicines, 2 hepatitis C treatments, 1 TB treatment, and 1 HIV technology platform. Seventeen manufacturers have received sublicenses from the medicine patent pool to produce generic versions of those compounds (De Luca & Calzavara, 2016). Unfortunately, despite the existence of TRIPS flexibilities and exceptions to current patent laws, many LMICs lack the technical regulatory capacity or manufacturing muscle to take advantage of such provisions.

Policies aimed at strengthening local capacity to take full advantage of the current R&D system have been identified as a possible measure to increase access to pharmaceuticals worldwide (WHO, 2016). While the vast majority of pharmaceutical R&D activities are conducted in high-income countries, there is evidence that local production of medicines offers advantages for national supply systems (Mackintosh, Banda, Wamae, & Tibandebage, 2016). For example, having sizable national pharmaceutical industries allowed the governments of Brazil and Thailand to effectively negotiate down the price of patented ARV medications by credibly threatening the use of compulsory licenses (Flynn, 2008). Recent work from WHO (2016) suggests that strengthening the development of national intellectual property systems and local production capacity in LMICs could improve access to medicines worldwide.

Availability: Country-Level Distribution Systems and Pharmaceutical Management

Access to pharmaceuticals depends on strong pharmaceutical supply systems to ensure the consistent availability of affordable and high-quality diagnostic and treatment commodities at the places where the target population seeks care. Furthermore, the supply chain is responsible for transferring information on supply and demand back to the central level where planners—along with policy and decision makers—handle financial flows, so that the system is adequately resourced and replenished.

Pharmaceutical Supply Chain Systems: Introduction and Scope

In recent years a series of global initiatives has greatly increased the resources flowing into LMICs for the procurement of medicines. The value of donor-financed health commodities now exceeds $10 billion, and it continues to rise. While these resources are greatly welcomed as a means to improve the availability of essential commodities, they also have the potential to place considerable pressure on the already weak supply chain management systems in LMICs.

The pharmaceutical management framework (**FIGURE 16-4**) provides the foundation for improving access to medicines. It illustrates four basic pharmaceutical management functions: selection, procurement, distribution, and use. These are all inter-related, with each major function building on the previous one and leading logically to the next. A breakdown in one part of the framework leads to failure of the whole pharmaceutical management process and compromises access (Management Sciences for Health, 2012).

- *Selection* involves reviewing the prevalent health problems, identifying treatments of choice, choosing individual medicines and dosage forms, and deciding which medicines will be available at each level of health care.
- *Procurement* includes quantifying medicine requirements, selecting procurement methods, managing tenders, establishing contract terms, assuring pharmaceutical quality, and ensuring adherence to contract terms.
- *Distribution* includes clearing customs, stock control, stores management, and delivery to medicines depots and health facilities.

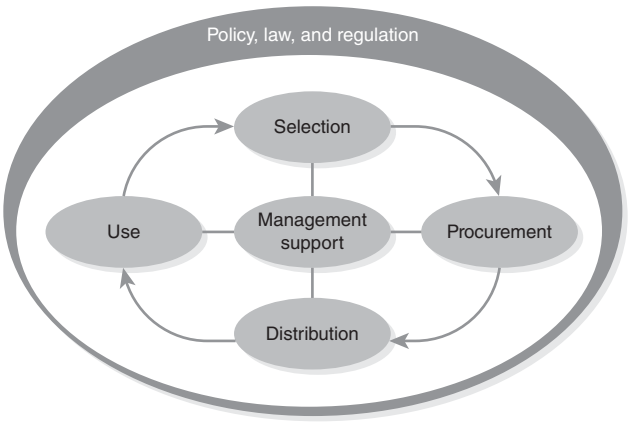

FIGURE 16-4 The pharmaceutical management framework.

Courtesy of Management Sciences for Health. (2012). *MDS-3: Managing access to medicines and technologies.* Arlington, VA: Management Sciences for Heatlh.

- *Use* includes diagnosing, prescribing, dispensing, and proper consumption by the patient.

At the center of the pharmaceutical management framework is a core of *management support* systems: organization, financing and sustainability, information management, and human resources management. Finally, the entire framework relies on *policy, law, and regulation*, which, when supported by good governance, establish and support the public commitment to quality essential medicine supply. This section focuses on the supply chain components of the framework: selection, procurement, and distribution. Medicine use is covered in a later section.

Selection

Essential medicines are those that satisfy the priority healthcare needs of the majority of the population. They are intended to be available within the context of functioning health systems at all times in adequate amounts, in the appropriate dosage forms, with assured quality and adequate information, and at a price the individual and the community can afford. Medicines should be selected according to the following criteria:

- Relevance to the pattern of diseases
- Proven efficacy and safety
- Evidence of performance in a variety of settings
- Quality
- Cost-effectiveness
- Pharmacokinetics
- Acceptability

In 1977, WHO defined the first *Model List of Essential Drugs*, a limited list of medicines whose use, it was hoped, would result in lower costs, better supply, and more rational use. The list has since been updated every two years, and many countries have used it as the basis for developing their own National Essential Medicines List. The 20th list was published in June 2017 (WHO, 2017g). In 2007, a separate *Model List of Essential Medicines for Children* was introduced. The sixth edition appeared in March 2017 and was amended in August 2017 (WHO, 2017f).

Procurement

Effective procurement ensures the availability of the right medicines of appropriate quality in the right quantities, at reasonable prices with timely delivery to avoid stock-outs. Effective procurement is a collaborative process between the procurement department of the national ministry of health and technical committees or

disease control programs (e.g., HIV/AIDS or malaria). These committees often make the final decision on which medicines to buy and in what quantities. In most cases in the public sector, a form of group purchasing is used in which a central procurement department, such as a central medical store, negotiates contracts for its members. The procurement process involves the following steps:

1. Review the medicine selections.
2. Determine the quantities needed, using the most appropriate method for forecasting based on the quality of data available (consumption and/or morbidity).
3. Reconcile needs and funds.
4. Develop supply schedules.
5. Choose the procurement method.
6. Locate and select suppliers.
7. Specify the contract terms.
8. Monitor the order status.
9. Receive and check the medicine.
10. Make payment.

Four main methods of procurement are used: open tender, restricted tender with performance monitoring, negotiated procurement, and direct procurement. Some countries and donors may opt for some form of direct procurement from nonprofit suppliers such as UNICEF or the International Dispensary Association Foundation. The Global Fund and most major donors require that tenders for the procurement of HIV/AIDS, malaria, and TB commodities be restricted to WHO-prequalified products wherever possible, to facilitate access to medicines that meet high standards of quality, safety, and efficacy (International Dispensary Association, 2017; United Nations International Children's Emergency Fund, 2017).

Challenges can arise at any point in the procurement process. For example, they may be the result of factors arising at the level of regulation, lack of financial and human resources, or broader management and organizational shortcomings such as fragmentation and corruption (**EXHIBIT 16-1**).

A number of tools are available to facilitate pharmaceutical procurement. The Global Fund secretariat developed the *Price and Quality Reporting System*, a publicly accessible online database, as a means to gather information about product prices, product quality, and supplier performance. This system represents a source of information that purchasers can use during negotiation of price and delivery conditions (Global Fund, 2017a). Management Sciences for Health has published an *International Drug Price Indicator Guide* since 1986 and updates it annually; it reports procurement prices from multiple international sources (Management Sciences for Health, 2017). In 2001, the Global Drug Facility was established by the Stop TB Partnership to enable health ministries in LMICs to procure quality medicines at competitive prices (Stop TB Partnership, 2017). Similarly, wambo.org is an online platform developed by the Global Fund to provide accessible price information, increased transparency, and improved reliability in the supply of medicines, health products, and nonhealth commodities necessary for HIV/AIDS, TB, and malaria programs. This platform is available to Global Fund recipients that use Global Fund grant funds to procure medicines through the Pooled Procurement Mechanism.

EXHIBIT 16-1 Common Procurement Challenges

- Absence of a comprehensive procurement policy
- Inadequate rules, regulations, and structures
- Public-sector staff with little experience of working with the private sector
- Government or donor funding that is insufficient or disbursed at irregular intervals
- Donor agencies with conflicting procurement regulations
- Fragmented medicine procurement at the provincial or district level
- Lack of unbiased market information
- Currency fluctuations
- Limited number of prequalified suppliers
- Long procurement lead times
- Insufficient product specifications
- Insufficient capacity and data for forecasting
- Poor procurement and supply planning
- Corruption and lack of transparency

Competitive tenders are recommended for most public-sector procurement. A formal tender process includes medicine selection, quantification, preparation of tender documents and contracts, notification and invitation to bid, receipt of bids, formal opening and collation of bids and supplier selection, award of contracts, performance monitoring of suppliers and clients, and enforcement of contract terms when necessary. Supplier selection should be based on formal written criteria.

Quantification and Forecasting

Quantification is the process used to estimate how much of a product is required for the purposes of procurement. It involves estimating the quantities needed of a specific item, the funding required for purchasing the item, and when the products should be delivered to ensure an uninterrupted supply for the program. The quantification process has two parts:

- *Forecasting:* Estimating the quantities of product required to meet customer demand that will actually be used during a particular time frame.
- *Supply planning:* Detailing the quantities required to fill the supply pipeline, costs, orders, and arrival dates of shipments.

Three main methods are used for forecasting medicine requirements. The *consumption method* uses historical data on medicine consumption. If these data are available from a reliable system of reporting, this technique provides the most accurate prediction of future needs. New programs or new treatments, however, will not have historical data on consumption available. Thus, in such cases, purchasers must rely on the *morbidity method*, which estimates future demand based on estimates of disease burden using data on incidence, cases (from attendance at health facilities) or episodes, and standard treatment guidelines. If there are no data on consumption or morbidity, it may be possible to use *proxy consumption*—that is, extrapolation of data from proxy facilities, regions, or countries—as a means of estimating need. **TABLE 16-3** summarizes the three main methods for quantification and forecasting. A fourth method, service-level projection of budget requirements, can be used for estimating budget needs.

Supply planning works alongside forecasting to ensure an optimal procurement and delivery schedule. Once the total requirements have been determined and the product specifications have been agreed, the estimated requirements should be translated into actual orders, including the timing of the orders, by taking the existing pipeline and seasonality into account (Management Sciences for Health, 2012).

Distribution

Effective and efficient distribution of medicines relies on good management and system design.

TABLE 16-3 Comparison of the Various Quantification Methods

Method	Uses	Essential Data	Limitations
Consumption	First choice for procurement quantifications given reliable data. Most reliable predictor of future consumption.	Reliable inventory records. Records of supplier lead time. Projected pharmaceutical costs.	Must have accurate consumption data. Can perpetuate irrational use.
Morbidity	Estimating need in new and scaling-up programs or disaster assistance. Comparing use with theoretical needs. Developing and justifying budgets.	Population and patient attendances. Actual or projected incidence of health problems. Standard treatments (ideal, actual). Records of supplier lead time. Projected pharmaceutical costs.	Morbidity data are not available for all diseases. Standard treatments may not really be used. Accurate attendance is difficult to predict.
Proxy consumption	Procurement quantification when other methods are unreliable. Comparing use with other supply systems.	Comparison area or system with good per-capita data on consumption, patient attendance, service level, and morbidity. Number of local health facilities by category. Estimates of local user population by age.	Questionable comparability of patient populations, morbidity, and treatment practices.
Service-level projection of budget requirements	Estimating budget needs.	Use by service levels and facility type. Average medicine cost per attendance.	Variable facility use, attendance, treatment patterns, and supply system efficiency.

Reproduced from Management Sciences for Health. (2012). *MDS-3: Managing access to medicines and technologies.* Arlington, VA: Management Sciences for Heatlh. http://apps.who.int/medicinedocs/documents/s19577en/s19577en.pdf

An efficient distribution system should have the following characteristics:

- Maintain an uninterrupted supply of medicines.
- Provide appropriate storage.
- Keep medicines in good condition throughout the distribution process.
- Minimize losses due to damage and expiry.
- Maintain accurate inventory management records.
- Use available transportation efficiently.
- Reduce pilferage.
- Provide accurate information for quantification.

A distribution system consists of four main elements (Management Sciences for Health, 2012):

- *System design:* Geographic or population coverage, number of levels in the system, push versus pull system, degree of decentralization.
- *Information system:* Inventory control, records, consumption reports, information flow.
- *Storage:* Selection of storage sites, building design, handling systems, order picking.
- *Delivery:* Collection versus delivery, choice of transport, vehicle procurement and maintenance, delivery schedules and routes.

As with procurement, distribution systems face a number of challenges that can arise at any point in the process (**EXHIBIT 16-2**). Some are a consequence of the system itself; for example, supply systems may be vertically multilayered and highly fragmented. The information management systems, which are needed to monitor stocks and enable proper planning and forecasting, may be poor or absent. There may also be a lack of adequate resources to provide the infrastructure and facilities necessary for effective distribution. For example, there may be insufficient funding to develop appropriate storage, distribution, and inventory management systems; and there may be a scarcity of warehousing and transport infrastructure, leading to limited geographic reach of the distribution network.

Management and organizational challenges at the local level include poor planning, poor security, and "leakage" of products. Limited provision of cold-chain facilities may lead to inadequate supplies of heat-sensitive medicines such as vaccines and sera. Problems with distribution chains may lead to medicines having a short shelf life when they finally reach their destination, to their reaching their expiry dates and having to be destroyed, and to stock-outs.

Stock-outs have serious implications for the implementation of programs, as they undermine the ability of health workers to follow treatment protocols. When a first-line medicine is not available, patients are either sent away to buy the medicine in the private sector, which leads to a progressive lack of confidence in the public health system, or treatment is adapted based on the availability of other medicines with a similar effect. Stock-outs can be prevented through efficient procurement and financial planning, accurate forecasting, and good inventory management.

Several initiatives have been undertaken to help prevent stock-outs in health facilities. The Stop Stock-outs Project is a consortium of civil society organizations in South Africa that monitors availability of essential medicines and vaccines in public health facilities. Its annual *National Stop Stockouts Surveys* are used to raise public awareness of the consequences of medicine stock-outs, and to provide information about medicine availability to the member countries' ministries of health to aid in their planning (Stop Stockouts Campaign, 2015). A number of countries use mobile phones and broadband access to track commodities and improve access to medical resources and health care to the rural poor (Zurovac, Talisuna, & Snow, 2012).

Storage and distribution costs represent a significant component of the health budget, and adequate resources must be allocated to these functions to ensure that the medicines get to their point of use. In fact, transport costs can be more than the value of the medicines themselves, especially when pharmaceuticals must be moved to remote, sparsely populated areas. At least five alternative ways have traditionally existed for supplying medicines and medical supplies to governmental and nongovernmental health services:

- *Central medical stores (CMS):* In the traditional public-sector pharmaceutical supply system, medicines are procured and distributed by a

EXHIBIT 16-2 Commonly Encountered Distribution Challenges

- Vertical and fragmented supply systems
- Insufficient funding for storage, distribution, and inventory management systems
- Poor planning
- Poor security and leakage
- Short shelf life of medicine
- Limited geographic reach
- Insufficient warehousing and transport
- Poor information management systems to monitor stocks for planning and forecasting
- Stock-outs and expiry
- Poor cold chain
- Vertical and parallel distribution chains

centralized government unit. The state is the owner and funder (using national or donor resources) for the entire supply system. This approach has been employed in a number of countries in Africa, Asia, Europe, and Latin America. In Ghana, the CMS distributes products to 10 regional medical stores, which in turn distribute those supplies to roughly 2,200 service delivery points. In Zambia, the CMS distributes products to 72 district medical stores, which then distribute the supplies to roughly 1,500 service delivery points.

- *Autonomous supply agency:* In this alternative to the CMS system, distribution is managed by an autonomous or semi-autonomous pharmaceutical supply agency. This strategy has been used in Tanzania and Benin.
- *Direct delivery system:* In this decentralized, non-CMS approach, medicines are delivered directly by suppliers to districts and major facilities. The government pharmaceutical procurement office selects the supplier and establishes the price for each item, but the government does not store and distribute medicines. This approach has been used in the Caribbean.
- *Primary distributor (or prime vendor) system:* In this non-CMS system, the government pharmaceutical procurement office establishes a contract with one or more primary distributors, as well as separate contracts with pharmaceutical suppliers. The contracted primary distributor receives medicines from the suppliers and stores, and distributes them to districts and major facilities. Thus, private channels are used to supply publicly funded medicines to government-operated health facilities. This strategy is used in the United States.
- *Primarily or fully private supply:* In some countries, medicines for public-sector patients are provided by private pharmacies in or near government health facilities. With this approach, measures are required to ensure financial support that facilitates access for poor and other vulnerable populations—for example, through insurance reimbursement. Private-sector supply is used in Canada and Australia.

These systems vary considerably with respect to the roles of government and the private sector and in terms of incentives for efficiency. Mixed systems in which different categories of pharmaceuticals are supplied through different mechanisms are increasingly needed to respond to expanding demands for products and services (Management Sciences for Health, 2012). The systems used are not static, but rather evolve over time; they are also subject to revision by governments in response to changing political and economic priorities (**EXHIBIT 16-3**).

EXHIBIT 16-3 A Semi-Autonomous Medical Supplies System in Sudan

In Sudan, a Central Medical Stores unit had originally been established in 1935 as a department of the Sudan Medical Services. In 1954, it became a department within the Ministry of Health and was renamed Central Medical Supplies. In 1991, its status was again changed to enable this system to exercise maximum autonomy within the framework of the government of Sudan. A Central Medical Supplies Public Corporation (CMS) was established as a semi-autonomous body to facilitate the selection, procurement, storage, and distribution of medical supplies for the public sector. Central Medical Stores then became the national center for procurement, storage, and distribution of medicines.

Prior to 1991, all medicines and medical supplies procured and warehoused by CMS were given free of charge to all public health facilities in Sudan. However, since 1992 and since it has become a semi-autonomous organization, CMS has operated on a cost-recovery basis. This change was introduced to bring it into line with the cost-recovery policy implemented by the government at all health facilities in the Sudanese public health sector.

Unfortunately, this policy resulted in reduced access to medicines for those patients who could not afford to pay. In 1996, the government announced a project to offer free treatment at hospital emergency units. This policy applied only to those needing emergency treatment in a hospital casualty department. All patients were entitled to free services, including medicines during the first 24 hours of admission. CMS receives a special budget from the Ministry of Finance and National Economy to cover the costs of this care. Medicines are distributed monthly, once the relevant sum has been deposited in the CMS account. The budget allocated for this amounted to SDG 60 million (approximately $20 million) in 2015, accounting for more than 35% of CMS sales.

CMS now provides 73% of its sales to the public sector, 26% to private pharmacies, and 1% to others. In Sudan, there is now also public procurement of medicines through the Revolving Drug Fund, through health insurance, and through police and military medical facilities. In addition to the increased access to these services fostered by the CMS, a number of initiatives are designed to increase demand for HIV, TB, and malaria services.

Alfadl et al., 2016.

EXHIBIT 16-4 The Private-Sector Distribution Chain for Antimalarial Medicines

In many LMICs, the retail sector plays an important role in the treatment of malaria. Retailers are perceived as being more accessible and responsive than other providers, and it is often claimed that they are better able to respond to public-sector failures. A wide range of retail outlets exist, including pharmacies, drug shops, general stores, market stalls, and itinerant hawkers, and the availability of antimalarial medicines is generally high. Yet important concerns have arisen regarding the performance of retailers in providing high-quality and affordable malaria treatment. Highly effective, but more expensive medicines are rarely available, especially in more remote and less formal outlets, and antimalarial medicines are often substandard or even fake.

A number of studies have explored the retail-sector distribution chain for antimalarial medicines, with a view toward understanding how retailers decide which medicines to stock and what prices to charge. Notably, variation in the number of levels within the chain has been found across countries. Within countries, there are generally more levels in the distribution chains serving more remote outlets and in those employing less qualified staff. As would be expected, fewer suppliers operate at the top of the chain than at the bottom, and some operate at more than one level, creating considerable overlap across chain levels. Different types of wholesalers usually supply different types of retail outlets. In Tanzania and Kenya, wholesalers that supply medicines alongside other commodities serve general shops, whereas wholesalers that specialize in handling medicines serve pharmacies and drug shops. Overall, wholesale markets tend to be relatively concentrated, especially at the top of the chain, where a relatively small number of importers account for most of the antimalarial volumes sold.

Wholesale price markups play a key role in determining affordability at the retail level. Markups vary significantly across chain levels, ranging from 2% to 67% at the level supplying retailers directly, and from 8% to 99% at those supplying higher levels. Retail markups tend to be higher, ranging from 3% to 566% in pharmacies, 29% to 669% in drug shops, and 100% to 233% in general shops.

Data from Patouillard, Hanson, & Goodman, 2010.

Private-Sector Supply of Pharmaceuticals

The for-profit private sector includes manufacturers at the international and local levels, importers and wholesalers, distributors, and private prescribers, pharmacies, retail outlets, and itinerant medicine vendors. It can play four roles in support of one or more channels within the health system (Ballou-Aares et al., 2008):

- Selling medicines, supplies, and equipment (e.g., manufacturers, wholesalers).
- Selling supply chain services, such as procurement, transportation, warehousing, and information and financial services to one or more channels. Services may include supply chain design, needs quantification, or logistics management and information system design.
- Providing a distribution channel (e.g., via a pharmacy, private health clinic, or franchise network).
- Assisting in implementation of supply-chain best practices, such as scheduled delivery networks, integrated supply chains, pay-for-performance systems, or cash-to-cash cycle time management approaches (e.g., consultants, trainers, educators, change agents).

Private pharmaceutical outlets are often more numerous than their government counterparts, and play an important role in the provision of health services in many countries, particularly in rural and underserved communities (Abuya et al., 2007). Many countries also have thriving illegal markets that offer pharmaceuticals at retail and sometimes wholesale levels. Understanding the systems that supply medicines to these providers is critical for designing effective interventions to improve quality and affordability in this sector (**EXHIBIT 16-4**).

Several strategies have been developed to engage the private sector, particularly retail shop owners, in an attempt to increase access to essential medicines. These efforts include training (Marsh et al., 2004; Patouillard, Hanson, & Goodman, 2010) franchising (Chiguzo, Mugo, Wacira, Mwenda, & Njuguna, 2008), and accreditation (Management Sciences for Health, 2010), all of which have had some success. **EXHIBIT 16-5** describes how Tanzania has used accredited drug dispensing outlets to increase access to artemisinin-based combination therapies for malaria.

Mixed Systems and Interconnectedness Between the Public and Private Sectors

Most countries have mixed public and private financing and delivery of care, such that the public sector may supply public health facilities, while the private sector supplies the public sector, private hospitals, clinics, and retail outlets. In many instances, there is a great deal of interaction between the two sectors, with both being

EXHIBIT 16-5 Increasing Access to Malaria Treatment in Tanzania Through Accredited Drug Dispensing Outlets

When Tanzania shifted its recommended first-line treatment to an artemisinin-based combination therapy (ACT), the National Malaria Control Program (NMCP) recognized that a public sector–focused program alone would not benefit the majority of Tanzanians who treat malaria at home. Nevertheless, providing malaria therapy through the private sector in this country has its challenges: Registered pharmacies are scarce and charge unaffordably high prices for ACT, while retail medicine sellers are untrained and largely unregulated.

With funding from Management Sciences for Health's Rational Pharmaceutical Management Plus Program, the Tanzania Food and Drug Authority and NMCP designed a plan to make subsidized ACTs available through accredited drug dispensing outlets (ADDOs) in the Morogoro and Ruvuma regions. The ADDO program is an innovative public–private initiative that uses accreditation, inspection, incentives, and training to increase access to essential medicines. Its design included allowing prescription ACTs to be sold in ADDOs, training ADDO dispensers on the new treatment, and collaborating with stakeholders to determine the price at which ADDOs would sell subsidized ACTs.

The pilot program covered approximately 2.9 million people, or approximately 8.4% of the population of Tanzania. In the Morogoro and Ruvuma regions, 1,363 ADDO dispensers from 650 ADDOs have been accredited and trained and are now identifying and treating uncomplicated malaria with ACTs. In comparison, only 600 pharmacists exist in the public and private sectors in the entire country.

One year after the pilot program was initiated, a review of records from 448 ADDOs indicated that the percentage of ADDOs that dispensed at least one course of ACT rose from 26.2% during July–September 2007 to 72.6% during April–June 2008, and that ADDOs dispensed more than 300,000 treatments over the same period. For the five districts in Ruvuma that reported data for July–September 2008, this percentage increased to 81.5%. These results illustrate the enormous potential of ADDOs to improve community access to recommended malaria medicines through the private sector.

Data from Rutta, 2013; Management Sciences for Health, 2010.

involved in procurement, importation, financing, service delivery networks, and market and product information. In many countries, illicit flows may also occur within and between the sectors due to leakage from public sector facilities, diversions from the port, and donations by nongovernmental organizations (NGOs).

FIGURE 16-5 illustrates the potential flow of medicines in the public and private sectors, highlighting interactions among the various sectors and stakeholders. Understanding these systems, and the connections between the public and private sectors, is critical to intervening to improve access and quality.

The Effect of Global Health Initiatives on the Pharmaceutical Distribution Chain

Since 2000, the emergence of several major disease-specific global health initiatives (GHIs) has contributed to an unprecedented increase in the resources available for programs targeting some diseases. Establishment of GHIs has led to large increases in the supply of and demand for medicines, vaccines, insecticide-treated bed nets, and diagnostic and laboratory materials, and has been associated with improvements in the quality, availability, and affordability of many of these commodities, particularly in relation to vaccines and antiretroviral medicines for HIV/AIDS (Chauveau, Meiners, Luchini, & Moatti, 2008; Hagmann, 2001; Samb et al., 2009; Sharma, 2003).

In some instances, national governments and GHIs have worked together to strengthen national procurement and distribution networks (Stillman & Bennett, 2005). Nevertheless, although alignment with country procurement systems is included as one of the indicators of aid effectiveness in both the 2005 *Paris Declaration on Aid Effectiveness* and the 2008 *Accra Agenda for Action*, such synergy has not always been realized (Sjöstedt, 2013). In other instances, GHIs have duplicated or displaced country supply chains, thereby creating parallel systems (Laing & McGoldrick, 2000).

Last Mile Distribution

Every supply chain has a literal last mile, the crucial final leg to reach the customer. In public health there is also the figurative "last mile," referring to reaching the most isolated segments of the population. Most of those persons who lack access to medicines and vaccines are either the most remote, living far from paved roads and affordable transport, or the most economically impoverished.

Several initiatives have been developed to address this last mile. Project Last Mile (PLM) is a public–private partnership that transfers Coca-Cola's supply-chain management and marketing expertise to

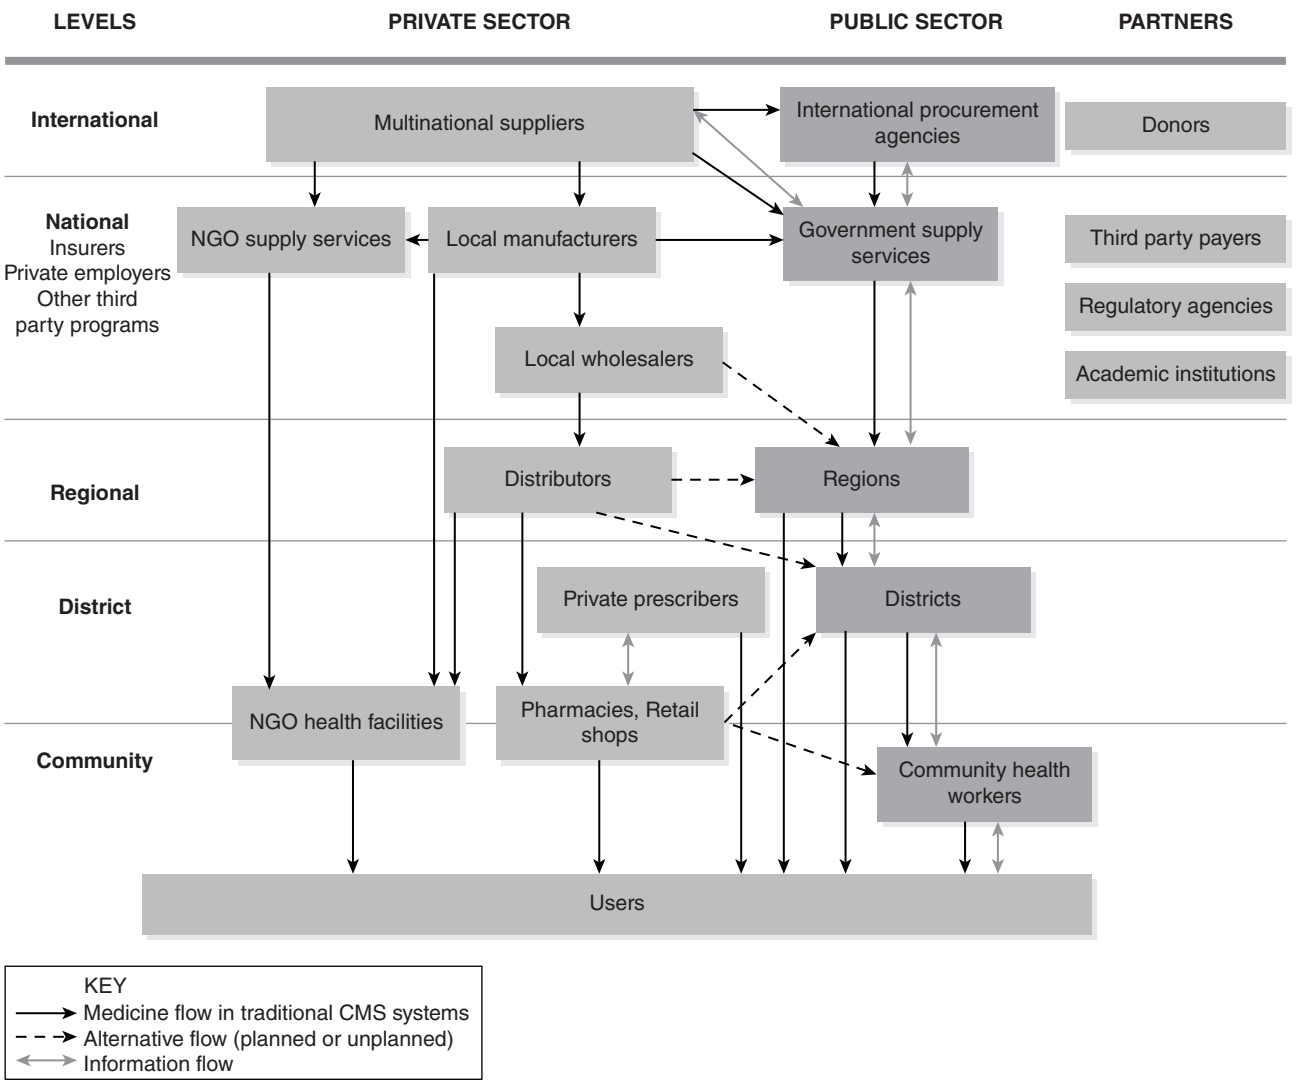

FIGURE 16-5 Flow of medicines in the public and private sectors.

Modified from Management Sciences for Health. (2012). *MDS-3: Managing access to medicines and technologies*. Arlington, VA: Management Sciences for Health.

help governments and health systems in seven countries deliver life-saving medicines and supplies to hard-to-reach communities across Africa. The initiative began in 2010 with a mission to transform the delivery of medical supplies in Tanzania, and expanded in 2014 with more than $21 million in additional investment and an ambition to help support 10 African countries by 2020. PLM teams have since worked with Ministries of Health in Ghana, Mozambique, Nigeria, and South Africa to improve the availability of essential medicines (Village Reach, 2012).

Affordability

Affordability is a key factor affecting access to pharmaceuticals. It relates the price that a patient must pay for a product to the amount that the person is able to pay. While medicines are sometimes provided for free at public health facilities, patients frequently seek care outside the public sector—for example, in private drug shops, clinics, or pharmacies. Even where medicines are officially free in the public sector, stock-outs and informal charges may mean that patients still incur payments to obtain them. Medicines are sometimes included in insurance benefit packages, but they may nonetheless require a copayment. Thus, in many cases, patients are required to make out-of-pocket payments to purchase medicines when they are ill.

Affordability of medicines is commonly measured in three ways (Niëns et al., 2012; WHO & Health Action International [HAI], 2008):

- The "catastrophic payment" method is based on the ratio of medicine expenditure to total household resources.
- The impoverishment method examines a household's residual income after paying for a good.

TABLE 16-4 Affordability of One Salbutamol Inhaler (100 mcg/dose) Purchased from the Private Sector in Selected Countries, 2013

Country (Date of Survey)	Originator Brand	Lowest-Priced Generic Brand
Burundi (August 2013)	4.2 days	1.4 days
Egypt (September 2013)	0.3 day	0.3 day
Sudan (February 2013)	2.5 days	1.4 days
Tajikistan (June 2013)	3.3 days	3.1 days

Data from Health Action International, 2017.

- The WHO/HAI method expresses affordability as the number of days' wages (e.g., of the lowest-paid, unskilled government worker in a given setting) required to purchase a treatment course.

To illustrate, the affordability of salbutamol inhaler, a medicine commonly used to treat asthma, purchased in the private sector is outlined in **TABLE 16-4**. As this example demonstrates, the significant variation in affordability for the same treatment is pronounced not only across countries, but also within countries between originator and generic brands (HAI, 2017).

This section examines some of the factors that have impacted the affordability of pharmaceuticals in LMICs, and explores the strategies that have been devised both to reduce the prices of pharmaceuticals and to increase financing for them.

Pharmaceutical Prices and Affordability

In LMICs, governments fund less than 35% of total pharmaceutical spending, compared with more than 60% of such spending in high-income countries (Lu et al., 2011). While the affordability of pharmaceuticals is a key issue in all countries, it is of particular importance in LMICs, where less-developed health systems and lower wages generally result in a greater share of personal income being spent on health, thereby exposing households to the risk of catastrophic health expenditures (Lu et al., 2011). This situation is compounded by the chronically low public-sector availability of pharmaceuticals, which forces many patients in these countries to purchase a high proportion of their pharmaceuticals from the private sector, often at greater cost (Cameron, Ewen, Auton, & Abegunde, 2011).

Price is the most immediate factor that affects the affordability of pharmaceuticals. In the public sector, the efficiency of the procurement process is an important determinant of both the affordability and the availability of public-sector pharmaceuticals. A 2009 study that examined the government procurement prices of 15 commonly purchased medicines in 36 countries revealed that, although the median government procurement prices for those medicines were only 1.11 times the international reference prices from open international procurements for generic products (indicating a relatively good level of procurement efficiency, on average), the range of procurement prices varied widely, from 0.1 to more than 5 times the international reference prices, indicating that the procurement process often did not secure the best value (Cameron, Ewen, Ross-Degnan, Ball, & Laing, 2009).

To understand why medicine prices vary or may become unreasonably high, their many components must be elucidated. Beyond the upstream influences operating at the manufacturer level described earlier, the "downstream" elements differ by country, by sector of the health system, and by type of pharmaceutical, but generally include the manufacturer's selling price; insurance, freight, port charges, inspection charges, and duties for imported products; the markups added by importers, wholesalers, and retail distributors; various taxes; and fees associated with dispensing.

Strategies to Improve Affordability by Reducing Pharmaceutical Prices

Several international panels have recommended a range of policies in an attempt to deliver more affordable pharmaceutical prices. Note, however, that the evidence for these recommendations comes largely from high-income settings, as research in this area has until recently been lacking in lower-income countries (Nguyen, Knight, Roughead, Brooks, & Mant, 2015). **EXHIBIT 16-6** synthesizes a number of these recommendations from WHO's Guideline on Country Pharmaceutical Pricing Policies and *The Lancet*'s Commission on Essential Medicines Policies (WHO, 2015c; Wirtz et al., 2017). Along with these recommendations, the panels agree on a number of key principles for consideration when choosing to act on high pharmaceutical prices. Generally, countries should select several complementary policy options that are appropriate to their particular health system, pharmaceutical market composition, national priorities, available resources, and human rights considerations.

EXHIBIT 16-6 Recommended Policies to Reduce Prices of Essential Medicines in LMICs

Procurement Interventions

- Pooled procurement using limited competitive bidding/tendering
- Pooled procurement or use of monopsony power (e.g., where large public or social health insurers operate), with price negotiation based on volumes procured or on inclusion in a reimbursement list

Pro-Generic Policies

- Use of international nonproprietary names when prescribing, rather than brand names
- Mandatory generic substitution or enablement of generic substitution by pharmacists and other dispensers
- Measures to enable early and prompt entry of generics

Pricing Interventions

- Reduction or removal of duties, tariffs, import taxes, or sales taxes, particularly for essential medicines
- Internal/within-country reference pricing by chemical entity, pharmacologic class, or indication
- External reference pricing for procurement and price benchmarking
- Regulation of wholesaler and retailer markups, with preference for regressive markups (i.e., lower markup for higher-priced products), rather than fixed-percentage markups
- Regulation of professional fees
- Regulation of annual factory-gate price increases
- Patent-related interventions such as encouragement of voluntary licensing and patent pools

Trade-Related Aspects of Intellectual Property Rights Flexibilities

- For LMICs, postpone the granting or enforcement of medicine patents or other market exclusivity rights that would prevent the registration of a generic product
- Parallel importation
- Compulsory licensing
- Government use licensing
- Application of strict patentability criteria

Modified from WHO, 2015c, Wirtz et al., 2017b.

Two of the price-reduction mechanisms in Exhibit 16-6 have more recently been debated: The reduction of taxes and tariffs and the use of the public health safeguards incorporated into the WTO's Agreement on Trade-Related Intellectual Property Rights (see the *International Trade and Health* chapter for greater detail on TRIPS).

Tariffs and taxation are important tools wielded by governments to ensure economic growth and national development. For medicines, it has been argued that measures such as import duties foster the growth of the local pharmaceutical industry by protecting it from international competition. However, tariffs and taxes levied on medicines are widely regarded as regressive, disproportionately affecting the poor, who are more likely to experience ill health and pay a larger share of their income for treatment than their richer counterparts. Recent studies have concluded that, although tariffs do contribute to the final price the patient pays for medicines in many countries, their overall share of the final price has been falling over time. Domestic taxes such as value-added tax (VAT) or sales tax are now more likely to be a key driver of medicine price, with these tax rates in LMICs ranging from 2.9% to 34% (Creese, 2011). Although government revenues raised by taxing medicines have been shown to be small (Olcay & Laing, 2005), advocates for removing or reducing these taxes have recognized the challenge of lobbying effectively for a loss of government revenue. "Healthy taxation," which sanctions the taxing of risky and unhealthy behavior and products (e.g., cigarettes) rather than targeting health-promoting ones (e.g., essential medicines), has become a potent argument to reform tax regimes to improve medicine affordability (Creese, 2011).

Although the TRIPS flexibilities designed to protect public health have not been widely used, they have been most successfully applied to supply generic antiretroviral medicines in a number of LMICs; less frequently, they have been used to secure access to affordable treatments for cancer, arthritis, and avian flu ('t Hoen, 2016). Even the simple threat of issuing

compulsory licenses by several LMIC governments has proved useful in the past to negotiate lower prices for patented medicines for HIV and cancer (Coriat, 2008; 't Hoen, 2016). Nevertheless, these flexibilities are under continual threat from the inclusion of so-called TRIPS-plus measures in bilateral and regional trade agreements between powerful trading nations and LMICs. These agreements include intellectual property rights obligations that go well beyond the TRIPS minimum standards and supersede them in these jurisdictions (Kerry & Lee, 2007).

External Financing of Pharmaceuticals

Chronic underfunding of their broader healthcare infrastructure has led some countries to rely on external funding to support access to medicines. For example, by 2016, 45% of the $30 billion disbursed by the Global Fund went directly to ministries of health, much of which was spent on pharmaceuticals and strengthening the distribution chain; another 30% of Global Fund disbursements went to civil society organizations, many of which run pharmaceutical-related programs that complement those found in the public sector (Global Fund, 2017b). Other prominent sources of external funding for pharmaceuticals include the GAVI Alliance, which has been co-financing country procurement of vaccines for immunization programs since 2007 (GAVI, 2016), and the Global Drug Facility, which provides financial and technical support to countries to procure TB treatments and other commodities (Arinaminpathy, Cordier-Lassalle, Lunte, & Dye, 2015; Stop TB Partnership & WHO, 2014).

Safe and Effective Use of Medicines

Even when the right medicines are in the right place and are affordable, many challenges remain in ensuring safe and effective therapy. Are the medicines of appropriate quality? Are they being used appropriately? What must be done to ensure their continued safety? These are the questions to which we now turn.

Rational Use of Medicines

The concept of rational medicine use has been adopted by many countries. According to WHO (2010d), the rational use of medicines requires that "patients receive medications appropriate to their clinical needs, in doses that meet their own individual requirements, for an adequate period of time, and at the lowest cost to them and their community." This definition is expressed in medical and financial terms, but patients have their own rationale for taking medicines. Thus, what may be seen as irrational from a medical perspective—for example, interrupting a treatment course of antimalarials when symptoms recede—may be perceived as entirely rational from the consumer's point of view.

Nonrational use of medicines takes many forms and can occur at the prescribing, dispensing, and patient administration stages. Studies in both high-income countries and LMICs have described numerous examples of nonrational medicine use (**EXHIBIT 16-7**).

The nonrational use of medicine carries enormous costs and impacts. In addition to inefficient use of limited resources, such use may lead to adverse clinical consequences and unnecessary suffering in patients. Wasting resources in this way may lead to increased costs later and the need to use more expensive medicines. In addition, nonrational use can lead to increased morbidity and mortality, along with increased risks of adverse drug reactions and the emergence of antibacterial resistance (discussed later in the chapter).

Medicine Use Behavior

The use of medicines has to be viewed in both biomedical and social contexts. A number of actors (principally prescribers, dispensers, and patients) are

EXHIBIT 16-7 Examples of Nonrational Medicine Use

- Polypharmacy (multiple prescriptions or over-prescription)
- Use of medicines that are not related to diagnosis
- Unnecessarily costly medicines
- Inappropriate prescription and use of antibiotics
- Indiscriminate use of injections
- Irrational self-medication with underdosing and overdosing
- Incorrect administration, dosages, timing, formulation, or duration
- The use of medicines when no medicine therapy is indicated
- Failure to prescribe available, safe, and effective medicines
- Poor adherence to tuberculosis treatment
- Underuse of effective medicines for hypertension and depression
- Hospital medicine use problems such as antibiotic misuse for surgical prophylaxis

Wiedenmayer, 2004.

engaged in this process, which involves a number of steps:

1. Diagnosis: Identification of what is wrong.
2. Therapy: Development of a therapeutic objective and plan.
3. Prescribing: Information, instructions, warnings, and prescription writing.
4. Dispensing: Supply, advice, counseling, instructions, and warnings.
5. Adherence by the patient: Understanding of the therapy, patient responsibility, and valuing of treatment.

The factors that determine patterns of individual medicine use are complex. The medicine use system in which they occur is part of a larger healthcare system, which is itself shaped by the social, cultural, economic, and political contexts of the country concerned. Furthermore, both prescriber and patient bring a host of beliefs and motivations to their interaction. For example, the use of medicines may be discouraged as a result of social stigma associated with enrollment in an HIV medicine program, as this signals the patient's HIV/AIDS status (Connelly & Rosen, 2006). Failure to understand the local cultural context is a common cause of inappropriate medicine use (Wiedenmayer, 2004). For example, in some countries, medicines that are red in color are thought to be good for the blood. Injections and suppositories may be more acceptable in some countries than others based on local beliefs. Moreover, there is a widespread belief that antibiotics are effective against viruses, as well as lack of trust in the safety of vaccines (Vaccine Confidence Project, 2015).

Strategies to Improve Medicine Use

Improving the use of medicines by health workers and the general public is crucial to reducing morbidity and mortality from both communicable and noncommunicable diseases, preventing and minimizing drug resistance, and controlling expenditures. Therapeutically sound and cost-effective use of medicines by health professionals and consumers needs to be achieved at all levels of the health system, in both the public and private sectors. A sound rational-use program has three elements that are formulated to reflect the main responsibilities of a national essential medicine program (**EXHIBIT 16-8**).

WHO and the International Network for Rational Use of Drugs (INRUD) have developed extensive resources and literature on the promotion of rational medicine use. INRUD's *Drug Use Bibliography* is an annotated list of published and unpublished articles, books, reports, and other documents related to medicine use, with a special focus on LMICs (INRUD, 2017). A framework linking strategies to improve use and other elements of the process has been developed (**FIGURE 16-6**).

EXHIBIT 16-8 Elements of Rational Medicine Use Programs

- *Rational use of medicine strategy and monitoring:* Advocating rational medicine use, identifying and promoting successful strategies, and securing responsible medicine promotion.
- *Rational use of medicines by health professionals:* Working with countries to develop and update treatment guidelines, national essential medicine lists, and formularies, and supporting training programs on rational use of medicines.
- *Rational use of medicines by consumers:* Supporting creation of effective systems of medicine information, and empowering consumers to take responsible decisions about their treatment.

Reprinted from Essential Medicines and Health Products. (2010). Activities, world health organization, rational use of medicines. http://www.who.int/medicines/areas/rational_use/rud_activities/en/

Effectiveness of Interventions to Improve Medicine Use

In general, medicine use can best be improved through interventions targeted at specific problems with an identifiable audience, or by a system change such as preventing the unnecessary prescribing of expensive branded medicines through use of nationally accepted clinical practice guidelines. The most effective medicine use intervention is one that is participatory, interactive, problem based, and focused. It is usually more efficient and effective to combine a number of strategies into a multifaceted intervention to improve medicine use.

Some strategies have proved more successful than others. A review by Laing et al. (2001) identified 10 key factors that have been shown to make a difference (**EXHIBIT 16-9**).

Quality of Medicines

A prerequisite for the rational use of medicines is that they should be of good quality, both at the time of manufacture and at the time of consumption by the patient. Unfortunately, a wide variety of potential hazards may emerge between the manufacture and end use of these products. Substandard and counterfeit medicines are major problems on a worldwide basis, as are smuggling and the illegal importation of

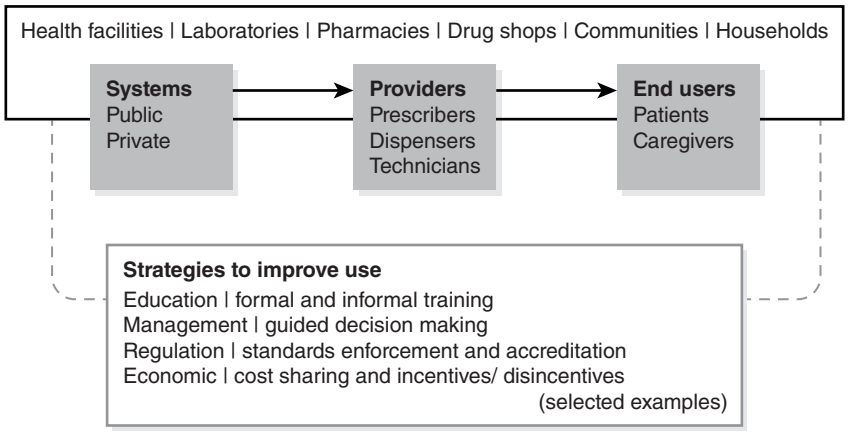

FIGURE 16-6 Framework for improving medicine use.

From Management Sciences for Health. (2012). *MDS-3: Managing access to medicines and technologies.* Arlington, VA: Management Sciences for Health. http://apps.who.int/medicinedocs/documents/s19577en/s19577en.pdf

EXHIBIT 16-9 Recommendations to Improve Use of Medicines in LMICs

1. Establish procedures for developing, disseminating, utilizing, and revising national (or hospital-specific) standard treatment deadlines.
2. Establish procedures for developing and revising an essential medicine list (or hospital formulary) based on treatments of choice.
3. Request hospitals to establish representative Pharmacy and Therapeutics Committees with defined responsibilities for monitoring and promoting quality use of medicines.
4. Implement problem-based training in pharmacotherapy in undergraduate medical and paramedical education based on national standard treatment guidelines.
5. Encourage development of targeted, problem-based, in-service educational programs by professional societies, universities, and the ministry of health, and require regular continuing education for licensure of health professionals.
6. Stimulate an interactive group process among health providers or consumers to review and apply information about appropriate use of medicines.
7. Train pharmacists and medicine sellers to be active members of the healthcare team and to offer useful advice to consumers about health and medicines.
8. Encourage active involvement by consumer organizations in public education about medicines, and devote government resources to support these efforts.
9. Develop a strategic approach to improve prescribing in the private sector through appropriate regulation and long-term collaborations with professional associations.
10. Establish systems to monitor key pharmaceutical indicators routinely so as to track the effects of health-sector reform and regulatory changes.

Data from Laing et al., 2001.

medicines. These activities present major challenges to national authorities, and seriously undermine initiatives aimed at rational medicine use.

Defining Quality of Medicines

Two concepts that need to be distinguished are quality assurance (QA) and quality control (QC). QA is the whole process of assuring quality from manufacturer to end user. By contrast, QC involves testing key characteristics of the final product, including the identity and potency of the active ingredient, the content range (with the acceptable range usually set at 95% to 110%), purity (involving checks to exclude contaminating substances or microorganisms), uniformity (in terms of color, shape, and size), bioavailability (the rate and extent of absorption of a medicine into the body), and stability (adequate shelf life and expiry). Thus, QA in pharmaceutical supply is not the same as QC in manufacturing.

Detailed descriptions of medicine characteristics and of analytical techniques to verify them are laid down in national pharmacopoeias such as the *United States Pharmacopoeia* (USP) and the *British*

Pharmacopoeia (BP). WHO publishes an *International Pharmacopoeia* (Ph.Int.), which from 1975 has focused on WHO's Model List of Essential Medicines (WHO, 2017c). More recently, it has emphasized medicines of major public health importance and those recommended by specific WHO disease programs, such as medicines to treat malaria, TB, and HIV/AIDS, as well as medicines for children. Priority is also given to medicines evaluated by WHO's Medicines Prequalification Program.

Two other concepts that need to be distinguished are substandard and counterfeit medicines. Counterfeit medicines are addressed later in this section. WHO (2010e) defines substandard medicines (also called out-of-specification [OOS] products) as "genuine medicines produced by manufacturers, authorized by the National Medicines Regulatory Authority (NMRA), which do not meet quality specifications set for them by national standards." Normally, medicines produced by manufacturers have to comply with a set of quality specifications, and NMRAs review products against these criteria before they are authorized for marketing. The quality of medicines reaching the patient can be affected by the manufacturing process, packaging, transportation and storage conditions, handling, and other factors.

These influences can be cumulative. Loss of activity due to the instability of the drug itself is unusual; instead, poor initial quality of the medicine is the more serious problem. Substandard medicines include those with a loss of potency due to poor bioavailability, expiry, or poor storage conditions; those with too-low or too-high concentration of active ingredients due to manufacturing or compounding error and counterfeiting; those that have degraded into toxic substances; those producing adverse reactions; and injectables, creams, syrups, and eye drops that have been contaminated with bacteria or fungi. Substandard medicines remain a serious problem in resource-poor settings (Caudron et al., 2008).

Quality Assurance Programs

The three main activities involved in assuring the quality of medicines are registration of medicines with the NMRA, inspection of manufacturing plants to ensure compliance with Good Pharmaceutical Manufacturing Practice (GMP), and testing of medicines based on product types and characteristics. GMP covers all aspects of production, with its guidelines focusing on personnel, facilities, equipment, sanitation, raw materials, manufacturing processes, labeling and packaging, quality control systems, self-inspection, distribution, documents and records, and complaints and adverse medicine reaction systems.

Quality assurance programs must include training and supervision of staff involved at all stages of the process. Effective information systems are essential for following up and documenting quality problems. Although the foundation of QA consists of regulations and standards, it is the people who enforce the regulations or work to comply with the standards who make the difference between QA and the lack of it (WHO, 2007). WHO's prequalification program is another mechanism for ensuring pharmaceutical quality, including the quality of new products (WHO, 2017e).

Role of Regulatory Agencies

An important determinant of both QA and medicine quality is effective medicine regulation. When enforcement is weak or lacking, pharmaceutical manufacturers, importers, and distributors may ignore regulatory requirements; in turn, the quality, safety, and efficacy of both imported and locally manufactured medicines may be compromised. In most countries, national legislation is often not equipped to deal with the extremely serious health consequences of counterfeit medical products, and penalties for counterfeiters are too light to act as real deterrents (International Medical Products Anti-Counterfeiting Taskforce [IMPACT], 2011).

Both NMRAs and WHO play an important part in ensuring the quality of medicines. Regulatory decisions on medicines have been compiled by the United Nations in its *Consolidated List of Products Whose Consumption and/or Sale Have Been Banned, Withdrawn, Severely Restricted or Not Approved by Governments* (United Nations, 2005; WHO, 2010c)

Counterfeit Medicines

A separate and distinct issue from substandard medicines is the proliferation of counterfeit medicines. The problem of counterfeit medicines was first addressed at the international level in 1985 at the Conference of Experts on the Rational Use of Drugs in Nairobi. A number of initiatives on this front have since been undertaken. In 2006, WHO launched the International Medical Products Anti-Counterfeiting Taskforce as part of the Declaration of Rome. Today, this body remains the main conduit for WHO's work against counterfeiting operations.

WHO has defined a counterfeit medicine as "one which is deliberately and fraudulently mislabeled with respect to identity and/or source. Counterfeiting can apply to both branded and generic products, and counterfeit products may include products with the correct

ingredients or with the wrong ingredients, without active ingredients, with insufficient active ingredients or with fake packaging" (IMPACT, 2006). This definition has not been universally accepted, however, which has made it difficult to exchange information between countries and to measure the size of the problem.

The cost of counterfeit medicines is not measured purely in financial terms (Burki, 2010), because these products constitute a serious health risk for the world's population. Trade in counterfeit medicines is a serious crime. In recent years, increasing international trade of pharmaceuticals and sales via the Internet have facilitated the entry of counterfeit products into the distribution chain. In areas in some LMICs, more than 30% of medicines sold are counterfeit. Counterfeiting is increasing, and it is estimated that more than 70% of this practice occurs in LMICs (IMPACT, 2006).

Medicines are attractive to counterfeiters for a number of reasons. They are high-value items for which demand exceeds supply, and their ingredient costs can be low. Moreover, production can often be undertaken using simple equipment, and overhead costs are minimal. Finally, patients are rarely in a position to judge the quality of a medicine. The counterfeiting of medicines tends to thrive where medicines distribution systems are weak or uncoordinated.

The majority of counterfeit cases involve tablets and capsules. Antibiotics, hormones, analgesics, antihistamines, and steroids account for almost 60% of reported cases of counterfeit medicines. In approximately one-third of cases, products contain no active ingredient; in 20% of cases, they contain an incorrect quantity of that ingredient. In a further 20% of cases, the medicines contain the wrong ingredient, and in almost 10% of cases, they contain high levels of impurities and contaminants (Deisingh, 2005). Counterfeit medicines pose a serious health risk to patients and are a major cause of waste of both public and private funds.

A wide range of methods are now available for the detection of counterfeit medicines (WHO, 2010a). Although some require the use of expensive equipment, simple chemical approaches have also been developed. An initiative of pharmaceutical companies in Germany, the Global Pharma Health Fund (GPHF) has developed an inexpensive field test kit or "Minilab" with rapid, simple-to-use tests for medicine quality verification and counterfeit medicine detection. More than 800 Minilabs have since been supplied across 95 countries; Cambodia, Laos, Vietnam, Madagascar, Nigeria, and Tanzania have also adopted this technology for postmarketing antimalarial drug quality monitoring (GPHF, 2017).

EXHIBIT 16-10 WHO-Recommended Steps to Curb Medicines Counterfeiting

- National laws should regulate the manufacture, trade, distribution, and sale of medicines effectively, with severe penalties being imposed for manufacturing, supplying, or selling counterfeit medicines.
- The NMRAs responsible for the registration and inspection of locally manufactured and imported medicines should be strengthened.
- NMRAs should develop standard operating procedures and guidelines for the inspection of suspected counterfeit medicines, and should initiate widespread screening tests for the detection of such products.
- Adequate training and powers of enforcement against counterfeit medicines operations should be given to personnel by NMRAs, the judiciary, customs personnel, and police.
- Partnerships should be established between health professionals, importers, industry, and local authorities to combat counterfeit medicines.
- Countries should systematically use WHO's Certificate Scheme on the Quality of Pharmaceutical Products Moving in International Commerce. Countries in the same region should work toward harmonization of their marketing authorization procedures.
- Countries should exchange experience and expertise in areas related to quality control, medicine detection, and enforcement.

Modified from World Health Organization (WHO). (2003). Counterfeit drugs: Action sheet. http://www.wpro.who.int/mediacentre/factsheets/fs_200311_Counterfeit_drugs/en/

WHO has published guidelines for the development of measures to combat counterfeit medicines. **EXHIBIT 16-10** lists the steps that should be taken to curb medicines counterfeiting.

Many countries are stepping up their offensives against the counterfeiting problem, but the results have so far been mixed. In Nigeria, intensive action has led to the proportion of fake or adulterated medicines in circulation being reduced from 70% to 16%; in contrast, in India, the share of spurious medicines has grown from 10% to 20% of the market (IMPACT, 2006). Global action will be necessary if this problem is to be contained, and suggestions have been made as to how this goal might be achieved (Attaran et al., 2012). In Europe, a concerted effort is being made to tackle the problem by means of a Falsified Medicines Directive (**EXHIBIT 16-11**).

EXHIBIT 16-11 Europe and the Falsified Medicines Directive

For several years the European Union has been concerned about the threat of counterfeit or "falsified" medicines to public health and safety in its member states. In 2011, the European Commission (2017) started work to amend Directive 2001/83/ED to address these concerns under the Falsified Medicines Directive (FMD). The FMD is designed to protect patient safety by minimizing the chances of counterfeit medicines entering the established medicines supply chain across Europe. It will enable manufacturers, wholesalers, distributors, and all parties who supply medicines to patients to verify the authenticity of a medicinal product, identify individual packs, and check whether the outer packaging of medicines has been tampered with. Manufacturers will be obliged to apply a range of safety features to every pack, including a tamper-proof security seal and a two-dimensional barcode, which will be authenticated before dispensing. Data will be managed by the European Medicines Verification Organization, supported by the Medicines Verification Organizations of EU member states. Manufacturers will check packs into the database, and only those that can be authenticated by scanning the barcode will be dispensed.

Data from Robinson, J., 2016; European Commission, 2017.

Medicine Safety Issues

The availability of medicines of appropriate quality presents its own problems, as the use of any medicine brings with it the possibility of unintended consequences. Any injury occurring at the time a medicine is used, whether or not it is identified as a cause of the injury, is described as an adverse drug event (ADE) (International Council for Harmonization of Technical Requirements, 1996). An adverse drug reaction (ADR) is a special type of ADE in which a causative relationship can be shown. Both ADRs and ADEs are different from accidental or deliberate excessive dosage and administration errors. They also differ from "side effects," as this term also applies to effects that may be beneficial (Nebeker, Barach, & Samore, 2004). A range of approaches are used to report and analyze ADRs, including pharmacovigilance and postmarketing surveillance.

Adverse Drug Reactions

An ADR has been defined as "any response to a medicine which is noxious, unintended, and occurs at doses normally used for prophylaxis, diagnosis, or therapy" (Kanjanarat et al., 2003). ADRs are unwanted effects of a medicine, including idiosyncratic ones, which occur during its proper use. They may occur following a single dose or after prolonged administration of a medicine, or result from the combination of two or more medicines; they can be either predictable or unpredictable. ADRs may be easily confused with outcomes of disease processes and are sometimes difficult to distinguish from other causes. WHO has proposed a stepwise approach to assessing possible ADRs and has published a guide to detecting and reporting adverse drug reactions (WHO, 2017a).

Patients may respond differently to the same treatment, so their risk of ADRs likewise varies. Genetic makeup and concurrent disease, for example, can make a patient more prone to ADRs. The very old and the very young are more susceptible to such reactions. Drug–drug interactions are some of the most common causes of adverse effects. Interactions can also occur with alcohol and traditional medicines.

Pharmacovigilance

Pharmacovigilance is defined as the science and activities relating to the detection, assessment, understanding, and prevention of adverse effects or any other medicine-related problem (WHO, 2017d). In recent years, pharmacovigilance has extended its remit to include herbals, traditional and complementary medicines, blood products, biologicals, medical devices, and vaccines. The major source of new information about ADRs is spontaneous reporting.

Pharmacovigilance also extends to the regulatory measures required to prevent future ADRs and improve the benefit–risk ratio of pharmaceuticals. It supports effective decision making by NMRAs and facilitates the exchange of medicine safety information between countries and the monitoring of global trends in ADRs.

Once limited to the high-income world, pharmacovigilance has developed rapidly. Reliable systems of pharmacovigilance are now recognized as a prerequisite for the rational, safe, and cost-effective use of medicines in all countries (Mahmood, Tahir, & Haq, 2011). A regional pharmacovigilance network and training center for West Africa has been developed (Strengthening Pharmaceutical Systems Program, 2011), and similar collaborations are under development elsewhere. Progress is patchy, however: In Pakistan, pharmacovigilance is practically nonexistent despite widespread recognition of the vital contribution it can make to best patient care (Hussain & Jamshed, 2016).

Postmarketing Surveillance

Premarketing trials of medicines are undertaken on relatively small numbers of patients and lack the

power to detect important but less common ADRs, to detect ADRs that occur in a delayed fashion after the original use of the medicine, or to detect consequences associated with long-term medicine administration. Premarketing trials often do not include special populations such as pregnant women, the elderly, or children, all of whom may be at risk from unique ADRs or from an increased frequency of ADRs compared with the general population.

For these reasons, postmarketing surveillance is an important tool to detect less common, but sometimes serious ADRs. The spontaneous reporting of ADRs is the cornerstone of postmarketing surveillance. Such reports can be made to the NMRA or to the pharmaceutical company concerned. Companies may also have to submit international reports, giving details of ADRs reported in other countries, to the national authority. In certain countries, only doctors are allowed to report suspected ADRs; in others, reports from a wider group of health professionals—sometimes including pharmacists and nurses—are accepted. The frequency of reporting varies considerably between countries, but it is estimated that only 1% to 10% of all cases are actually reported to the authorities.

Postmarketing surveillance also includes the inspection of premises, documents, products, and the practice of personnel in charge to ensure compliance with laws and regulations (Chaiyakunapruk & Jones, 2016).

Many countries have established monitoring systems for early detection and prevention of medicine-related problems. Postmarketing surveillance is mainly coordinated by national pharmacovigilance centers, which collect and analyze case reports of ADRs, distinguish signals from background noise, make regulatory decisions based on strengthened signals, and alert prescribers, manufacturers, and the public to new risks of ADRs. The number of national centers participating in WHO's International Drug Monitoring Program increased from 10 in 1968 to 120 in 2014, greatly strengthening its ability to detect ADRs (WHO, 2017h).

Antimicrobials and Antimicrobial Resistance

Antimicrobial medicines, which kill or inhibit the growth of microbial organisms, are fundamental to modern medicine. They have made control and treatment of previously incurable infectious diseases possible and enabled myriad medical procedures to be performed. Antimicrobial resistance (AMR), which refers to the ability of microbes to grow in presence of antimicrobials, presents a serious and imminent threat to global public health by undermining the effectiveness of existing antimicrobials in treating infections (see also the *Infectious Diseases* and *Public Health Infrastructure* chapters).

In a narrow sense, the term "antimicrobial resistance" is used loosely to refer to antibiotic resistance. Although, scientifically speaking, both "antimicrobials" and "antimicrobial resistance" are umbrella terms that apply to all types of microbes, including bacteria, viruses, parasites, and fungi, many problems and challenges associated with antimicrobial resistance mainly concern the resistance of bacterial species. In those cases, policy makers, scientists, and the media alike sometimes use the term "antimicrobial" interchangeably with "antibiotic" or "antibacterial"; the latter actually concerns medicines that act only against bacteria (Mendelson, 2017).

AMR is driven by human activities. While AMR is a natural phenomenon that manifests the principles of Darwinian evolution, human activities can accelerate its generation and amplify its spread in a highly dynamic and interconnected ecological network (Holmes et al., 2016). Bacteria naturally colonize all types of physical environments of the socio-ecosystem, including residential, agricultural, aquacultural (fish farming), and industrial settings. They also reside in the living organisms that live within these settings, such as humans, farm animals, crops, and fish. Both extensive use of antibiotics in medicine, livestock production, and fish farming, and industrial antibiotic pollution, which directly or indirectly releases antibiotics into these environments and the living organisms within them, increase the exposure of bacteria to antibiotics, and consequently the selection pressure for antibiotic resistance. The resultant resistant genetic elements and bacteria are liable to spread across geographies and systems.

Consequences of Antibiotic Resistance

Antibiotic resistance across the globe has reached an alarming level. High rates of resistance to some of the most advanced antibiotics (such as third-generation cephalosporins and carbapenems) and to some of the most widely used antibiotics (such as fluoroquinolones) have been observed in bacteria that cause common healthcare-associated and community-acquired infections in all WHO regions (WHO, 2014). In healthcare settings, a mix of gram-positive and gram-negative pathogens identified by the acronym ESKAPE (*Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas*

aeruginosa, and *Enterobacter*) are the major causes of nosocomial infections (Boucher et al., 2009). At the community level, the leading causes of resistant infections are pneumonia- and meningitis-causing *Streptococcus pneumoniae*; the enteric pathogens *Vibrio cholerae*, *Salmonella*, *Shigella*, *Escherichia coli*, and *Campylobacter*; and the urinary tract pathogens *Escherichia coli and Neisseria gonorrhoea* (Laxminarayan et al., 2013).

The health and economic burdens imposed by such resistance are immense. Antibiotic resistance leads to increased morbidity and mortality, as well as longer treatment durations and higher costs (Friedman, Temkin, & Carmeli, 2016). In the United States and Europe, resistant infections cause an estimated 23,000 and 25,000 deaths, respectively, each year; in LMICs, neonatal sepsis attributable to resistant infections alone causes an estimated 214,000 deaths each year (Laxminarayan, Sridhar, Blaser, Wang, & Woolhouse, 2016). The economic burden of antibiotic resistance, although under-studied, is considered substantial. The overall economic burden of antibiotic resistance is roughly estimated to be $1.8 billion in Europe (European Centre for Disease Control, 2009) and $55 billion in the United States (Centers for Disease Control and Prevention [CDC], 2011). However, the lack of broader consideration for the fundamental role of antibiotics in medicine means that even existing upper-limit estimates are likely to be underestimates (Smith & Coast, 2013). In the worst-case scenario, the foundation of modern medicines could be shaken by an "antibiotic apocalypse," in which effective antibiotics run out in the face of rising resistance.

Upstream Availability of Antimicrobials

The scale of the challenge of AMR, as illustrated by the global disease burden of infectious diseases and its potential economic costs, contrasts sharply with the dwindling pipeline for novel classes of antimicrobials, especially antibiotics. Despite being one of the most widely used and profitable class of medicines—accounting for 5% of the global pharmaceutical market and generating global sales of $42 billion in 2009 (So & Shah, 2014)—there has been significant stagnation in the R&D of antibiotics. After the discovery of penicillin by Alexander Fleming in 1928, most other major classes of antibiotics, such as cephalosporins, tetracyclines, macrolides, and quinolones, were discovered between the end of the 1940s and the early 1960s (Monnet, 2005). Between 1960 and 2000, no new classes of antibiotics with novel molecular structures were approved (Walsh & Wencemicz, 2016). Although interest in antibiotic discovery has revived in recent years with the approval of several "first in class" antibiotics, the current pipeline does not offer potential treatment options for priority resistant bacteria, especially for multidrug- and extensively drug-resistant TB and gram-negative pathogens such as *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and Enterobacteriaceae (WHO, 2017b).

This lack of investment is the result of a market failure created by the misalignment between the incentives created by the current pharmaceutical business model and basic public health considerations. First, the target diseases of antimicrobials—infectious diseases—are categorized as Type II and III diseases, which mostly affect low-income countries; compared with high-income countries addressed by medicines for Type I diseases, the target market of antimicrobials is considered far less lucrative.

Second, in a system where maximum profit is achieved by products that can be launched early, maintain effectiveness during their shelf life, and be sold as widely as possible, the unique properties of antibiotics make them an especially unattractive business proposition. To start with, efforts to preserve the effectiveness of these novel products significantly limits their window of sales. Novel antibiotic products are advanced treatments whose launch is likely to be delayed until the effectiveness of existing products is near exhaustion. Moreover, the highly regulated and restricted consumption of novel antibiotics constrains the volume of sales. The duration of antibiotic treatment in general is already short, and use of novel products is constrained due to considerations for conservation. This creates a paradox that disincentivizes the pharmaceutical industry: The more advanced a novel product, the less often it can be used and the lower its revenues.

With new antibiotics urgently needed, an increasing number of innovative financing mechanisms and initiatives are being introduced to address this market failure and stimulate the R&D pipeline. These mechanisms aim to resolve the tension between antibiotic conservation and the current volume-based business model by delinking financial rewards from volume of sales. Delinkage rewards companies for successful innovation on some basis other than sales volume, such as value- or milestone-based payments (Rex & Outterson, 2016). With such a scheme, previously underestimated public health and societal benefits of antibiotics are recognized and realigned with economic values. These include option value (in allowing preparedness for future epidemics), enablement value (in allowing other medical procedures to be undertaken), and diversity value (in reducing selection pressure on existing medicines) (Laxminarayan, Matsoso, et al., 2016; Laxminarayan & Weitzman, 2002).

Numerous push, pull, and mixed incentives for delinkage have been proposed since the mid-2000s (Mossialos et al., 2010), and some of these mechanisms have been implemented by initiatives in Europe and North America (Renwick, Simpkin, & Mossialos, 2016). Prominent examples of international public–private partnership programs are the European Commission's Innovative Medicines Initiative, WHO's Global Antibiotic Research and Development Partnership, and Combating Antibiotic Resistant Bacteria Biopharmaceutical Accelerator (CARB-X), a partnership of the U.S. Department of Health and Human Services, the Wellcome Trust, and Boston University School of Law (Renwick, Brogan, & Mossialos, 2016).

Access to, and Safe and Effective Use of, Antimicrobials

In tackling AMR, stimulating innovation of antimicrobials would be futile without ensuring adequate access to quality antimicrobials and their safe and effective use. Without access, innovation would be unjust; without efforts to conserve their effectiveness, investments in innovation and access would be wasteful (Hoffman & Outterson, 2015).

Access to novel antimicrobials is vital to treating increasingly resistant infections. Under the existing business model, the pricing of a novel medicine that has to be held back from the market and restricted in sales would likely be prohibitively high. Delinkage, with its rationale of separating costs from volume-based sales by rewarding innovation itself, could also facilitate access by enabling scale-up of affordable products through licensing arrangements such as patent buy-out or other upfront agreements conditioned to ensure affordable access (Laxminarayan et al., 2013; So & Shah, 2014). However, delinkage is an indirect mechanism for addressing access, and practical challenges arise in incorporating access-enabling features in the design of such mechanisms (Outterson et al., 2016).

Access to "old" but still useful antimicrobials is vital to safeguarding global health. Adequate access to antimicrobials has been a decisive factor in enabling modern medical procedures, significantly lowering the mortality associated with infectious diseases and leading to progress in maternal, neonatal, and child health worldwide (Laxminarayan et al., 2016; Mendelson et al., 2016). However, the lack of access to antibiotics remains a critical and worsening problem that affects both high-income countries and LMICs (Pulcini et al., 2017). The most influential upstream barrier to access concerns the lack of market availability, as pharmaceutical companies are deterred from entering the old antibiotics market—a generics market—due to low profit margins (Pulcini et al., 2017). The main downstream barriers are financial (affecting affordability), structural (affecting supply and distribution), and human resources (affecting capacity and management) barriers.

While there are currently no specific mechanisms to support access to antibiotics, experience can be drawn from novel organizational, financing, logistic, and procurement models developed for infectious diseases including malaria, HIV, and TB, exemplified by the Global Fund's Affordable Medicines Facility–Malaria and the U.S. President's Emergency Plan for AIDS Relief (Årdal et al., 2016; Mendelson et al., 2016). Implementation of WHO's Essential Medicines Policy, which has recently been overhauled in response to the escalating AMR crisis (Gulland, 2017), can also help LMICs improve access to quality assured antibiotics (Holloway & Henry, 2014). The Access to Medicine Foundation (2017) has developed a framework for benchmarking actions of pharmaceutical companies in improving global access to antimicrobials.

As much as ensuring adequate access is a critical issue, conserving the effectiveness of antibiotics by promoting rational use is a top priority at a time when consumption of antibiotics in humans is increasing worldwide (Van Boeckel et al., 2014). WHO's Essential Medicines Policy is a good example of how improvement in access can be combined with explicit policies for promoting rational use (Holloway, Rosella, & Henry, 2016).

One key strategy to improve rational antibiotic use is to change behaviors through addressing determinants of antibiotic use. The behaviors of healthcare providers (doctors and pharmacists) and users (patients) are influenced by multiple layers of factors that shape their respective incentives for antibiotic use (Belongia & Schwartz, 1998; Haak & Radyowijati, 2010; Hulscher, Grol, & Van Der Meer, 2010; Radyowijati & Haak, 2002, 2003; Teixeira Rodrigues, Roque, Falcão, Figueiras, & Herdeiro, 2013; Tonkin-Crine, Yardley, & Little, 2011). These factors are summarized in **TABLE 16-5**.

Although some of the structural and cultural determinants of antibiotic use can be addressed only indirectly by large-scale healthcare reforms or health system strengthening, determinants of antibiotic use in both hospital and community settings can be targeted by specific policies and interventions (Dar et al., 2015). These interventions, which are referred to as antibiotic stewardship, represent an organizational or healthcare system-wide approach to promoting and monitoring judicious use of antimicrobials to preserve their future effectiveness (NICE, 2015).

TABLE 16-5 Determinants of Antibiotic Use

Level of Determinants	Factors That Mainly Influence Providers	Factors That Influence Both Users and Providers
System	Governance, organization, financing, and delivery of healthcare in the health system; major policies and regulations in the healthcare and pharmaceutical sectors; role and influence of the pharmaceutical sector	Cultures, beliefs, values, and medical universes in different societies; availability, accessibility, and quality of healthcare services and medicines
Organization	Governance, organization, financing, and delivery of healthcare in hospitals; organizational policies and regulations specific to hospitals; interactions with the pharmaceutical sector	Availability, accessibility, and quality of healthcare services and medicines local to patients
Provider–user interpersonal		Interactions and relationships between doctors and patients
Individual		Personal background, experience, and socioeconomic characteristics; interactions with other actors in the health system; level of medical knowledge; attitudes and expectations toward health care and medicine use

In healthcare settings, antimicrobial stewardship can be introduced at national, hospital, and individual levels in the forms of national guidelines and programs, hospital antibiotic and therapeutic policies and guidelines, and training and educational activities. Effective implementation (Hulscher et al., 2010) of antimicrobial stewardship in inpatient (Davey, Wilcox, Irving, & Thwaites, 2015) and outpatient settings (Arnold & Straus, 2005) requires a multidisciplinary team comprising doctors, pharmacists, microbiologists, epidemiologists, and infectious disease specialists (Davey et al., 2015; Lee, Cho, Jeong, & Lee, 2013). In community settings, where both prescribed and nonprescribed use of antimicrobials take place and noncompliance and self-medication are prevalent (Kardas, Devine, Golembesky, & Roberts, 2005; Morgan, Okeke, Laxminarayan, Perencevich, & Weisenberg, 2011), antimicrobial stewardship activities target both providers (in this case, retail pharmacies) and patients.

On the supply side, more stringent regulation of over-the-counter sale of antibiotics can be introduced to restrict access to nonprescribed antibiotics (Santa-Ana-Tellez, Mantel-Teeuwisse, Dreser, Leufkens, & Wirtz, 2013). On the demand side, national-level public campaigns and lower-level educational interventions aimed at the public can improve patients' knowledge of antibiotic use and their use behaviors, especially when those campaigns are introduced alongside stewardship interventions aimed at providers (Haynes & Mcleod, 2015).

Other strategies to improve rational antibiotic use include measures to reduce reliance on antibiotics by reinforcing prevention and infection control measures (including consistent hand washing, and developing and ensuring adequate access to vaccines), developing alternative treatments to antibiotics, and ensuring the availability of convenient diagnostic technology to assist decision making.

Antimicrobial Resistance as a Multisectoral Issue

In addition to the challenges surrounding antibiotic use in humans, tackling AMR involves addressing human drivers of resistance in other sectors. The emergence and spread of carbapenem resistance mediated by the NDM-1 enzyme in drinking and sewage water in India, and colistin resistance encoded by the *mcr-1* gene in pig farms in China, are examples of how human activities in different sectors can significantly contribute to the rise of resistance to antibiotics that are medically important to humans in an interconnected and increasing globalized socio-ecosystem. For this reason, national and international strategies

to contain resistance recognize that AMR is a cross-sectoral problem requiring global collective action by international agencies, national governments, and NGOs (Hoffman et al., 2015).

A comprehensive set of multisectoral policies to tackle AMR set out by WHO in 2001 (WHO, 2001b), and reiterated in 2012 (WHO, 2012), helped trigger a series of policy responses at international and national levels. Nonetheless, implementation of these policies during this period remained partial and uncoordinated (Carlet, Pulcini, & Piddock, 2014; Gelband & Delahoy, 2014; WHO, 2015d).

Political interest and policy action in AMR has grown significantly since the 2010s. The initial focus on antibiotic R&D and other economic issues pertinent to AMR has gradually expanded to encompass a wide-ranging set of global health activities involving international agencies, national governments, and NGOs around the world (Carlet et al., 2014; Outterson, Powers, Daniel, & McClellan, 2015; Review on Antimicrobial Resistance, 2016). Political momentum around AMR culminated in the adoption of a Political Declaration to tackle AMR at the General Assembly of the United Nations in 2016 (OPGA/WHO/FAO/OIE joint news release, 2016), and progress continues to be made in the implementation of WHO's Global Action Plan on AMR (WHO, 2015a) and Global AMR Surveillance System (WHO, 2015b), and in efforts to enable monitoring and evaluation of policies related to AMR (**EXHIBIT 16-12**).

EXHIBIT 16-12 Objectives of WHO's Global Action Plan on AMR

- To improve awareness and understanding of AMR through effective communication, education, and training
- To strengthen the knowledge and evidence base through surveillance and research
- To reduce the incidence of infection through effective sanitation, hygiene, and infection prevention measures
- To optimize the use of antimicrobial medicines in human and animal health
- To develop the economic case for sustainable investment that takes account of the needs of all countries, and to increase investment in new medicines, diagnostic tools, vaccines, and other interventions

Pharmaceuticals for Noncommunicable Diseases

As discussed in detail in the *Chronic Diseases and Risks* chapter, noncommunicable diseases (NCDs) are now the leading cause of morbidity and mortality globally, and account for half of the burden of disease in lower-middle-income countries and one-third of that burden in low-income countries. Nevertheless, health systems, especially in LMICs, have struggled to adapt to the demands of this changing burden of disease. Ensuring availability, affordability, and rational use of pharmaceuticals for NCDs is one of the challenges yet to be conquered.

This section addresses the specific issues of medicines for NCDs, focusing primarily on cancers, diabetes, and cardiovascular and respiratory diseases as the most prevalent of these conditions, and as those for which pharmaceutical intervention is clearly indicated in the majority of cases. WHO's (2017g) Model List of Essential Medicines (MLEM) identifies antineoplastic and immunosuppressive medicines used in cancer treatment (Section 8), cardiovascular conditions (Section 12), insulins and other medicines used for diabetes (Section 18.5), and asthmatic conditions and chronic obstructive pulmonary disorder (COPD) (Section 25.1); these are the medicines considered here.

Concordance of National Essential Medicine Lists

A number of studies have assessed the extent of inclusion of those medicines recommended by the MLEM in national formularies. The 2015 MLEM added a significant number of new cancer medicines (which were retained in the 2017 list), recognizing the rising burden of disease from common cancers. Analysis of national medicines lists indicates that the degree of concordance with the MLEM varies considerably, with low-income countries including fewer of the recommended anticancer medications in their own national formularies (Cuomo & Mackey, 2017; Robertson, 2016).

Concordance between the MLEM and national formularies may be considered a necessary but not sufficient condition for rational prescribing: Consistency with treatment guidelines and training are also needed, as well as inclusion of medication specifications in procurement lists, reimbursement lists, and management guidelines (Bissell, 2015). For instance, a study in Papua New Guinea identified a range of inconsistencies between the medicines included in the Medical and Dental Catalogue and those included in standard treatment guidelines (Joshua, Passmore, & Sunderland,

2016), creating a source of confusion that may contribute to the high levels of irrational prescribing that have been documented in the country.

Availability and Affordability of NCD Medicines

The WHO/HAI database of medicine prices, availability, affordability, and price components (HAI, 2017) has been used to benchmark progress toward a target of 80% availability of affordable essential NCD medicines by 2025 (Ewen, Zweekhorst, Regeer, Laing, 2017). The surveys included in the database cover 50 medicines, 24 of which are indicated for cardiovascular diseases, diabetes, and COPD. The lowest-price generic medicines were available in a median of between 25% and 75% of public-sector medicine outlets and between 44% and 87% of private-sector medicine outlets surveyed across the categories of low-, lower-middle-, and upper-middle-income countries.

Affordability is measured in the WHO/HAI surveys in terms of the number of days' wages of the lowest-paid unskilled government worker. The level of 1 day's wage for a monthly supply of the medicine in question is used as a benchmark of affordability. On this basis, most low-price generics are classified as affordable when sourced from the public sector in the median medicine outlet, except for medicines for COPD in lower-middle-income countries. On the same basis, most were not affordable when sourced from the private sector, except for cardiovascular disease medicines in low-income countries (marginally at a median of 0.9 day's wage), and for diabetes and COPD medicines in upper-middle-income countries. Collectively, the proportion of public-sector outlets that had available and affordable the lowest-price generic medicine when surveyed ranged from 11% for cardiovascular medicines in low-income countries to 46% for diabetes medicines in upper-middle-income countries; in the private sector, these figures ranged from 9% for COPD medicines in lower-middle-income countries to 51% for cardiovascular medicines in upper-middle-income countries. Hence, the bulk of experience across the 30 countries included in the WHO/HAI database demonstrate the need for improvement to meet WHO's newly proposed target.

Babar et al. (2013) conducted their own survey using the WHO/HAI methodology, examining the availability and affordability of corticosteroids and a bronchodilator in 52 countries. These researchers found large variations between countries in terms of availability, pricing levels, and practices. For example, some countries subsidize asthma medicines purchases to a significant extent (e.g., Mozambique provides an 83% subsidy for generic salbutamol), while others leverage substantial margins on the sale of similar products (e.g., Peru charges 206% of the procurement price for generic budesonide). Other multicountry and national-level affordability analyses include those conducted by Mendis et al. (2007), Beran et al. (2015), Nguyen et al. (2009), Balasubramanian et al. (2014), and Jingi et al. (2014).

Other approaches have been used to measure the same concepts. For example, Jacobs et al. (2016) evaluated the capacity of the district level in Cambodia to manage NCDs, including an assessment of availability of key medicines for hypertension and diabetes. Unsurprisingly, given the absence of these medicines from the national formulary as described by Robertson et al. (2016), these researchers found the district system ill equipped to manage NCDs, and specifically found that the quantity of medicines provided allowed for only a few patients to be treated for short periods. Katende et al. (2015) used a similar approach to establish the lack of readiness of Ugandan health services, including the nonavailability of essential medicines for dealing with NCDs, which was most pronounced at the primary level. Choudhry et al. (2014) used data obtained from 4,000 "stockists" (wholesalers) of statins in India to track the rising rate of prescriptions of statins between 2006 and 2010, noting that this rate remained well below the estimate of need based on rates in high-income countries.

Pandey and Meltzer (2016) modeled the financial burden and impoverishment that would occur if households purchased cardiovascular medications according to need in India. They estimated that 17% of rural households and 32% of urban households would benefit from using these medications, but suggested that 17 million rural households and 10 million urban households would be impoverished by doing so.

In the private sector, the retail price of pharmaceuticals presents even more extreme issues for affordability. A recent survey examined the monthly cost of a basket of four commonly used cardiovascular disease medicines (aspirin, beta blocker, angiotensin-converting enzyme inhibitor, and statin) in retail pharmacies across 596 communities in 18 countries participating in the Prospective Urban Rural Epidemiology (Khatib et al., 2016). Using the catastrophic payment method described earlier, the study found that the combined monthly cost of all four medicines was potentially unaffordable for 0.14% of households in high-income countries, 25% in upper-middle-income countries, 33% in lower-middle-income countries, and 60% in low-income countries.

Robertson et al. (2016) compared the results of various approaches to measuring the availability of diabetes and hypertension medicines. As well as providing a range of data points from three methodologies, all of which suggested problems of low availability of NCD medicines, particularly in the public sector, these authors clarified the need for a standard approach on the basis of the divergence of estimates of the same outcome.

Causes of Poor Availability and Affordability of NCD Medicines

Mackay and Liang (2012) have established that patent protection is not the source of high medicine prices and low affordability of NCD medicines. Indeed, all of the active ingredients of medicines listed by the MLEM as treatments for cardiovascular and respiratory disease, cancers, and diabetes at the time of their research were available in generic versions.

Irrational prescribing has been measured in a range of settings such as East and South India (Bhavika, Prasanna, & Swathi, 2016; Prasad, Pradhan, Datta, Samajdar, & Panda, 2015), Pakistan (Riaz et al., 2016), and Moldova (Ferrario et al., 2016). The last study describes the inclusion of salbutamol syrup for children in the list of reimbursable medicines in Moldova's health insurance system, and in clinical protocols for family physicians, despite its higher price and lower effectiveness than inhaled formulations of salbutamol. Clearly, if the most cost-effective medicines are not purchased, then public-sector availability and/or affordability must be reduced; if private patients are prescribed less cost-effective medicines, then affordability is reduced.

Irrational prescribing and procuring may be caused by poor knowledge of the most cost-effective options on the part of prescribers or procurers. Some have alleged the deliberate promotion of inappropriate medicines by an industry that profits from their greater use. For example, Yudkin (2012) argues that analog insulins are being promoted to low-income countries as appropriate medicines, even though evidence suggests they are not a cost-effective option. Gill et al. (2017) resist an attempt to get analog insulins included in the MLEM on the same grounds. In some cases, resistance to the use of generics by both physicians and pharmacy staff drives the continued prescription and dispensing of medicines that are less cost-effective. For example, Flood et al. (2017) describe this situation in Guatemala. Patient pressure favoring brand-name products can also play a role.

A number of studies have explored the role played by the expansion of insurance systems on the availability and affordability of NCD medicines (Bigdeli et al., 2016; Ferrario et al., 2016; Garabedian, Ross-Degnan, Ratanawijitrasin, Stephens, & Wagner, 2012). Increasing insurance coverage might be expected to increase the availability and affordability of medicines if it is associated with increasing public subsidy; it might also increase the purchasing power of those who procure medicines for the insurance system, and thereby enhance their leverage over prices. Conversely, if purchasing is not well organized, the increased demand for NCD medicines may increase price; or if insurance is not universal, those excluded from coverage may face lower availability and higher prices.

In Thailand, Garabedian et al. (2012) found that the Universal Coverage Scheme increased access to medicines for noncommunicable diseases in primary care but not in secondary or tertiary care. In Moldova, Ferrario et al. (2016) found improvements over the period since introduction of national health insurance in the affordability of subsidized cardiovascular medicines, but suggested that this trend was due more to rising incomes of the period than to expanding coverage. Bigdeli et al. (2016) compared the patterns of access to NCD treatments and medicines under health equity funds and insurance schemes with those of two specific NCD-focused interventions, finding that coverage for NCDs under the two financing schemes was limited, leaving people shopping around in the private sector and often accessing higher-cost, less effective treatments. The disease-focused interventions were better at supporting NCD management using cost-effective strategies.

Strategies for Resolving the Issues of Access and Affordability of NCD Medicines

A number of commentators have suggested that the strategies used to extend access to antiretroviral drugs for HIV patients could be replicated for NCDs (e.g., Hogerzeil et al., 2013; Kishore, Vedanthan, & Fuster, 2011). These strategies have been enumerated by Kishore et al. (2011, p. 1982) as follows:

1. Enhancing capacity for generic substitution.
2. Expediting generic availability by overcoming legal barriers related to patents and licenses.
3. Optimizing local procurement practices in the public sector.
4. Broadening global procurement via third-party price negotiations.

5. Engaging the private sector to differentially price CVD medicines in LMICs.
6. Regulating retail markups in the supply chain.
7. Eliminating tariffs on medicines.
8. Developing a fixed-dose combination (FDC) for CVD (the "Polypill").

An example of the implementation of this thinking is the Asthma Drug Facility. This program was established by the International Union Against Tuberculosis and Lung Disease to organize the purchase of generic asthma inhalers for LMICs while assuring quality and reducing the price of these medicines. Although it succeeded in approximately halving the price of inhalers (Beran et al., 2015), funding ran out in 2014 and a new funding source has not been secured (Bissell, Perrin, & Beran, 2016).

Other strategies are implied by the problems mentioned earlier in this section. For example, reducing irrational prescription and procurement, and "joining up" national formularies, standard treatment guidelines, and training content all have the capacity to improve availability and affordability. When Barber et al. (2017) modeled the impact of full use of generic medicines for cancers in India, they found that a 56% price reduction in average price across 18 medicines compared could be achieved.

Agodokpessi et al. (2015) make the case for a revolving drug fund for essential asthma medicines in a country such as Benin where universal health coverage is far from achieved.

Conclusion

This chapter has identified a number of challenges to ensuring access to pharmaceuticals. These issues include the need to finance R&D for new medicines and vaccines for neglected diseases; the drive to strengthen national pharmaceutical distribution and management to ensure that the right pharmaceutical products are consistently available throughout the health system; the problems of affordability and the need to generate sustainable financing for medicines that are reasonably priced; and the challenges of ensuring safe and rational medicine use.

In many ways, these unmet needs are "old" problems that have challenged pharmaceutical systems in low- and middle-income settings for decades. In addition, a number of new challenges will demand further flexibility and responsiveness from these systems in the future. These issues include AMR and the need to both incentivize the development of new medicines and protect the effectiveness of existing products, and the epidemiologic transition away from infectious diseases and toward NCDs, which will mean that growing numbers of patients will need medicines on a lifelong basis.

The environment within which pharmaceuticals are developed, procured, and distributed is becoming increasingly more complex, particularly in the context of the epidemiologic transition and the move toward universal health coverage. A plethora of new actors are involved in this sometimes chaotic environment. At the national level, insurance funds and regulators will increasingly exert influence over pharmaceutical decisions that once were the main responsibility of national health ministries. At the international level, new actors include new corporate and philanthropic funding sources, new funding mechanisms and intermediaries, multinational pharmaceutical firms based in the Global South, and regional and international regulatory bodies. These agents may have different incentives for their engagement and sometimes face conflicting priorities. While this new environment has had a generally positive impact on the availability of pharmaceuticals to meet the needs of the low- and middle-income world, it also poses clear risks to the strength and stability of national pharmaceutical systems, and the new initiatives have at times created duplication, inefficiency, and resulting inequities.

From the material presented in this chapter, it should be clear that the functioning of the pharmaceutical system provides a snapshot of the performance of the health system as a whole. The measures that are needed to strengthen health systems in low- and middle-income settings—such as improved governance, universal coverage of equitable healthcare financing mechanisms, and an adequate, high-performing, and appropriately distributed workforce—will all have positive repercussions for the pharmaceutical system, and represent an important step toward ensuring access to pharmaceuticals for all. At the same time, many actions specific to the pharmaceutical sector can be taken across the patient, provider, and system levels to improve availability, affordability, and use of medicines.

Discussion Questions

1. Availability, affordability, and safe and effective use are the main challenges to improving pharmaceutical access. Define what is meant by each, and explain how they can be addressed.
2. What are "neglected diseases" and why are they neglected? Which policy interventions are

available to stimulate investment in pharmaceuticals to address these conditions?
3. Describe three approaches to improving affordability of medicines and some of the challenges of implementing them.
4. In what ways have global health initiatives had positive and negative impacts on medicine access?
5. Which strategies can be employed to improve supply chain management?
6. What are the implications of AMR? Which strategies can be used to contain the problem?
7. What is the impact of AMR on global health security?
8. What are some of the strategies for addressing AMR?
9. What are some of the challenges to continuous availability, affordability, and effective use of medicines to manage noncommunicable diseases?

CHAPTER 17

Innovation, Technology, and Design

Brady Hunt, Mary Natoli, Eric Richardson, Maria Oden, and Rebecca Richards-Kortum

Introduction

Why is it so challenging to use technology to solve critical global health challenges? In this chapter, we address this question by examining the process of technical innovation and engineering design, with a focus on how technology can be used to develop solutions that equitably improve lives throughout the world. Although we emphasize the design of medical technologies, the same general principles can be applied to design technical solutions to meet other global health needs, such as better sanitation and agriculture.

We begin by considering the importance of innovation and technology for the student of global health. We then explore three promising areas of technical innovation that are impacting global health: (1) mobile health technologies, (2) point-of-care diagnostic technologies, and (3) improved access technologies. In the third section, we give an overview of the innovation process, with an eye toward approaches that address global health challenges. Because technical progress alone does not guarantee equitable health outcomes (Fong & Harris, 2015), we also consider the important question of how to scale up successful technologies. Finally, we conclude by discussing some of the high-priority gaps that could be addressed with new innovations.

Innovation: A Catalyst for Change in Global Health

What is innovation, and what does it look like when applied to a vast global health problem? We begin our discussion of innovation and global health by defining technical innovation, and then extend that definition into the context of global health.

Innovation is one of the hallmarks of human civilization. The success of the human race as a species is innately tied to our ability to understand a problem, explore possible solutions, and then find new and better ways to solve it. Innovation is often accompanied by scientific discovery—a better understanding that opens up new possibilities. For our discussion of innovation and technology in the context of global health, we define *technical innovation* as the use of science to meet a social need in the face of economic constraints (Niemeier, Gombachika, & Richards-Kortum, 2014).

Technical innovation is responsible for many significant advances in medical care and public health in high-income countries (**FIGURE 17-1**). Technology to

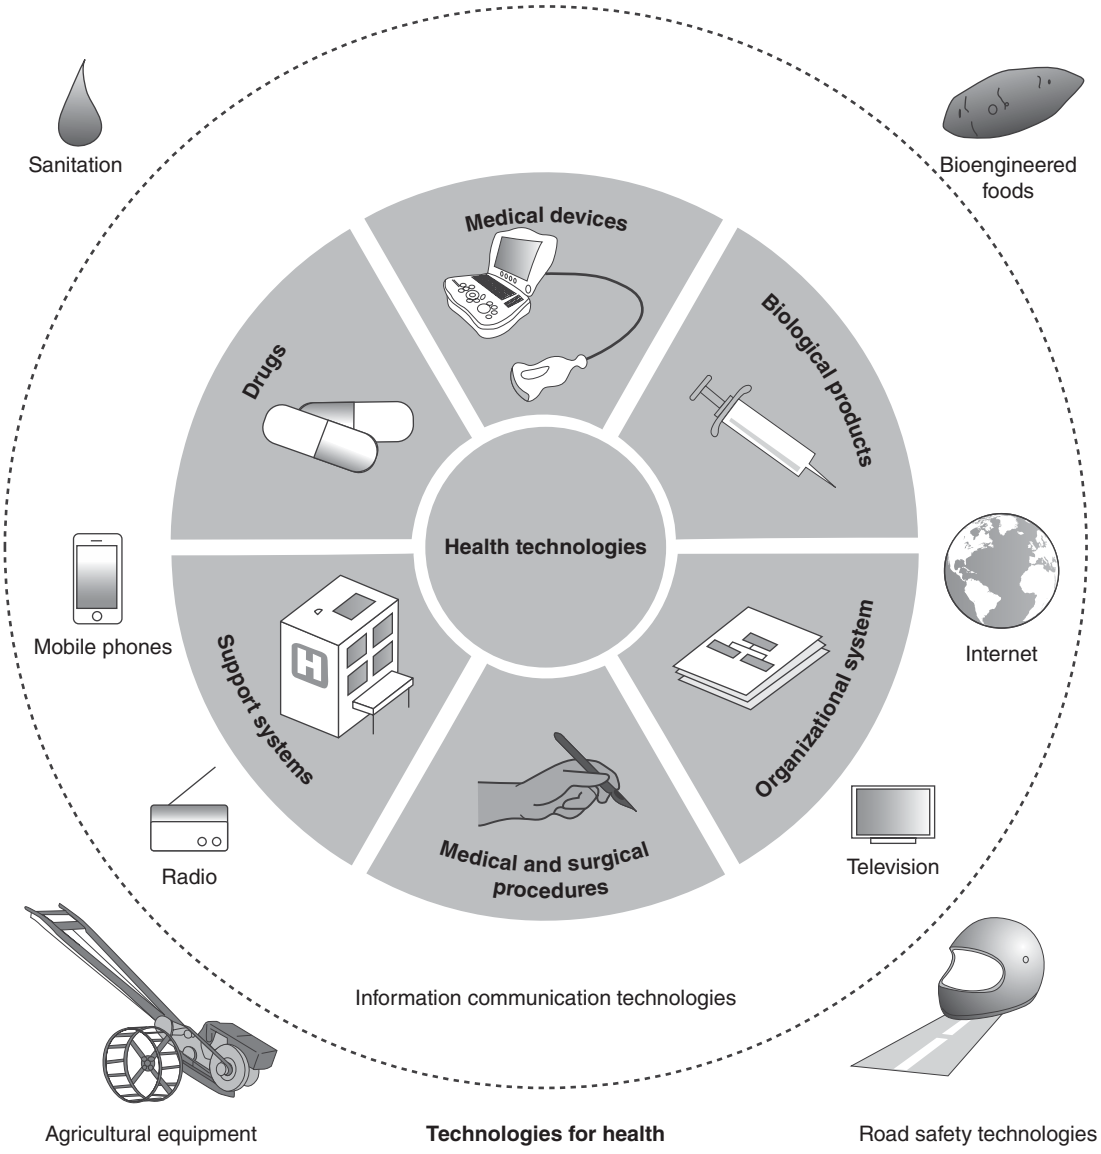

FIGURE 17-1 Overview of technologies that could improve global health.

Reprinted from Howitt, P., Darzi, A., Yang, G. Z., Ashrafian, H., Atun, R., Barlow, J., . . . Wilson, E. (2012). Technologies for global health. *The Lancet, 380*(9840), 507–535. Copyright © 2012, with permission from Elsevier.

improve global health includes medical tools such as antibiotics, vaccines, and medical devices, as well as tools to improve road safety, sanitation, and agricultural productivity (Howitt et al., 2012). Yet, with the exception of vaccines and pharmaceuticals, medical technology and innovation have not yet played a major role in global public health (Piot, 2012). For example, engineers have known how to produce safe drinking water and build toilets for more than 100 years, yet 2.5 billion people still lack basic sanitation (Niemeier et al., 2014). Indeed, more of the world's population has access to cell phones than to basic sanitation facilities (Niemeier et al., 2014). Yet, despite the ubiquity of medical technology, it was not until 2007 that the World Health Organization (WHO) issued the first global directive on medical devices (Sinha & Barry, 2011).

In achieving global health goals, improving equitable access to technical progress is just as important as the technical progress itself. In 2013, the Commission on Investing in Health called for a reduction in preventable infectious disease, maternal, and child deaths to universally low levels by 2035 (Yamey & Morel, 2016). Modeling shows that scaling up existing health technologies will bring low-income countries only two-thirds of the way to this "grand convergence in global health"; full convergence can be achieved only through the development and deployment of new health technologies (Yamey & Morel, 2016). These predictions are consistent with historical evidence of the benefits of adopting innovation in low-resource settings; data show that countries that rapidly adopt new technical innovations reduce their child

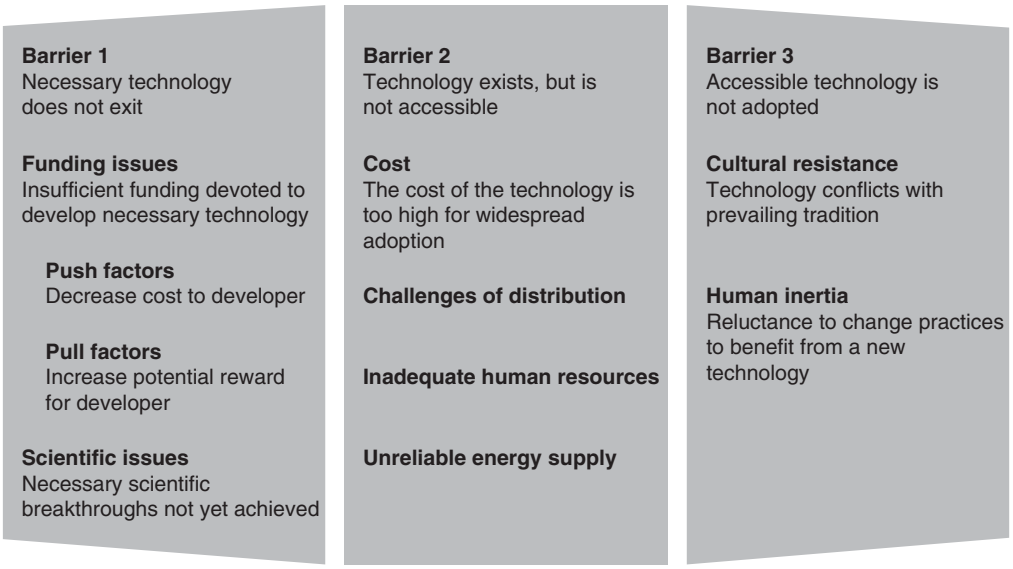

FIGURE 17-2 Three fundamental barriers to the use of technology to improve global health.

mortality rates by an additional 2% per year compared to non-adopting countries (Yamey & Morel, 2016).

FIGURE 17-2 summarizes the three major barriers to increased use of medical technology to improve global health—namely, the necessary technology (1) does not exist, (2) is not accessible, or (3) has not been adopted (Howitt et al., 2012). Where the necessary technology does not yet exist, successful innovation requires that innovators have a deep understanding of the local context in which the solution will be used (Sinha & Barry, 2011). This context dictates constraints that a successful solution must satisfy, including, for example, any limitations on cost, the supply chain for consumables, the available infrastructure to support a solution, and the educational level and number of personnel who will use and maintain the solution. These considerations are paramount for medical equipment.

Most medical equipment in many low-income countries consists of devices donated from high-resource settings (Howitt et al., 2012). Often, these donated devices fail because of line voltage incompatibilities, unavailability of consumables and spare parts, and harsh environmental conditions (Howitt et al., 2012); studies show that as much as three-fourths of donated devices do not work (Richards-Kortum & Oden, 2013). Thus, there is an important need for medical technologies that are explicitly designed to meet the needs of low-resource settings, with full understanding of the constraints that the technologies must deal with. The process of technical innovation discussed later in this chapter is designed to guide innovators through a process that addresses barriers to access and adoption through contextually specific needs finding, as well as development of locally relevant business and marketing strategies.

Society as a whole must value and foster innovation if all people are to reap its benefits. Because economic disparity is the primary driver of health disparity, where innovation takes place will play an important role in determining whether the gap of health disparity widens or closes. There is a great need for innovation leaders who are willing to engage in solving global health challenges, not only to create solutions for today's challenges, but also to train the leaders who will solve the challenges of the future.

Technology Platforms Impacting the Global Health Landscape

Low-resource areas are often physically separated from good healthcare facilities by poor and unreliable transportation networks. Furthermore, deep-rooted economic inequality leads to very low numbers of healthcare workers per capita. As such, global health problems have a number of unique needs, which are discussed throughout this chapter. Platforms that alleviate human resources requirements and other economic constraints can significantly impact the global health landscape. Here, we highlight three such platforms: mobile health technologies, point-of-care diagnostic technologies, and improved access technologies.

Mobile Health Technologies

Nearly 90% of the world's population now has access to wireless phone service; building on this opportunity, many efforts are under way to use mobile phone technology to address health challenges (mHealth). mHealth approaches have shown promise in a variety of low- and high-income settings, ranging from helping patients in Toronto, Canada, reduce their blood pressure and monitor blood glucose levels to reducing the cost of influenza surveillance in Kenya (Hampton, 2012).

A variety of mHealth applications have been developed to help community health workers provide improved services with a particular focus on maternal and child health, human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), and sexual and reproductive health (Braun, Catalani, Wimbush, & Israelski, 2013). mHealth applications have enabled community health workers to collect high-quality health data in the field with fewer errors and less data loss compared to paper records (Braun et al., 2013). Moreover, mHealth tools provide real-time access to reminders and decision support tools, facilitating compliance with clinical care guidelines (Braun et al., 2013). For example, a study in Tanzania showed that midwives who received reminders about past-due patient visits by cell phone improved the number of timely visits to pregnant women (Braun et al., 2013).

In recent years, pharmaceutical companies and other medical research institutions have begun utilizing mHealth to conduct large-scale clinical research (Check Hayden, 2016). Both the iOS and Android communities have launched open-source projects to facilitate creation of clinical research apps for specific diseases. For example, the mPower study team launched an app for people with Parkinson's disease and enrolled more than 6,800 participants—three times more participants than were included in the previous largest Parkinson's disease study (Check Hayden, 2016). The mPower app transforms the smartphone's built-in accelerometer and microphone into a measurement tool for evaluating the steadiness of participants' gait and speech, respectively (Check Hayden, 2016). **FIGURE 17-3** compares mHealth research to standard clinical research and highlights some of the advantages and disadvantages of each approach. Although initial app-based mHealth studies have provided a proof of concept for large-scale clinical trials, most studies have encountered a decline in participant engagement over time and have patient demographics that are biased toward those who own a smartphone (Kvedar & Fogel, 2017).

Smartphone-linked wearable sensors have the potential to significantly expand the impact of mHealth applications (Steinhubl, Muse, & Topol, 2015). As shown in **FIGURE 17-4**, a wide variety of wearable sensors are under development, including tools to monitor electrocardiography (ECG), blood pressure, galvanic skin response, heart rate variability, and blood glucose (Steinhubl et al., 2015). Many of these sensors are produced using traditional microfabrication methods that support low-cost production at high volume. In addition, a number of new processes to develop flexible, wearable electronic sensors have recently been reported (Wang, Liu, & Zhang, 2017). While promising, the majority of these sensors are in early stages of development.

In addition to wearable sensors, a number of lab-on-a-chip mHealth technologies are in development. Many of them couple microfluidic devices that process small volumes of biological fluids together with cell phone–based readers, leveraging miniature light-emitting diodes (LEDs), optical elements, cell phone cameras, and smartphone screens to create low-cost sensors with sophisticated detection capabilities (Steinhubl et al., 2015).

	Advantages	Disadvantages
mHealth 	√ Significantly easier to recruit participants √ Lower cost to scale up and maintain √ Continuous data collection	x Requires software development expertise x Self reported data x Less clinician and patient engagement
Traditional clinical research 	√ More robust patient selection and data validation processes √ Lower cost and complexity to initiate √ More clinician and patient engagement	x Significantly more labor and time intensive x Limited geographic reach x Discrete data collection

FIGURE 17-3 Advantages and disadvantages of app-based mHealth versus standard clinical research.

Microscopes are one of the most commonly used pieces of equipment in medical labs; however, their cost and complexity often limit the utility of these devices in low-income countries (Miller et al., 2010). As shown in **FIGURE 17-5**, Fletcher and colleagues transformed a smartphone into a high-resolution microscope that could provide image in both bright-field and fluorescence modes, with comparable spatial resolution and image quality to much more expensive laboratory-grade microscopes (Breslauer, Maamari, Switz, Lam, & Fletcher, 2009; Skandarajah, Reber, Switz, & Fletcher, 2014). In more recent years, the smartphone-based microscope has been used to quantify levels of parasitic worms in an unprocessed patient blood sample, without need for an expert clinician to analyze the sample (D'Ambrosio et al., 2015).

The smartphone quantified the parasites by taking a video of the blood sample and detecting the motion of the live parasites in the blood, highlighting how increasingly powerful processors available in smartphones can be used for medical diagnosis.

To date, relatively few rigorous, well-controlled trials have evaluated the health impact of mHealth tools (Shuchman, 2014). Moreover, mHealth developers often use platforms that are not mutually compatible, limiting the technologies' potential impact in the field. Although small-scale efforts and pilot projects to measure program outcomes are increasing (Braun et al., 2013), significant gaps in large-scale, rigorous assessment remain. Finally, experts question whether existing mHealth applications provide sufficient utility to convince patients to use them; a recent survey of 1,700 mHealth projects found none that provided essential, actionable guidance for patients facing the acute health conditions that are common in low-resource settings (Royston et al., 2015). Despite these limitations, as smartphones continue to be adopted globally, smartphone-related innovation will likely play an increasingly important role in solving global health challenges.

Point-of-Care Diagnostic Technologies

Throughout history, medicine has typically involved testing within a laboratory of a well-resourced facility such as a hospital, clinic, or diagnostic laboratory. This often requires sending specimens off-site for analysis and waiting hours or days to learn the results. Because care must continue without diagnostic information in the meantime, this type of wait can have unfavorable results for patients. Furthermore, in low-resource settings where clinics are sparse, patients are often unable or reluctant to return to the clinic to receive their test results. In response to this need for more rapid testing, point-of-care diagnostics has developed as an area of research and innovation in the past several decades. Point-of-care diagnostic tests are performed with few resources, and can provide results within a single patient visit. Tests can also be performed by minimally trained technicians, helping alleviate some of the problems created by the chronic shortage of healthcare workers in many countries.

The lateral flow test is the simplest and most successful point-of-care diagnostic technology to date (Sharma, Zapatero-Rodriguez, Estrela, & O'Kennedy, 2015). This technology is based on a series of porous membranes that absorb and wick a fluid laterally. When reagents are included within these membranes, a reaction takes place as the fluid wicks along, and visible markings appear. Typically, a lateral flow test includes one control line that indicates that the test worked properly, and one or more test lines that indicate the presence or absence of an analyte or analytes of interest. One well-known application of lateral flow technology is the home pregnancy test, which functions by capturing the pregnancy marker human chorionic gonadotropin (hCG) from a urine sample (Cole, 2012). Based on technology developed in the 1950s, lateral flow assays helped decentralize laboratory testing in high-resource settings in the 1970s (Sharma et al., 2015). In low-resource settings, lateral flow assays have primarily been used to detect infectious diseases, including HIV and malaria (Sharma et al., 2015).

Adult HIV diagnostics have been one of the greatest global health successes of the past several decades. Whereas someone who acquired HIV in the pretreatment era could expect to live only 12.5 years, a young person in an industrialized country who becomes infected today can expect to live a near normal lifespan (Collaborative Group on AIDS Incubation and HIV Survival, 2000; Samji et al., 2013). Research suggests that comparable results are achievable in low-resource settings as well, due to two factors: (1) the advance of point-of-care diagnostics for HIV and (2) a massive global scale-up of access to life-saving antiretroviral therapy.

In the early 2000s, point-of-care tests to detect HIV-related antibodies and proteins enabled rapid HIV diagnosis. After reaching a peak in 2005, the number of AIDS-related deaths declined from approximately 2 million per year to the current 1.1 million per year (**FIGURE 17-6**). HIV testing continues to become more convenient as HIV self-testing increases in popularity (Hurt & Powers, 2014). The impact of these simpler diagnostics would have been minimal, however, if critical treatments remained difficult to access. After stakeholder consultations in all regions of the world, tremendous efforts were undertaken to reduce the cost of medications and improve ease of access in remote areas. As a result, in the region most affected by HIV—that is, eastern and southern Africa—the number of HIV-positive people receiving treatment has more than doubled since 2010, reaching nearly 10.3 million people today (UNAIDS, 2016). AIDS-related deaths in this region have decreased by 36% during the same time period. The widespread successes seen so far with HIV illustrate what can be accomplished when technical innovation is paired with access pathways that put the innovations in the hands of the users most in need. According to the United Nations Programme on HIV/AIDS, the quest to end the AIDS epidemic "will inspire broader global health and development efforts, demonstrating

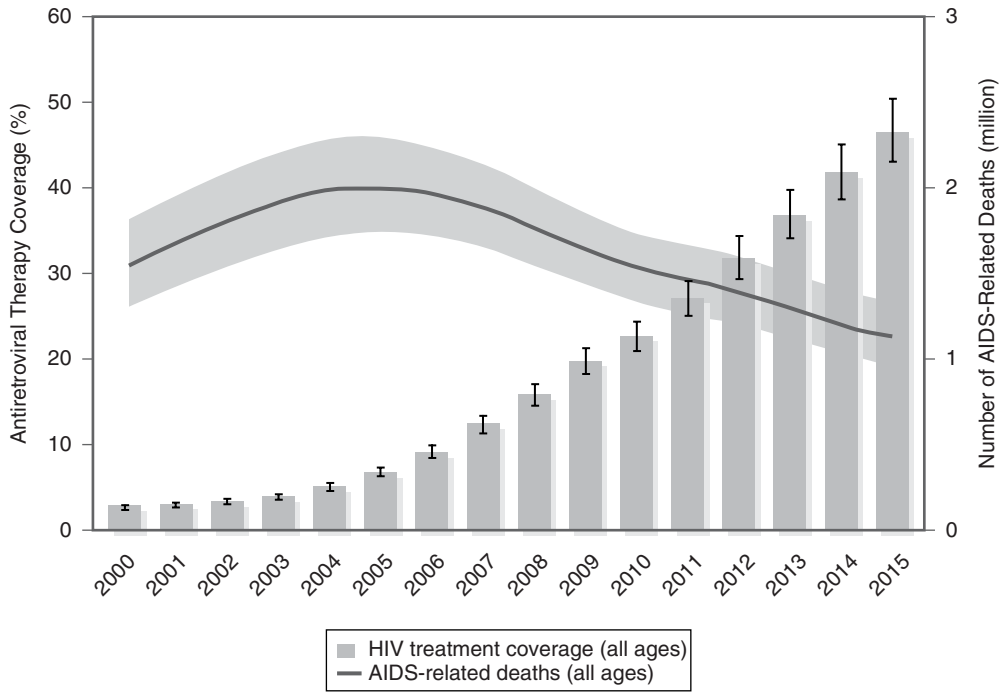

FIGURE 17-6 Antiretroviral therapy coverage and number of AIDS-related deaths, global, 2000–2015.

Reproduced from UNAIDS. (2016). Global AIDS update 2016. Retrieved from http://www.unaids.org/sites/default/files/media_asset/global-AIDS-update-2016_en.pdf

what can be achieved through global solidarity, evidence-based action, and multi-sectoral partnerships" (UNAIDS, 2017).

The development of point-of-care diagnostics for malaria has also dramatically transformed the global health landscape. Traditionally, malaria was diagnosed by direct observation of malaria parasites within peripheral blood smears under microscopy (Wilson, 2012). However, many settings do not have access to good-quality microscopy services. Rapid diagnostic tests for malaria take the form of a typical lateral flow test, which captures antibodies produced in response to the disease. Implementation of these tests has been widespread, with manufacturers reporting a total of 270 million sales of malaria rapid diagnostic tests in 2015 (WHO, 2016b). Most of these sales are in Africa, where the disease burden of malaria is highest. Malaria mortality rates are estimated to have decreased by 29% globally between 2010 and 2015 (WHO, 2016b). In the WHO African Region, reduced mortality due to malaria alone added 1.2 years to average life expectancy at birth between 2000 and 2015.

The last decade has seen rapid progress in the development of novel technologies that can provide molecular diagnostics at the point of care in low-resource settings, moving from lateral flow assays to instrumented systems for blood chemistry to detection of nucleic acids (Sharma et al., 2015) (**FIGURE 17-7**). For example, Cepheid's GeneXpert provides sample-to-answer nucleic acid testing for *Mycobacterium tuberculosis* (MTB) and drug resistance in a fully automated platform that can be used with minimal technical expertise (Lawn et al., 2013). The assay has better sensitivity than microscopy, although it is not as sensitive as liquid culture. A four-module GeneXpert platform costs approximately $17,000 and, with subsidization from a variety of funders, each single test cartridge costs $9.98, significantly more than the per-test cost of microscopy (Lawn et al., 2013). Even at this higher cost, initial analyses suggest the GeneXpert assay will be cost-effective in settings with a high burden of tuberculosis (TB). However, its high relative cost, sophisticated hardware, and need for infrastructure (wall power and climate-controlled environment) are likely to limit implementation of this technology (Lawn et al., 2013).

Despite the promise of the currently available affordable, sensitive point-of-care diagnostics, a number of important unmet needs persist. Indeed, the 2013 Ebola epidemic highlighted the need for continued development of point-of-care diagnostic technologies. During the epidemic, diagnosis was performed in the laboratory using polymerase chain reaction (PCR) at a cost of approximately $100 per test. Although PCR requires only 2–6 hours to perform, test delays of up to 1 week were reported at the peak of the epidemic, likely contributing to increased risk of transmission (Nouvellet et al., 2015). In late 2014, WHO called for rapid, simple, and sensitive Ebola diagnostics; four tests have been approved that detect Ebola-specific RNA or virus

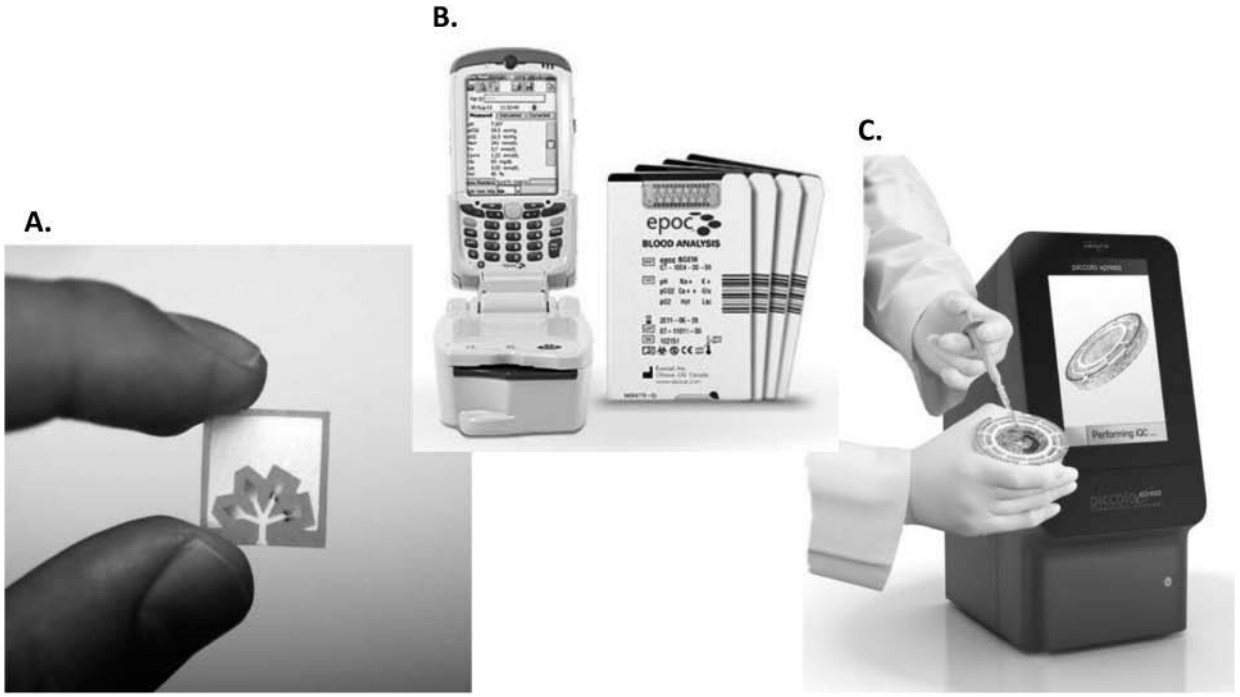

FIGURE 17-7 Examples of point-of-care diagnostic devices under development. **A.** Two-dimensional paper network to quantify glucose and other analytes in urine. **B.** Lab-on-a-chip system to profile blood chemistry developed by Alere. **C.** Lab on a disk device developed by Abaxis.

antigen. Although antigen-based rapid tests typically have lower sensitivity and specificity compared to PCR, modeling shows an approach using rapid tests for screening together with confirmatory PCR for those patients who test positive could have reduced the scale of the 2013 epidemic by more than one-third (Nouvellet et al., 2015). Further technical innovation is needed to support Ebola testing at the point of care; the newly approved tests require cold storage, high biosafety levels, and, in some cases, access to a PCR machine.

Improved Access Technologies

> Imagine the challenge of getting a vaccine from a pharmaceutical company to a remote village in Africa. The vaccine leaves by truck, is flown to Africa, and then is carried across dirt roads by truck or bicycle to eventually reach a refrigerator in a rural clinic that has sporadic electricity. The journey may take days or weeks, during which the vaccine is constantly at risk of being exposed to too much heat, sapping its potency.

This scenario, described by the Program for Appropriate Technology in Health (PATH), illustrates why technologies that improve access are among the most important global health innovations.

Vaccines can be damaged when the cold chain is interrupted during delivery or storage, causing heat-sensitive proteins to denature (WHO, 2012). The stability of a vaccine must be determined through testing, and careful handling must ensure that the vaccine's potency is preserved. The general temperature sensitivity of vaccines has resulted in cold-chain requirements for vaccines. However, in low-resource settings where vaccines must be removed from the cold chain for the last step of distribution, another monitoring method was developed. The vaccine vial monitor (VVM) is a technology that measures cumulative exposure to heat on vaccine vials. A colored disk indicates to health professionals whether a vaccine is still effective and can be used, or whether it should be discarded. Since their introduction in 1996, VVMs have become a critical part of vaccination efforts (Eriksson, Gessner, Jaillard, Morgan, & Le Gargasson, 2017). VVMs have allowed low- and middle-income countries (LMICs) to increase the availability of life-saving vaccines to their populations and reduce under-5 mortality (Eriksson et al., 2017).

Another example of a technology that improves access to critical health care is the Pratt Pouch. During childbirth, the transmission of HIV from mother to child is a significant risk, but can be prevented if the infant receives antiretroviral medication shortly after birth. Antiretroviral therapy has been shown to

decrease the risk of mother-to-child transmission from 21% to less than 7% (Torpey et al., 2010). However, a large percentage of mothers in sub-Saharan Africa deliver at home, and it is difficult to keep antiretroviral drugs outside of the clinic due to their short shelf life. Without treatment, millions of children are at risk of contracting HIV during delivery or breastfeeding.

In response to this problem, the Pratt School of Engineering at Duke University developed a packaging method that extends the life of two common antiretroviral medications by as much as 12 months (Choy, Ortiz, & Malkin, 2015). The Pratt Pouch is made of polyethylene, a heat-stable material that has been used in the food industry for many years (Malkin & Howard, 2012). After heat-sealing, this choice of material preserves the shelf life of the contents far longer than a foil pouch would (Malkin & Howard, 2012). The Pratt Pouch resembles a fast-food ketchup pouch in appearance, and provides a mother with a 14-day to 6-week supply of pre-dosed medication pouches. At home, a caretaker simply tears the pre-dosed package and delivers the drugs orally to the infant. Mothers studied in clinical trials reported that the device was easy to use, and access to medication for HIV-exposed infants born outside of a health facility increased from 35% before the introduction of the pouch to 94% after (Dahinten & Malkin, 2016).

Often, cost is the primary barrier to implementation of technologies in low-resource settings. In response, academic and commercial groups have sought to build medical tools using the cheapest materials possible. One example of an ultra-low-cost tool is the Foldscope, an origami-based paper microscope developed at Stanford University (Cybulski, Clements, & Prakash, 2014). The Foldscope is constructed from three pieces of paper, a spherical ball lens, lens-holder apertures, an LED with a diffuser or condenser lens, a battery, and an electrical switch (**FIGURE 17-8**). Early tests have shown that the device can show bright-field images of several organisms that cause serious infections, including *Giardia lamblia* and *Leishmania donovani*, as well as the commonly studied *Escherichia coli*. A low-magnification version (140×) costs only $0.58, while a high-magnification version (2,180×) costs $0.97.

The Foldscope is also extremely rugged, self-aligning itself during folding, and using components that can survive being stepped on. Taken together, these qualities give the device the potential to be applied not only to diagnostics, but also to education. Many children around the world, even in developed countries, have never had the chance to use a microscope due to these devices' cost and complexity. The Foldscope has the potential to expand science/technology/engineering/mathematics (STEM) education, fostering curiosity and early interest in science that could provide a more sustainable model for global health.

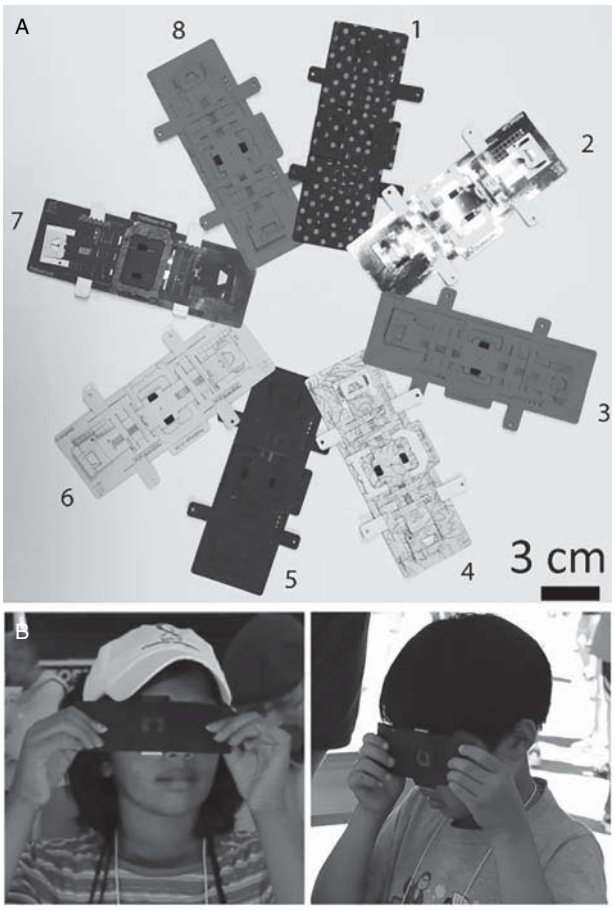

FIGURE 17-8 **A.** Multiple Foldscopes constructed out of different colored cardstock. **B.** Novice users using the Foldscope.

Mobile health, point-of-care, and improved access technologies each address a specific difficulty of delivering health care to remote settings. Furthermore, each of the technologies within the platforms highlighted in the preceding discussion was developed in response to a specific global health need. To be as effective as possible, the technology was developed with the end user in mind, and multiple iterations were, or are still, being produced. In the next section, we investigate the steps typically involved in the innovation process for global health problems.

Global Health Innovation Processes

How do innovators identify unmet clinical needs and begin to develop new technologies that meet the needs of patients and healthcare providers? How do

implementers take a promising innovation from an early-stage prototype to a commercial product that is delivered at scale? Technical innovation can be divided into four phases: (1) identifying needs; (2) solution development; (3) business plan creation; and (4) scaling up. In the next sections, we consider each step in the innovation process in more detail.

Identifying Needs

Innovators from high-income countries are often not familiar with the unique needs of LMICs, which are home to the majority of the world's population. The tendency of many innovators is to assume that the needs of LMICs are similar to the needs of high-income countries, but with the additional constraint of cost. Many multinational companies have failed in their attempts to penetrate these markets because they do not take the time to study differences in market dynamics (Khanna, Palepu, & Sinha, 2005). LMICs represent a diverse set of needs, many of which are unique to the particular country and do not involve cost constraints.

To develop sustainable, impactful technologies in global health, innovators spend a significant amount of time identifying and analyzing market needs prior to generating concepts. Importantly, the needs-finding process is solution-agnostic, and innovators need to resist the temptation to jump into solutions before needs are studied closely. A common cause of failure of new ventures is that there is no market need for the venture's product; to mitigate this risk, many methods have been developed to identify needs (Blank, 2013). The focus on market needs (a market-pull approach) instead of searching for technology applications (a technology-push approach) is particularly important in a global setting where the innovator may not fully understand the complexities of healthcare systems and cultures that are not her or his own.

As a first step toward understanding a complex healthcare system, the innovator can map the patient journey using a patient flow diagram; each step of the patient journey is captured as a block in the diagram (Yock et al., 2015). **FIGURE 17-9** shows an example of a patient's journey through the diagnosis of chronic kidney disease (CKD) and treatment of peritoneal dialysis in Costa Rica using a methodology described by Knapp, Zeratsky, and Kowitz (2016). The players (or stakeholders) in the process are listed on the left, and the desired outcome on the far right. This example shows the one successful pathway the patient can take; more complex patient flow diagrams have decision points and other bifurcations that represent several possible pathways for the patient. It is often helpful to map the most common patient pathway at the start of the needs-finding process, then continue to add branches as alternative pathways are discovered through additional research or observation.

While the patient is of primary importance, equally important to a sustainable innovation is the flow of money through the healthcare system (Yock et al., 2015). A money flow diagram can be created to

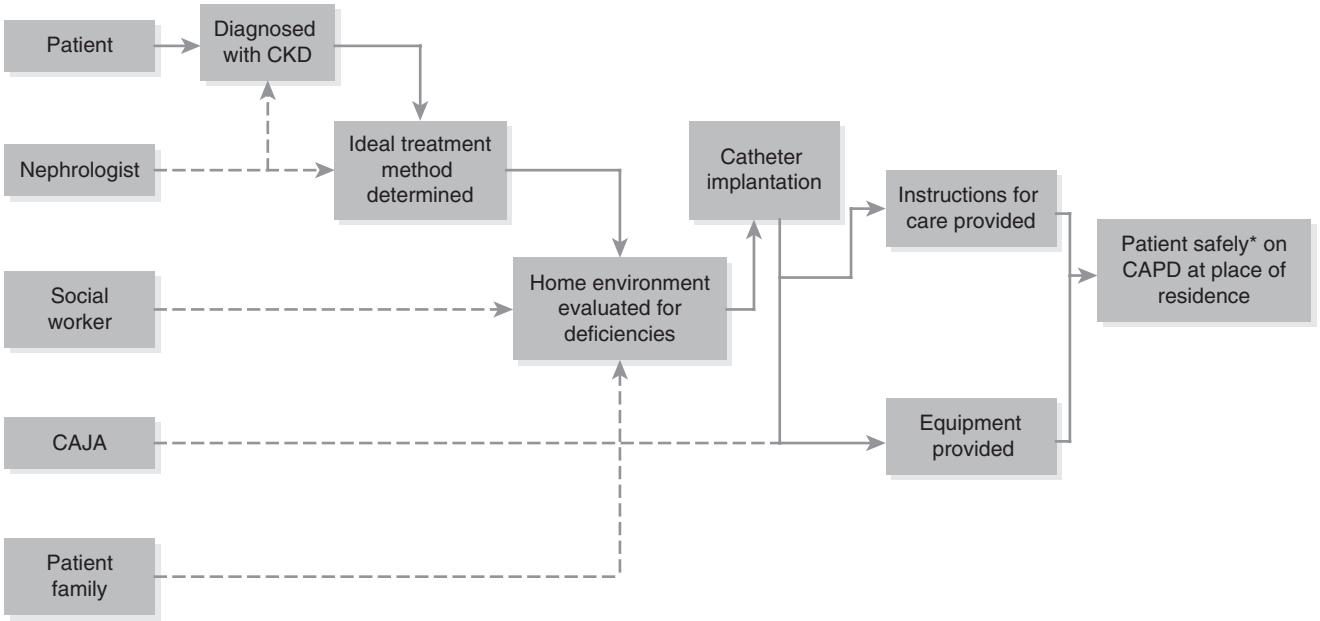

FIGURE 17-9 A flow diagram for a patient with chronic kidney disease, who is treated with peritoneal dialysis in Costa Rica.

Abbreviations: CAJA = Costa Rican Department of Social Security, which is primarily responsible for public health care; CAPD = continuous peritoneal ambulatory dialysis.
The diagram was developed by a team of graduate students at Rice University.

show where, when, and how money is exchanged in the healthcare system. These diagrams may be equally (or even more) complex as patient flow diagrams. If the innovator is not familiar with a country's healthcare payment structure, she or he may find it helpful to create separate diagrams for the public and private sectors, as well as separate diagrams for different phases of care (e.g., screening, diagnosis, and treatment).

Both patient and money flow diagrams will indicate stakeholders in patient diagnosis and care. Stakeholders can be conveniently categorized into patients, providers (such as physicians and nurses), payers (such as insurance companies or government institutions), and facilities (such as hospitals and clinics). While a formal stakeholder analysis is typically done later in the process, it is helpful to assess the amount of stakeholder need in different phases of care to focus the needs-finding efforts.

Once a potential area of interest has been identified, innovators can use a variety of techniques to gather as many needs as possible. As with other divergent phases of product development (such as brainstorming concepts), quantity is key to finding quality. It is not uncommon for a team to find hundreds, and sometime thousands, of needs before narrowing its options down to one choice that continues into the concept generation phase.

Needs-finding strategies that are particularly helpful in global health can be organized into three categories: observation, interviewing, and secondary research. A mix of these three strategies used in parallel is likely to yield the best results. Other forms of primary market research, such as questionnaires, focus groups, video ethnography, and competitive analysis, may be useful in the context of global health, but are beyond the scope of this chapter.

Direct observation of human behavior, or ethnographic research, is an excellent way to uncover needs that a stakeholder or user may not be able to articulate in an interview. It also serves as an effective way to develop empathy for the patient or provider. Efforts should be made to observe the work of all stakeholders, including nurses, administrators, supporting hospital staff, and patient families. If possible, stakeholders should be observed in as many stages of care as possible to get a holistic view of the experience and to validate a patient flow map. During the observation process, the innovator looks carefully for "systems" problems such as bottlenecks, inefficiencies, and cost drivers.

Interviews should likewise be conducted with as many stakeholders as possible. As described in conjunction with the contextual inquiry method (Privitera, 2015), it is often best to follow an observation session with interviews to confirm the understanding of what occurred in the clinical setting, ask clarifying questions, and uncover the reasons for certain behaviors. While interview techniques have been widely described in the literature (Burchill & Brodie, 1997; Privitera, 2015; Yock et al., 2015), the following technique may be especially helpful in needs-finding interviews:

1. Encourage storytelling to get specific examples and details.
2. Ask open-ended questions that cannot be answered by a simple "yes" or "no."
3. Continue to ask "why" until you can get to the root cause of a problem.
4. Ask people to discuss problems that their colleagues are facing, as it is often easier to describe others' challenges rather than your own challenges.

It is helpful to schedule time immediately after the observation or interview to analyze the findings. Indeed, it is not uncommon for a team to spend an hour of analysis for every hour of clinical observation.

Causes or problems identified through this process can be translated into need statements. A good need statement defines a problem, population, and outcome (Yock et al., 2015). The need can then easily be articulated with a statement of the following form: "A way to (problem), in (population), in order to (outcome)." For example, a need statement might be "A way to access the pericardium without ultrasound in rural patients with acute cardiac tamponade in order to quickly and safely remove fluid."

To ensure that a need statement is not too general or too broad, the innovator can scope the need up (make it more general) or down (make it more specific) to confirm that the need is at an appropriate level of resolution. For example, the need statement given previously could be scoped up to "A way to treat cardiac tamponade in patients in order to restore their hemodynamic stability." It could be scoped down to "A way to quickly access the pericardium in the emergency department in patients with acute cardiac tamponade in order to quickly and safely remove 100 mL of fluids."

Likewise, all need statements should be checked for an embedded solution. An embedded solution prescribes the manner in which to solve the problem, unnecessarily constraining the innovator during concept generation. For example, a need statement that begins with "A catheter that . . ." has an embedded solution because it prescribes that a catheter must be used. Perhaps other solutions could address the need without the need of a catheter.

To select a small handful of needs to begin concept generation, a screening or prioritization process is helpful. This is done by ranking potential needs against a set of criteria developed by the team. After screening leads to a smaller group of needs, performing more observations can validate these needs and offer further insights.

Solution Development

Once a need has been identified, refined, and validated, it is appropriate to move on to the solution development stage of innovation. Throughout this section, we use examples from a global health design project completed by undergraduate students at Rice University to illustrate various steps of the design process (Brown et al., 2013) (**EXHIBIT 17-1**).

The first step of solution development is to carefully define design criteria and constraints that must be met (**EXHIBIT 17-2**). This is essentially a translation of the needs (of the customer) into the specifications (to be met by the designer). Design criteria should be stated in a manner that is measurable. For example, "The system must cost less than $200" is a measurable criterion, whereas "The system should be low cost" is not. Some important design criteria should become

EXHIBIT 17-1 BubbleCPAP: The Need

Half of all premature infants suffer from respiratory distress and need support to breathe in the first few days of life. Continuous positive airway pressure (CPAP) is a method of respiratory support used in neonates who struggle to breathe. CPAP maintains inspiratory and expiratory pressures above the ambient pressure to increase a baby's functional residual capacity and improve static lung compliance, thereby making it easier for an infant to breathe.

Overall goal: Design a CPAP machine that is safe, simple, easy to use, and less expensive to make than conventional CPAP machines.

EXHIBIT 17-2 BubbleCPAP: Design Criteria

After defining their problem, the CPAP team identified a set of design criteria and specified testable, quantifiable targets for their solution. This table shows the most important design criteria for CPAP.

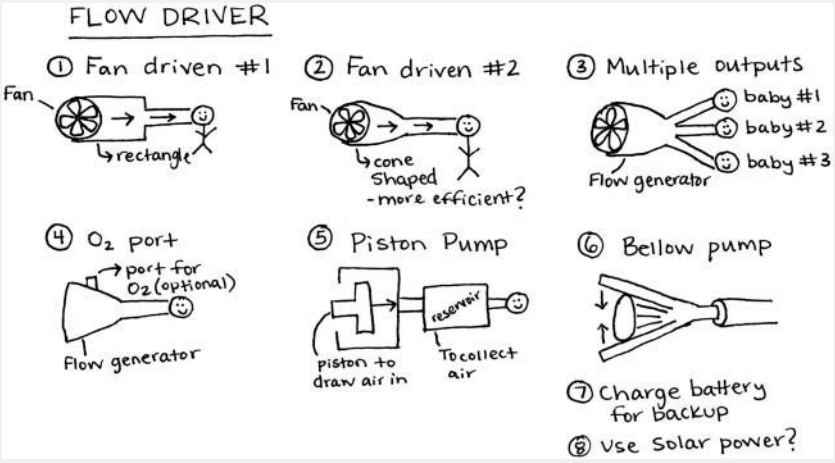
Criterion	Design Goal and Evaluation Method
Controllability	Ambient air flow must be adjustable over a range of 5–10 L/min and flow from optional O_2 port must be adjustable over a range of 1–10 L/min. CPAP must be adjustable over a range of 5–10 cm H_2O.
Safety	Flow from the generator must not exceed 10 L/min and CPAP must not exceed 10 cm H_2O. The device must alert the user if pressure in the circuit drops to atmospheric pressure.
Ease of use	The time required to set up the system on a patient for treatment must be less than 15 minutes.
Power requirements	The system must require a maximum of 240 V to operate and require less than 50 W.
Reusability/durability	The tubing, patient interface, and water bottle must be reusable for a minimum of 5 uses. The flow generator must function properly by producing pressure of 7 L/min after a 5-foot drop onto a concrete floor.
Sterilizability	After sterilization of the used device with 1:4 bleach solution, mechanical properties must remain unchanged.
Cost	The cost of goods, including the flow generator, CPAP circuit, and alarm, must be less than $200. Subsequent costs for tubing and the patient interface must be less than $10 per patient.

Cultural acceptance	The system must be considered culturally acceptable by greater than 80% of surveyed users (doctors, nurses, or other healthcare providers) in developing countries.
Portability	The total size of the system must not exceed 1 ft^3 and the weight must not exceed 5 kg.

EXHIBIT 17-3 BubbleCPAP: Brainstorming

During the brainstorming process, the CPAP team developed solutions for many different major components of their design. First, they brainstormed different methods of delivering CPAP and settled on a bubbleCPAP concept. Next, the team brainstormed concepts for tubing, patient interface, alarms and safety mechanisms, pressure control, and air flow drivers.

To make brainstorming more manageable, the team isolated the flow driver as a subset of a challenge as a topic for brainstorming rather than the whole challenge. The CPAP team knew that the system needed to pump room air at flow rates up to 10 L/min continuously. It was critical to identify or build a pump that was durable, yet low cost and easy to repair. Some of the resulting concepts from a brainstorming session on flow drivers are shown in the figure.



clear from the team's interviews and background research. It is important to note which criteria must be met to ensure success of the project and which may be flexible if tradeoffs are required. In addition, relevant regulatory standards for the category of product should be identified early in the process. A good place to start when seeking the relevant standards for a new product is to review the specific standards that are met by competing products.

Common design criteria used by global health innovators include the following:

- Cost
- Safety considerations
- Performance characteristics
- Ease of use
- Power requirements
- Size/portability
- Compatibility with existing systems or consumables
- Environmental and sustainability requirements
- Government regulations and standards
- Durability

When specifying the criteria, it is helpful to consider how they will be measured or tested. To demonstrate that the design meets all the goals, testing will be required.

After defining the design criteria, innovators brainstorm as many new ideas as possible (Ulrich & Eppinger, 2012). Building on patent searches, existing product reviews, expert consultations, and literature reviews that were previously been completed, the team can brainstorm specific solution concepts (**EXHIBIT 17-3**).

By considering the advantages and disadvantages of each brainstormed solution, it is possible to rank and identify the best options to move forward toward prototyping (**EXHIBIT 17-4**). Sometimes, final

EXHIBIT 17-4 BubbleCPAP: Ranking Conceptual Solutions

Knowing they wanted to focus on a piston pump, the CPAP team members identified three piston pump types and applied a concept scoring matrix to their ideas. The table shows this matrix, where the criteria are weighted and the design options are given a score of 0–5 for each criterion. The weighting and the score for each design and criterion were multiplied and summed to get a final score. Using this technique, the CPAP team determined that a diaphragm pump was the most promising type of piston pump for their need.

Design Criterion Specific to Pump	Weight	Piston Flow Drivers		
		Diaphragm	Tire Inflator	Nebulizer
Cost	25%	4	4	3
Durability	25%	4	3	3
Flow	15%	4	5	5
Pressure	15%	5	5	5
Power	10%	5	4	4
Portability	10%	5	4	4
Loudness	5%	5	2	3
Total Weighted Score		**4.35**	**3.95**	**3.75**

choices cannot be made with only the screening and scoring techniques. This can happen when there is uncertainty—for example, about whether a concept can really work—or where cost and feasibility are not yet determined. In that case, it may be advisable to move more than one concept forward to initial prototype development so that new and innovative concepts can be tested and evaluated.

Next, working prototypes of the most promising solutions are built (**EXHIBIT 17-5**). Successful prototypes aim to demonstrate the concept or concepts in the design solution. Sometimes, more than one option is prototyped for a certain component for comparison purposes. The prototype needs to be of sufficiently high fidelity that testing can be performed to evaluate whether it meets the design criteria. Often initial prototypes are instrumented with data acquisition systems so that data can be collected to demonstrate the function of the system. Later in the process, once design concepts have been validated, electronics can be downsized to a microcontroller to create a smaller, stand-alone form factor.

Prototypes are tested to evaluate how well they meet the design goals for a particular problem, and to identify areas for improvement. At all stages of solution development, the design and prototype should be constantly improved based on learnings from the previous steps. The first round of testing occurs in the laboratory, and after improvements, testing might progress to pilot clinical evaluations. To use the system with patients, the innovator must obtain ethics review board approvals at all institutions involved in the study. Striving to meet all standards in the design and collecting safety information in early laboratory-based studies can support later regulatory applications.

Finally, through this iterative process of design and evaluation, the innovator arrives at an appropriate solution for the clinical need. The innovator is now ready to consider a business plan for delivering the innovation to the user.

Business Plan Creation

A robust business plan is a key component of the strategy to bring a global health innovation to sustainable scale. A comprehensive business plan includes a thorough understanding of the relevant market and user needs, a plan for manufacturing and distribution, and

EXHIBIT 17-5 Bubble CPAP: Prototypes

To evaluate the CPAP prototype, the pressures and air flow from the CPAP system were compared to those of a commercial system in use at a local hospital. The frequency and magnitude of these parameters were the same, indicating that the prototype was able to deliver therapeutic benefit to a patient. At the same time, the prototype was demonstrated to nurses and doctors at numerous hospitals throughout Africa. Focus groups including clinical experts were asked to evaluate the system during trainings and simulations. Data on the user interactions with the device were collected. This led to a series of improvements that were incorporated into the subsequent design in preparation for the pilot clinical evaluation.

The figures show the progression of prototypes for the CPAP system. The first prototype (A) used a low-cost plastic shoebox as an enclosure for the initial device. Of course, this was not suitable as a system that would be used on a patient, but rather represented a quick solution to create a model that could undergo laboratory-based performance testing. The second prototype (B) used a commercially available container that was stronger and suitable for a clinic-ready system for pilot evaluation. Over time and in moving toward the commercial product (C), the CPAP designs become progressively more professional and incorporated improvements to the user interface and improved manufacturability, but the basic design concepts remained fairly unchanged.

A. Early conceptual prototype. **B.** Clinic-ready evaluation unit. **C.** Commercial product.

a plan to obtain regulatory approval from the appropriate governing bodies.

The first step in creating a business plan is to define the value proposition of the innovation—that is, a succinct summary of the value of the innovation in comparison to alternative solutions (Osterwalder, Pigneur, Bernarda, & Smith, 2014). Value is considered from the perspective of the patient, the provider, and the payer. If the proposed solution does not offer significant value to each of these stakeholders, it is unlikely to succeed at scale. In many cultures, society and tradition influence value in a way that it is difficult for innovators from other parts of the world to understand. Because culture often affects the uptake of a new product, it should be researched and considered when developing a business plan. Likely, effective interviews during the needs-finding stage will have illuminated some of these challenges.

As early as possible in the design process, innovators should develop a manufacturing strategy and understand the costs associated with actually producing the innovation. The cost comprises several components: materials, labor, and burden. Material costs include all materials that are used in the production of a single product, including those wasted (or scrapped) in production. The yield—that is, the material used in the final product divided by the total material used in the process—can play a significant role in medical device costs given the high standard of quality that is required. Labor will play a large role in the cost of medical devices that require significant assembly. Labor costs are typically projected through an hourly, per-person rate. They include the time of the person directly assembling or manufacturing the product, but exclude the labor of engineers or managers who support manufacturing (these are accounted for in burden). Burden accounts for the overhead associated with manufacturing. This includes facility costs, utility bills, maintenance costs, the salaries of engineers and managers who support the manufacturing line, consumables, and many other costs.

Medical devices are required to obtain regulatory approval and must meet specific standards before they can be sold for clinical use. These standards normally depend on the complexity and risk profile of the particular technology. Low-risk devices, such as tongue depressors and examination gloves, are subject to fewer requirements than complex, life-saving, or implantable devices such as heart valves. In addition, the specific regulations and regulatory approval

processes vary by country. The United States, Canada, Australia, Japan, and the European Union have fairly well-defined regulations and processes for obtaining regulatory approval (Yock, 2015). In contrast, other countries, including many in Africa, do not have a specific agency or well-defined regulatory process. This, of course, complicates efforts to import and distribute new medical technologies.

Identifying an appropriate regulatory pathway for a newly developed medical product is a key part of the global health innovation process. The chosen regulatory pathway will dictate the exact scope of any clinical validation required. In addition to noting the current state of regulation, good regulatory strategists consider trends that may affect regulation in the months or years before approval can be obtained. Indeed, regulation in most countries, especially those with large, emerging economies, is changing rapidly as the medical technology industry is globalizing. Several case studies of successful introduction of health technologies worldwide are presented in the USAID series "Idea to Impact" (Center for Accelerating Innovation and Impact, 2015).

Overall, the business plan plays an important role in the successful adoption of technical innovations by articulating the return on investment from both a public health perspective and a financial perspective, considering the incentives for all people involved in the purchase and use of the innovation. With the business plan laid out, focus then shifts toward introducing the innovation into the marketplace and scaling up its adoption.

Scaling Up

The final step in creating impact with a global health innovation is to scale up the technology to a broad audience (see the *Culture, Behavior, and Health* chapter for information on the diffusion of health innovations model). Achieving grand convergence in global health would have enormous global health impact, preventing 10 million deaths every year (Kruk et al., 2016). Unfortunately, the landscape of global health is littered with examples of innovations that are known to be effective but remain underutilized. For example, the scientific foundation of oral rehydration therapy (ORT) was developed in the 1960s, but its potential impact was not realized until it was incorporated into community health strategies in the 1980s (Frost & Reich, 2008); three decades later, however, significant coverage gaps persist in use of ORT. **TABLE 17-1** compares current coverage levels of representation maternal and child health interventions to levels needed to

TABLE 17-1 Examples of Scale-Up of Maternal and Child Health Interventions Required to Achieve Grand Convergence by 2035

Intervention	Current Coverage in Low- and Lower-Middle-Income Countries	Coverage Rate by 2035 That Will Be Required to Reach Convergence
Modern family planning methods	30%	50%
Skilled birth assistance in labor	65%	99%
Neonatal resuscitation	28%	84%
Pregnant women sleeping under an insecticide-treated bed net for malaria prevention	26%	100%
Treatment of malaria in pregnant women	55%	100%
Kangaroo care (skin-to-skin contact for the newborn)	4%	95%
Oral rehydration therapy (ORT) for childhood diarrhea	40%	99%

Reproduced from Kruk, M. E., Yamey, G., Angell, S. Y., Beith, A., Cotlear, D., Guanais, F., . . . Goosby, E. (2016). Transforming global health by improving the science of scale-up. *PLoS Biology, 14*(3):e1002360, https://creativecommons.org/licenses/by/4.0/

Note: Coverage is the percent of the population in need receiving the intervention.

achieve convergence. The gaps highlighted serve as a reminder that innovations do not deliver themselves (Yamey & Morel, 2016).

Why is it so challenging to bring successful innovations to scale? Innovators often underestimate the challenges associated of moving from successful pilot test to field evaluation to implementation at scale. For example, innovators developing point-of-care diagnostics did not anticipate the tremendous strain on the healthcare system associated with a move to suddenly decentralize testing from a few central labs to hundreds of point-of-care sites (Peeling, 2015). It can be difficult to secure financial support for scale-up; often, policy makers are more interested in supporting the introduction of new products than in sustaining and scaling access to existing affordable technologies (Piot, 2012). Funding mechanisms are often more likely to emphasize technical innovation over simplicity, resulting in complex and costly technologies that are difficult to scale (Richards-Kortum & Oden, 2013).

Fortunately, there is a precedent for successful scale-up in the global health arena: The scale-up of drugs and vaccines has been successful in recent decades. Since its inception 16 years ago, the Global Alliance for Vaccines Initiative (GAVI) has helped create a healthy global vaccine landscape through four guiding principles: (1) product development, (2) health systems strengthening, (3) financing, and (4) market shaping. All of these principles are critical and often unfilled needs for diagnostics and medical technologies in low-resource settings. Recognizing the success of GAVI, innovators have called for a Global Alliance for Medical Diagnostics Initiative (GAMDI) to coordinate the development, introduction, and utilization of medical diagnostics (Mugambi, Palamountain, Gallarda, & Drain, 2017).

TABLE 17-2 summarizes the factors associated with successful scale-up of innovations based on field work in East Africa (Yamey, 2011). Innovations that are simple and that are accompanied by robust technical policies are easier to scale (Yamey, 2011). Designs that minimize the use of consumables may be most sustainable in the face of weak supply chains (Richards-Kortum & Oden, 2013). Integrated packages of technologies that address focused clinical areas (e.g., surgery) may be easier to scale because they allow implementers to more efficiently navigate implementation barriers for the package as a whole rather than for one technology at a time (Richards-Kortum & Oden, 2013).

Others argue that rather than asking "How do you scale up?", innovators, especially those associated with nonprofit organizations, should begin early in the innovation process to define their endgame—that is, the role they tend to play in the overall solution once they have proved the effectiveness of their innovation (Gugelev & Stern, 2015). In studying nonprofit organizations that successfully scaled interventions, Gugelev and Stern identified six possible endgames, identifying those that are best suited to various types of innovations (**FIGURE 17-10**).

TABLE 17-2 Factors Associated with Successful Scale-Up of an Innovation

Innovation	■ Keep the innovation as simple as possible. ■ Develop robust technical policies and training materials for scale.
Implementers	■ Ensure strong leadership and governance. ■ Engage local implementers and stakeholders. ■ Partner with government and nongovernmental organizations.
Delivery strategy	■ Use a phased approach to scale-up. ■ Tailor scale-up to the local context. ■ Integrate innovations within the health system.
Context	■ Incorporate innovations in national policies. ■ Secure country ownership of innovations.

Produced for this book chapter by the authors at Rice University.

Technological Opportunities: Filling the Gaps in Global Health

While innovations have played a central role in improving health in high-resource settings, more than 50 years later these innovations remain largely unavailable in low-resource settings. Although there is no clear process whereby the global public health community sets an agenda for innovation (Piot, 2012), a number of high-priority areas of need have been identified. We conclude by reviewing four areas where medical device innovations are urgently needed: newborn health, maternal health, surgery, and the growing global burden of chronic disease.

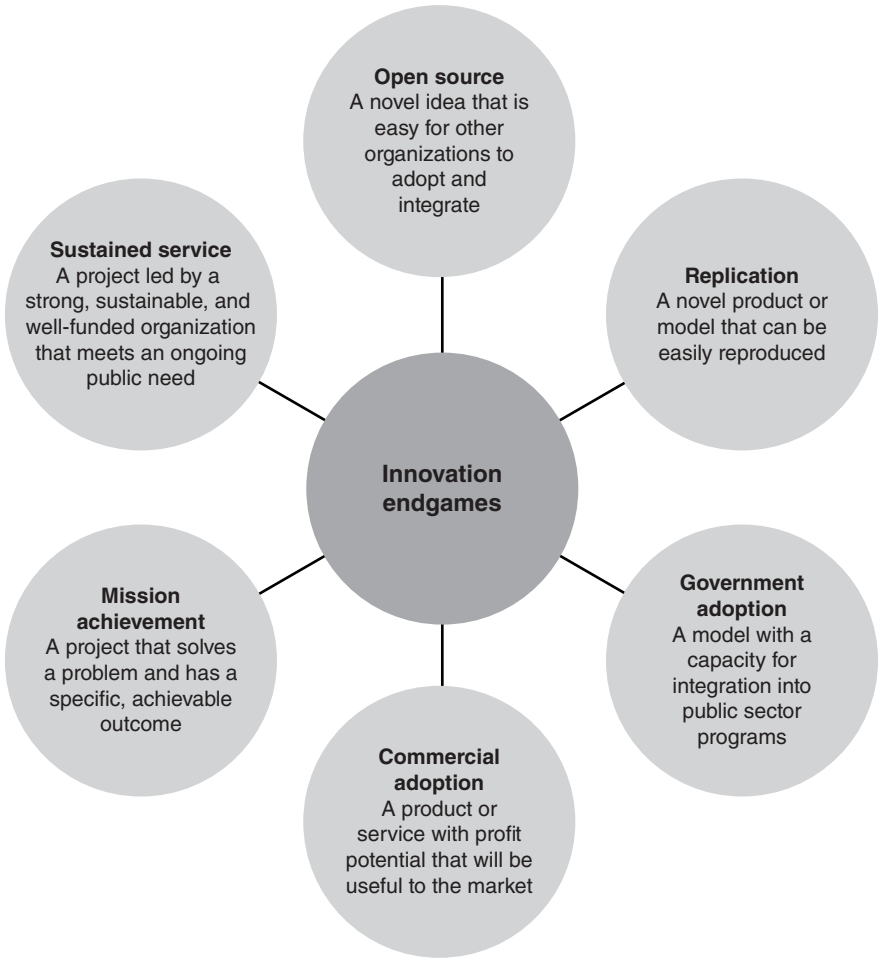


FIGURE 17-10 Six possible endgames for nonprofit organizations to consider as they scale new innovations.

Newborn Health

Since 1990, global child mortality has dropped by half. By comparison, neonatal mortality (death within the first 28 days of life) has declined much more slowly (see the *Reproductive Health* chapter for further detail). Newborn deaths now represent 45% of under-5 deaths (Lawn et al., 2014; Liu et al., 2012) and complications of preterm birth are the world's leading killer of children (Lawn & Kinney, 2014). In Africa, which has one of the highest neonatal mortality rates in the world, more than 1 million newborns die every year, the majority from preventable causes. Evidence shows that providing comprehensive hospital care during labor, delivery, and the first week of life, including for small and sick babies, can reduce newborn deaths by 75% (Bhutta et al., 2014; Kinney et al., 2015; Lawn, 2014; Lawn et al., 2013). Although most African mothers now deliver in hospitals, technologies to provide comprehensive care for newborns (defined as facility-based care with the infrastructure, technology, and skills to manage common complications especially for preterm newborns [WHO, 2016a]) are simply not available in most African hospitals (Bhutta et al., 2014), the region of the world where progress to improve newborn survival is slowest (Opondo et al., 2009).

FIGURE 17-11 shows the three main causes of neonatal death, which can be prevented or treated through seven pathways of care: (1) provide hydration and nutrition; (2) provide temperature stability; (3) monitor and treat jaundice; (4) monitor and treat hypoglycemia; (5) monitor labor and delivery; (6) provide breathing support; (7) prevent and treat infections. Figure 17-11 also identifies technologies required to accomplish these seven functions; these technologies are a high priority for innovation efforts and would enable a low-resource facility to address the majority of causes of neonatal death (Maynard et al., 2015). Improvements in obstetric care are also needed to help prevent birth asphyxia (Engmann, Khan, Moyer, Coffey, & Bhutta, 2016).

In the last 25 years, maternal mortality have dropped by half in high-income settings; in contrast, maternal mortality rates in sub-Saharan Africa have plateaued (Engmann et al., 2016). Using expert consultation together with a 22-criteria decision matrix,

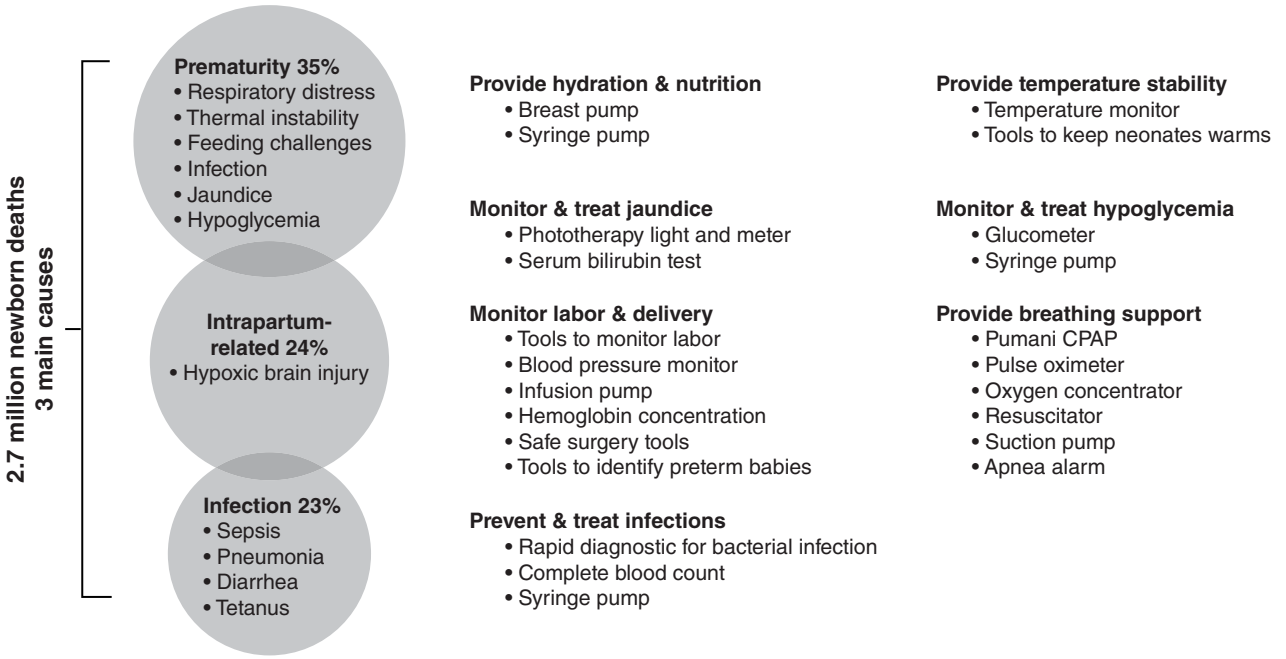

FIGURE 17-11 Leading causes of neonatal death and their corresponding clinical care pathways and management tools.

PATH identified five innovations with high potential to improve maternal health:

- Technologies to improve use of oxytocin to prevent and manage postpartum hemorrhage
- Uterine balloon tamponade to control severe postpartum bleeding
- An improved proteinuria test to diagnose preeclampsia
- Simplified dosing of magnesium sulfate to treat preeclampsia and eclampsia
- Better methods of blood pressure measurement validated for use in pregnant women (Herrick et al., 2014)

TABLE 17-3 details the assessment criteria used to evaluate technologies to address postpartum hemorrhage, preeclampsia, and eclampsia; the criteria span all the steps of the innovation and scale-up process. Other priorities identified to improve maternal health in low-resource settings include point-of-care diagnostics to identify and differentiate bacterial and viral sepsis; biomarkers to identify which women are likely to experience premature labor; tools to help safely deliver blood products; heat-stable and inhalable forms of oxytocin; and low-cost infusion systems for delivery of magnesium sulfate (Engmann et al., 2016).

Chronic Disease

As prevention and treatment of infectious diseases has improved in low-resource settings, noncommunicable diseases (NCDs) have increasingly emerged as a cause of morbidity and mortality (Hunter & Fineberg, 2014). NCDs, including chronic diseases such as cardiovascular disease, diabetes, cancer, and chronic obstructive pulmonary disease (COPD), now account for two-thirds of all global deaths (Checkley et al., 2014). Eighty percent of these deaths occur in LMICs (Checkley et al., 2014), and there is an important need for innovations to identify patients at risk and provide appropriate, effective prevention and treatment strategies.

For example, mHealth applications have the potential to play an important role in efforts to help patients with cardiovascular disease self-manage their disease, especially in combination with community health worker outreach (Checkley et al., 2014). However, a recent review examining the impact of mHealth interventions for NCDs in LMICs found that only 20 of 1,274 studies published in this area evaluated the impact of the intervention in a randomized clinical trial; overall results of these 20 studies showed a positive but modest effect on processes of care and clinical outcomes (Beratarrechea, Moyano, Irazola, & Rubinstein, 2017).

COPD often results from exposure to indoor air pollution associated with cooking fueled by biomass. Better low-cost spirometers are needed for diagnosis of COPD; improved cookstoves that reduce particulate matter to acceptable levels are urgently needed (Checkley et al., 2014).

TABLE 17-3 Assessment Criteria for Technologies that Address Postpartum Hemorrhage and Preeclampsia and Eclampsia

Category	Criteria	Evaluation Approach (high, medium, low)*
Gap	Gap-filling potential for health	Evaluate what layers of the treatment continuum could most greatly reduce mortality (e.g., prevention, diagnostics, treatment), the strength of the available data, and the percentage of cases that could be managed
Technology performance	Clinical evidence (efficacy/effectiveness)	Superior to benchmark,** similar to benchmark, inferior to benchmark
	Safety (patient/healthcare worker)	Superior to benchmark,** similar to benchmark, inferior to benchmark
	Ease of use	Superior to benchmark,** similar to benchmark, inferior to benchmark
	Usage requirements (e.g., durability, shelf life, electricity, storage temperature)	Technology has two or fewer usage requirements, technology has between three and five usage requirements, technology has greater than five usage requirements
Enabling factors	Alignment with internationally recognized guidelines (e.g., the World Health Organization, the International Federation of Gynecology and Obstetrics, and the International Confederation of Midwives)	Technology is recommended by at least one organization, divergent opinions exist, technology is not recommended
	Donor financial support (product development or implementation)	Funding greater than US$5 M, between US$1 M and US$5 M, less than US$1 M (or no funding identified)
	Other nonfinancial support	Placeholder for other nonfinancial supporters that may not be captured elsewhere; not scored
	Acceptability profile	Broadly acceptable, mixed, acceptable in few geographies (South Asia and sub-Saharan Africa)
	Organizational capabilities	All key partners have experience with the technology, a subset of key partners has experience with the technology, none of the key partners has experience with the technology
Market analysis	Manufacturing costs	Superior to benchmark** (lower cost), similar to benchmark, inferior to benchmark (higher cost)
	Distribution system requirements (warehouse, cold chain, transportation factors)	Infrastructure for a distribution channel(s) exists and high likelihood of utilization, infrastructure for distribution channel(s) exists and moderate likelihood of utilization, distribution channel(s) does not exist or a low likelihood of utilization

	Manufacturing plan established	Capture manufacturing information including delays, hurdles, risk, and complexity; not scored
	Target setting (community, primary health care, hospital)	Capture setting(s) where the technology would be used; not scored
	Target provider/administrator	Community healthcare worker, nurse or midwife, physician
	Potential multiple markets (additional value to the healthcare system)	Additional uses identified (high), no additional uses (low)
	Technology readiness level (clinical/regulatory development)	Regulatory or commercialization, confirmatory, discovery, or exploratory
	Cost of clinical development	Less than US$5 M, between US$5 M and US$50 M, greater than US$50 M
	Clarity of regulatory/clinical pathways	Class I US Food and Drug Administration (USFDA) device, class II USFDA device, class III USFDA device or requires efficacy data (e.g., drugs)
Unique considerations	System requirements (disruption)	Low system requirements (training/infrastructure), modest system requirements, high system requirements
	Product bundling	No other technologies required for impact, likely need to bundle with one technology, likely need to bundle with two or more technologies
	Other	Placeholder for other unique considerations; not scored

**Benchmark based on WHO treatment guidelines or the best benchmark for that technology category.

Surgery

Surgical care is an important component of care for maternal health, many noncommunicable diseases, and injuries, yet until recently it had been a neglected component of the global health agenda (Meara et al., 2016). A recent *The Lancet* Commission on Global Surgery recommended investment to strengthen access to safe surgical and anesthesia care (Meara et al., 2016). **EXHIBIT 17-6** outlines 10 high-priority needs to enable surgical care; technical innovation is needed to meet many of these needs, including infrastructure needs, sterilization capacity, ensuring a safe and adequate blood supply, and better patient monitoring technologies that can be used in settings with limited healthcare personnel (Meara et al., 2016). Expert groups have called for an international device consortium to encourage innovation to support surgical care in low-resource settings (Meara et al., 2016).

Conclusion

While technology has already changed the landscape of global health, there remains significant untapped potential to apply the tools of innovation to address many unmet global health needs. The examples discussed in the areas of mHealth, point-of-care diagnostics, and improved access technologies illustrate both the promise of new innovations and the significant challenges in translating these new tools to the field. Innovators can maximize their chances for

EXHIBIT 17-6 Criteria for Provision of Safe Surgical and Anesthesia Care

1. Trained surgical provider
2. Trained anaesthesia provider
3. Infrastructure, equipment and supplies necessary to perform safe general anaesthesia, loco-regional anaesthesia, laparotomy, caesarean delivery, and treatment of open fracture (including, for example, electricity, water, personal protective equipment for staff, basic laboratories, and HIV-testing capabilities)
4. Decontamination and sterilisation capacity
5. Blodd supply that is safe and affordable (screened and cross-matched blood)
6. Drugs, including antibiotics, pain medicines, and anaesthetics (from the WHO Model List of Essential Medicines)
7. Nursing care, which includes a record of appropriate physiological observations
8. 24 h surgical cover with the ability to review and respond to a deteriorating patient
9. Quality-improvement processes, including audit of perioperative mortality
10. Risk assessment and operation planning for planned procedures

success by following a well-defined process to ensure that they consider the specific needs of users from the beginning and have a pathway to deliver their solution at scale. Multidisciplinary collaborations within the global health, technology, and business communities will be needed if we are to achieve the promise of innovation and close the gaps in global health.

Discussion Questions

1. How do innovation and technology help address the underlying reasons for global health inequities? Give examples.
2. It is commonly observed that medical equipment from high-income counties that is donated to low-income counties tends to collect dust and not be used. Why do you think this is the case? What could be done differently to avoid this problem?
3. What are examples of successful applications of mHealth? Propose two new applications for mobile devices in global health.
4. Point-of-care diagnostic technologies have had a significant impact on global health, but they are not without their drawbacks. What are some potential drawbacks of point-of-care testing?
5. Pick a country and a clinical area you are interested in working on. Which strategies would you employ to identify needs in that clinical area for that particular country?
6. Identify a medical technology used in high-income countries that could be used in a selected low-income country. Describe the barriers that might prevent the technologies to be used in the selected country.

CHAPTER 18

Evaluations of Large-Scale Health Programs

Melinda K. Munos, Benjamin Johns, and Cesar G. Victora

Why We Need Large-Scale Impact Evaluations

In spite of large investments aimed at improving health outcomes in low- and middle-income countries (LMICs), there is a growing realization that few such programs and initiatives have been properly evaluated ("Evaluation," 2011; Evaluation Gap Working Group, 2006; Oxman et al., 2010). Global targets like the Millennium Development Goals (MDGs; http://www.un.org/millenniumgoals/) and Sustainable Development Goals (SDGs; http://www.un.org/sustainabledevelopment/) have also highlighted the need for more accountability in global health. In response, accountability initiatives for global health proliferated during the MDG era, including the Commission on Information and Accountability for Women's and Children's Health (World Health Organization [WHO], 2014), the Global Strategy (Every Woman Every Child, 2015a), the Unified Accountability Framework (Every Woman Every Child, 2015b), and Countdown to 2015 (http://countdown2030.org/2015/2015-final-report). Accountability initiatives were renewed in the SDG era, now including the Independent Accountability Panel (https://www.everywomaneverychild.org/2016/07/28/independent-accountability-panel/) and the Countdown to 2030 (https://www.countdown2030.org).

Notably, the emphasis has been primarily on tracking progress toward global and country targets, rather than understanding whether and why programs are improving health outcomes in LMICs. The problem of large programs not being evaluated (or only superficially evaluated) remains, making it difficult to understand what does and does not work to reduce mortality and improve health. The Evaluation Gap Working Group (2006) has summarized the issue well:

> Each year billions of dollars are spent on thousands of programs to improve health, education, and other social sector outcomes in the developing world. But very few programs benefit from studies that could determine whether or not they actually made a difference. This absence of evidence is an urgent problem: It not only wastes money but denies poor people crucial support to improve their lives.

This chapter covers a specific area of evaluation science: The rationale for and design and implementation of summative evaluations of programs being scaled up—that is, being delivered to large populations

(Mangham & Hanson, 2010). The chapter does not cover formative evaluations, which are aimed at improving program design prior to large-scale implementation, nor does it address program evaluations using qualitative methods.

The focus here is on evaluating the implementation of programs at scale that are aimed at delivering one or more biological and/or behavioral interventions simultaneously. Most, if not all, interventions packaged in these programs have been submitted to randomized trials that established their efficacy—for example, vaccines, antibiotic or antiviral drugs, micronutrients, and insecticide-treated nets. Thus, little doubt exists that these interventions would reduce mortality and improve health status, if they were delivered with appropriate quality to those who need them.

International and bilateral organizations often pay lip service to the need for evaluations of their large-scale initiatives. Some even pledge a given proportion of their program budgets for evaluation. Despite these lofty statements, few comprehensive evaluations of large health programs have been carried out, perhaps because independent evaluations can be threatening, given their potential for revealing shortcomings or lack of impact of a program.

Such evaluations often include several players with different—and sometimes conflicting—interests: the funders of a program or initiative (e.g., foundations or bilateral organizations), program implementers (e.g., international organizations such as WHO or the United Nations Children's Fund [UNICEF], their country missions, and national government counterparts), and the external evaluation team. In this chapter, we provide our perspective as independent evaluators, but many of the concepts and methods presented are applicable to internal evaluations as well. Although we focus on the technical aspects of design, implementation, and analyses, we also use our experience in a number of multi-country studies to highlight the political tensions that inevitably underlie evaluation science.

Throughout this chapter, three evaluations are consistently used as examples: the evaluation of Integrated Community Case Management in Burkina Faso, Ethiopia, and Malawi (**EXHIBIT 18-1**); a retrospective evaluation of the Accelerated Child Survival and Development Initiative (**EXHIBIT 18-2**); and an evaluation of the Tanzanian national voucher scheme for insecticide-treated nets (**EXHIBIT 18-3**). Key evaluation terms used throughout the chapter are defined in **EXHIBIT 18-4**.

EXHIBIT 18-1 The Evaluation of Integrated Community Case Management in Burkina Faso, Ethiopia, and Malawi

Integrated Community Case Management (iCCM) of childhood illness is a strategy that uses trained lay workers (often called community health workers [CHWs]) to manage uncomplicated cases of childhood illness and to refer more serious cases to health facilities. The strategy aims to treat sick children in their communities so as to reduce delays in care seeking and to reach sick children who might not otherwise be taken to a health facility (WHO & UNICEF, 2012). A scale-up of iCCM for childhood illness was implemented by the Ministries of Health (MoH) in Burkina Faso and Malawi with technical support from UNICEF and WHO, respectively, from 2009 to 2013. Simultaneously, the Government of Ethiopia expanded its iCCM strategy to include case management of pneumonia, in addition to diarrhea and malaria.

The programs in Burkina Faso and Malawi were funded by the Bill & Melinda Gates Foundation (BMGF) through the Partnership for Maternal, Newborn, and Child Health (PMNCH). In Ethiopia, support was provided by Canada's Department of Foreign Affairs, Trade and Development (DFATD) through UNICEF. The funders also commissioned a prospective independent evaluation of the program in these countries by the Johns Hopkins Bloomberg School of Public Health.

Three different evaluation designs were used to account for differences in program design and implementation in the three settings. In Burkina Faso, the evaluation used a quasi-experimental design, as the MoH had already identified the nine districts that would receive the program; seven comparison districts were selected using group matching. In Ethiopia, the evaluation was commissioned early enough that the evaluation team was able to randomize woredas (small administrative areas) to receive the expanded iCCM program or the existing program. In Malawi, where iCCM was scaled up to every district in the country and supported by different partners, the evaluation made use of a dose–response design, which assessed the extent to which changes in under-5 mortality at the district level were associated with the strength of implementation of the iCCM program in the district.

Detailed descriptions of the evaluations and results are available in several publications (Amouzou et al., 2016; Amouzou et al., 2016; Munos et al., 2016).

Data from Amouzou et al., 2016a; Amouzou et al., 2016b; and Munos et al., 2016.

EXHIBIT 18-2 The Retrospective Evaluation of the Accelerated Child Survival and Development Program

The Accelerated Child Survival and Development program (ACSD) was implemented by UNICEF in 11 West African countries between 2001 and 2005 with support from the Canada International Development Agency. The aim of ACSD was to increase coverage for proven interventions grouped in three broad packages: EPI+ (immunizations, vitamin A supplementation, insecticide-treated nets), IMCI+ (case management of malaria, diarrhea, and pneumonia; breastfeeding promotion), and ANC+ (antenatal and delivery care, postnatal vitamin A supplementation, intermittent presumptive treatment of malaria). The ultimate aim of the program was to reduce under-5 mortality by 20%.

In each participating country, ACSD high-impact districts were selected to scale up these interventions rapidly to full coverage. At the same time, a smaller set of interventions was supported, to a greater or lesser extent, in additional districts in each country—the so-called ACSD expansion areas. The countries that first moved ahead with rapid implementation were Benin, Ghana, Mali, and Senegal. More information on ACSD is available at the following website: https://www.unicef.org/health/23958_survivaldevelopment.html.

UNICEF commissioned the Bloomberg School of Public Health at Johns Hopkins University to conduct an independent retrospective evaluation of the ACSD project. The objective was to provide valid and timely evidence to child health planners and policy makers about the effectiveness of the ACSD project in reducing child mortality and improving child nutritional status, as a basis for strengthening child health programming in the future. From 2006 to 2008, the evaluation team reviewed documentation on ACSD implementation, evaluated intervention coverage using standard international indicators, and measured the program's impact, focusing on under-5 mortality in Benin, Ghana, and Mali. An evaluation in Senegal was also started but could not be completed due to a lack of information on comparison areas. Because the evaluation was retrospective, information on coverage and mortality was obtained through reanalyses of national surveys, comparing the ACSD high-impact districts with the remaining rural districts in the country.

The evaluation results are available in a publication (Bryce, Gilroy, et al., 2010) and at the following website: https://www.jhsph.edu/research/centers-and-institutes/institute-for-international-programs/completed-projects/accelerated-child-survival-and-development/.

EXHIBIT 18-3 Evaluation of the Tanzanian National Voucher Scheme for Insecticide-Treated Nets

Insecticide-treated nets (ITNs) are a cost-effective means of preventing malaria, which remains one of the major killers of children younger than the age of 5 in Africa. The Tanzania national voucher scheme is a targeted subsidy program that relies on the commercial sector to distribute ITNs throughout the country. Every pregnant woman who attends antenatal care in a government organization or nongovernmental organization (NGO) facility is eligible to receive a voucher that can be used as partial payment for an ITN.

The Tanzania national voucher scheme was rolled out gradually, starting in late 2004 in districts near Dar es Salaam, and ending with some of the most remote districts in the country 18 months later. Program managers decided that a phased rollout was necessary on programmatic grounds because of the size of the country. It was not feasible or acceptable to randomize districts by rollout phase. Nevertheless, the gradual scale-up allowed the evaluation team to compare areas with and without the voucher scheme at three points in time using cross-sectional household and facility surveys. Within-district changes were compared in the analysis with the length of time that the program had been operating in each district to determine whether program duration was associated with increases in net coverage.

The objectives of this study were to assess the changes in the level and socioeconomic distribution of ITN coverage over the period 2005–2007, during which the voucher scheme was initiated and expanded to a national scale, and to examine the link between program duration and change in household net ownership as a measure of program impact.

The evaluation was carried out by a team of U.K.- and Tanzania-based investigators (Hanson et al., 2009; Hanson et al., 2008; Mulligan, Yukich, & Hanson, 2008). Particular emphasis was given to describing the intermediate steps in the process leading to high ITN coverage, as well as to the assessment of costs and of impact of the program on reducing socioeconomic inequalities in net ownership.

EXHIBIT 18-4 Key Terms

Formative evaluation: An evaluation that aims to describe, quantitatively and/or qualitatively, *how* a program is being implemented, and its immediate outputs, with the aim of improving program implementation.
Summative evaluation: An evaluation that aims to quantify the impact or effect of a program on a population.
Input: An item necessary for the implementation of a program, such as funding, policies, plans, and human resources.
Process: Program activities such as training, systems or management improvements, infrastructure improvements, or demand generation.
Output: Short- or medium-term result of program processes, including changes in utilization, service quality, health worker competence or knowledge, and population knowledge or attitudes.
Outcome: Change in population-level intervention coverage or behavior.
Impact: Change in health status, such as mortality, morbidity, nutritional status, or fertility.
Contextual factor: A factor external to the program being evaluated that either *confounds* (masks) the program's true effect or *modifies* the effect of the program in the setting in which it is implemented.

These definitions apply to the terminology used in this chapter. Different agencies and researchers may vary in the way they define these concepts.

Planning the Evaluation

Who Will Carry Out the Evaluation?

Internal evaluations are carried out by the implementing institutions themselves, sometimes with the help of external consultants for specific tasks. Such evaluations often address levels of inputs and utilization (e.g., whether expected quantities of drugs or mosquito nets were procured and distributed) and issues related to process and outputs (e.g., surveys of the quality of care being provided or the frequency of supervision). Less frequently, internal evaluations include population-based coverage surveys, which may be subcontracted to consultants. Internal evaluations are classified into two main categories: (1) formative—that is, aimed at improving the program in its early implementation stage or (2) summative—that is, attempting to document an effect of the program on coverage levels or on health indicators. They may or may not include a comparison with other areas without the program.

The main difference between internal and external evaluations is the lack of independence between implementers and evaluators in internal evaluations, which creates an obvious conflict of interest because the continuity of funding for the program is affected by evaluation results. Nevertheless, internal evaluations are essential for fine-tuning a program, and are increasingly required or strongly encouraged by funders. For example, USAID's (2016) Child Survival and Health Grants Program has strongly encouraged grantees to conduct internal evaluations.

External, or independent, evaluations are carried out by researchers who are not involved in implementation. As a rule, the evaluation is funded by a third party—either the institution that provided funds for the implementation agency or an outside agency, such as the International Initiative for Impact Evaluation (3ie; http://www.3ieimpact.org/). Although external evaluators must collaborate closely with the implementation team—as will be discussed later in this chapter—they retain a level of independence that is essential for ensuring the credibility of the evaluation findings and can contribute to both formative and summative evaluations. In the ACSD evaluation (UNICEF, 2005), the results of internal evaluations proved to be more optimistic than later results from the independent team's external evaluation. This chapter focuses on external evaluations.

In-country research institutions that are independent of program evaluation can and should play an important role in these evaluations, bringing context-relevant experience and expertise to the team, serving as a first point of contact with program implementers, and providing continuity in the dissemination and eventual uptake of evaluation findings. The selection of the in-country research partners should be based on objective criteria that include research capacity relevant to the evaluation design and credibility with the ministry of health. Partnerships between in-country and external research institutions can result in expanded capacity and objectivity that will contribute to the success of the evaluation.

What Are the Evaluation Objectives?

The first task of the evaluation team is to review the available documentation on program objectives and goals, and to turn these items into evaluation

objectives. This transformation is best achieved by involving implementers and funders at the beginning of the evaluation design process. The evaluation objectives should be informed by the program *impact model* (described in more detail later in this chapter), which details the pathways from program inputs and processes to hypothesized impacts. A good impact model requires implementers and evaluators to make explicit the assumptions and hypotheses about how the program will work.

An early decision is to agree upon what is being implemented and what is being evaluated. For example, in the Burkina Faso iCCM evaluation (Exhibit 18-1), the program included both iCCM and some facility-based maternal and newborn activities, including training health workers on emergency obstetric and newborn care (EmONC) and acquiring materials such as obstetric delivery tables. However, discussions with implementers indicated that the program's objective was to reduce under-5 mortality by 25%, that the maternal and newborn health (MNH) activities were being implemented in other regions of the country with funding from other sources, and that there were no foreseen synergies between the iCCM and MNH components. In addition, modeling indicated that most of the impact of the program would be attributable to the iCCM interventions. For all these reasons, the evaluation team decided to focus the evaluation on the implementation and impact of the iCCM interventions, while also documenting MNH activities and assessing changes in coverage of MNH interventions.

The ACSD strategy (Exhibit 18-2) included three packages—EPI+, IMCI+, and ANC+—that were implemented with variable intensities in different countries. Although it may be tempting to try to design an evaluation of such a program in ways that disentangle the effects of different components, in practice this parsing is often impossible, because one cannot predict which components will end up being more strongly implemented, and in which part of the country. Also, many strategies are designed to take advantage of the potential synergies among its components—for example, ACSD—so that trying to break out their effects separately contradicts the entire concept underlying the program.

A related issue is the challenge of trying to attribute program impact to a single donor when a program is funded by several sources, each of which supports one or more components. Thus, the definition of what is being evaluated—and what is not being evaluated—must be agreed upon with evaluation funders and program implementers early in the process of evaluation design.

Large-scale programs and initiatives often establish quantitative goals in terms of what they expect to achieve. These aims are frequently expressed in terms of coverage (e.g., 70% of all pregnant women receiving a long-lasting mosquito net) or impact (e.g., a 25% reduction in under-5 mortality). Program goals are often expressed in ways that allow different interpretations. For example, the target coverage of a program based in health facilities could be calculated for the whole population or only for those persons living within a given distance (catchment area) of the facility.

A more complex example is how to interpret a "25% reduction in mortality." In this case, four interpretations are possible:

- Endline mortality being 25% lower in program areas than baseline levels in the same areas
- Endline mortality being 25% lower in program areas than in comparison areas (regardless of baseline differences)
- The reduction in mortality from baseline to endline in program areas being 25% greater than the corresponding reduction in comparison areas
- The rate of decline over time in the program areas being 25% faster than the rate of decline in comparison areas (e.g., 5% annual decline in areas covered by the program and 4% annual decline in comparison areas)

These four options have different implications for study design and sample size calculations, and it is essential to reach agreement on a common interpretation at the beginning of the evaluation. For example, in the Burkina Faso iCCM evaluation, the Ministry of Health's objective was to reduce under-5 mortality by 25% from baseline to endline, whereas the donor wanted to know whether under-5 mortality was reduced by 25% from baseline to endline relative to a comparison area. The evaluation team had to assess whether each of these targets was achieved and power the evaluation accordingly.

Once the overall evaluation objectives are defined, they must be broken down into specific evaluation questions that the study will try to answer. These questions are detailed later in this chapter. The ultimate objective of an evaluation is to influence decisions. Evaluation objectives and design depend on who the decision maker is and which types of decisions will be taken as a consequence of the findings. Program funders—for example, high-income-country organizations providing aid to health programs in LMICs—are typically interested in providing evidence to their governments and taxpayers that their funds led to a measurable impact on health outcomes, such as mortality, at a reasonable cost.

The decisions to be made in such cases include whether to continue funding the program and at what level, and whether the program strategy needs to be reformulated. Funders often work on a short timeline: They need results soon, in accordance with funding and electoral cycles. They also tend to be more interested in impact measurement than in intermediate results such as inputs, processes, outputs, or outcomes, although there is increasing interest is using intermediate data (e.g., quality of service provision) to improve programs.

In contrast, local implementers—for example, senior officials at the ministry of health—may seek reassurance that the program is moving in the right direction, that the quality of services is adequate, and that high population coverage is being or will be achieved. Their decisions primarily focus on improving the program through specific actions. Evaluation results may also have an important role in advocacy and provide political gains at country level.

Later in this chapter, we describe the importance of building a conceptual model that takes into account the different needs of different partners and the decisions they must make as a result of the evaluation findings. Obtaining information on health impact measures such as mortality is important, but just as important is to understand why the program had—or failed to have—a measurable impact.

When Should Planning for the Evaluation Occur?

Many advantages accrue from planning the evaluation at the time the program is being designed. Developing an evaluation plan and conducting a high-quality baseline survey can take 6 to 12 months, depending on the complexity of the program, the number of implementation and evaluation partners, and the size and scope of the survey. Early-onset, prospective evaluations allow collection of baseline data before implementation starts. They also allow thorough, continuing documentation of program inputs and the contextual variables that may affect the program's impact. Under some circumstances, early planning may enable the evaluation team to influence how the program is rolled out, thereby improving the validity of future comparisons. A disadvantage of prospective evaluations that include a comparison area is that program implementation may change over time for reasons that are outside the control of the evaluation team—for example, similar activities may be implemented in the comparison districts, or some of the program districts may have insufficient implementation.

In reality, evaluation is often an afterthought. Studies are frequently launched when implementation is already underway—and in some cases after the program cycle is completed. Such retrospective evaluations have important limitations. Documentation requires the reconstruction of project assumptions and activities by requesting the assistance of project implementers to produce records of activities and inputs. In such cases, the resulting information is often incomplete, inconsistent, and difficult to verify. Baseline (and sometimes endline) data are often unavailable. Even when they exist, they may be of poor quality, be based on sample sizes that are too small to address the evaluation questions, or lack information on all needed indicators. The importance of carrying out evaluations prospectively cannot be overemphasized.

How Long Will the Evaluation Take?

The answer to this question depends on whether the evaluation is retrospective, prospective, or a mixture of both techniques (ambispective) (Kleinbaum, Kupper, & Morgenstern, 1982). Fully prospective evaluations should include several sequential steps:

1. Collect baseline information.
2. Implement a system to document program activities and contextual factors.
3. Wait until the large-scale program is fully implemented and reaches high population coverage.
4. Conduct assessments of implementation strength (IS) and/or the quality of care (QoC).
5. Allow time for program adjustments based on IS/QoC assessment and documentation results, if time allows and implementers are receptive.
6. Allow time for a biological effect to take place in participating individuals.
7. Wait until such an effect can be measured in an endline survey.
8. Clean the data and conduct the analysis.

Each step can easily take one year, often longer. In our experience, steps 3 and 5 usually take longer than initially anticipated, due to delays in staff deployment, training, and commodity procurement. Step 6 can be fairly short for interventions with a rapid effect on outcomes. For example, case management of disease episodes or interventions that prevent disease transmission—such as insecticide-treated nets or indoor residual spraying for the prevention of malaria—can reduce mortality rapidly. In contrast, the time needed for an intervention to achieve its

biological effect can be much longer for interventions that require changes in behavior, such as changing breastfeeding practices to improve nutrition.

Step 7 can also slow down the production of final results. For example, assessment of child mortality is retrospective, and often the calendar midpoint of the mortality estimate is one to two years prior to the date of the endline survey.

Cleaning the data and conducting a full analysis (step 8) is often overlooked when planning an evaluation, but requires considerable time and effort to do well. The introduction of computer-assisted personal interviewing (CAPI) technology, in which paper questionnaires are replaced with data input through tablets and other devices, has greatly reduced the time needed to clean data, but evaluators need to allocate sufficient time both to program the CAPI questionnaires prior to data collection and to conduct data quality checks during and after data collection.

Donors, policy makers, and evaluation funders frequently organize their work in periodic cycles of 5 years or less. Because of delays in awarding contracts and implementing programs, this can lead to evaluation timelines of 12 to 36 months. Prospective impact evaluations of complex programs under real-life conditions, however, often require longer time frames. Because few policy makers are willing to wait so long for study results, it is important that data on intermediate outcomes, such as quality of care or achieved coverage, become available in the first year or two of the evaluation. This issue is discussed in further detail in the section on implementation.

Where Will the Evaluation Be Carried Out?

Many large-scale programs are implemented simultaneously in more than one country. For these programs, evaluations may include all countries covered by the program or only a subset of countries. The type of evaluation—for example, formative versus summative; adequacy versus plausibility or probability—may also vary by country. This decision is often made by the donor, with or without input from the evaluation team or implementers; less frequently the decision is made by the evaluation team in consultation with the donor or implementing agencies.

Decisions about which countries to select should be based on factors such as the likely strength of the implementation (or, for retrospective or ambispective evaluations, the strength of implementation to date), the availability of local research partners, and the need for the group of countries to be reasonably representative of geographic areas or epidemiologic patterns (e.g., the presence or absence of high levels of human immunodeficiency virus/acquired immunodeficiency syndrome [HIV/AIDS] or malaria). For example, when evaluating a program being rolled out in many LMICs, selection criteria should include both characteristics that are desirable in all participating countries (e.g., political stability, availability of local research partners, likelihood of strong implementation of the program) and characteristics that are desirable in the set of countries as a whole (e.g., reflecting the diversity of all implementing countries in terms of geography, health system strength, and epidemiologic profiles).

Whether country selection is done by evaluators, donors, or implementing agencies, it is important to keep track of the rationale for selecting some countries and not others, because these criteria will affect the external validity—or generalizability—of the evaluation findings (Bryce, Victora, Habicht, Vaughan, & Black, 2004). For example, if the evaluation is conducted only in countries that have performed well in implementing the program, then it is more likely that an impact of the program may be detected, but extrapolating the results to all implementing countries may not be justified. Similarly, evaluation teams may be more likely to select stable, non-conflict-affected settings for evaluation, but their results then may not be generalizable to implementations of the program in conflict settings. In cases where the decision about which countries to select is made by donors or implementers, it is particularly important for the evaluation team to examine and document the rationale behind country selection and to be alert to the possibility of conscious or unconscious bias—that is, the possibility that donors and implementers might tend to select better-performing countries (or countries where the program is likely to perform better) for evaluation.

The prospective multi-country evaluation (MCE) of Integrated Management of Childhood Illness (IMCI) is an example of an evaluation where country selection was conducted by the independent evaluation team based in part on inputs from implementers. IMCI is a strategy for reducing mortality among children younger than 5 years of age that includes case management guidelines for the integrated management of sick children in first-level health facilities, improvement of health systems support, and promotion of key family and community practices related to child health. IMCI was first introduced at the country level in 1996 by Tanzania and Uganda; by 2006, it had been adopted at the national level by ministries of health in more than 100 countries. The MCE aimed to provide information about the barriers to IMCI implementation, the effects of the strategy on health services and communities, the cost of the program, and the number of lives saved. Based on

early reports of strong implementation at the national level, 12 countries participated in the initial round of MCE assessments and data collection about IMCI implementation. More in-depth evaluations were conducted in 5 countries: Bangladesh, Brazil, Peru, Tanzania, and Uganda. Although the 5 countries selected for in-depth evaluation were judged to best meet the selection criteria among the 12 countries originally assessed, there were wide variations in the strength of implementation and, therefore, reasonable external validity to support generalization of the findings (Bryce, Victora, Habicht, Black, & Scherpbier, 2005).

In contrast, the ACSD evaluation in West Africa was retrospective, and UNICEF preselected 4 countries among the 11 participating in the program based on the fact that they were judged to have the strongest implementation of all program components. This decision likely introduced a positive bias into the design and limited the extent to which the results could be generalized to the remaining countries (Bryce, Gilroy, et al., 2010).

Once the country or countries for the evaluation are defined, there is a need to select which districts will be included in the study or, less commonly, to design an evaluation that covers all districts in the country; these options are discussed later in this chapter. As discussed in the context of country selection, the criteria by which districts are chosen may strongly influence the external validity of the evaluation results. Criteria for selecting countries and districts within countries should be reported in the main results publications arising from the evaluation.

Developing an Impact Model

The development of an impact model—also known as an operational or logic model, a model of change, or a conceptual framework—for the program's assumed effects is an essential step in designing an evaluation of a large-scale program. This model lays out how the program inputs are expected to lead to an effect on health. It is typically developed by the program evaluation team through discussions with program implementers prior to the start of the evaluation. The impact model may go through many iterations over the course of the evaluation to account for changes in the program itself, as well as changes in implementers' and evaluators' understanding of the program and its intermediate effects. Recording these changes in the impact model is an important aspect of documenting program implementation.

A commonly used framework includes the following sequence: inputs → process → outputs → outcomes → impact (Bryce et al., 2011). This generic framework must then be adapted to the particular program. **EXHIBIT 18-5** describes the IMCI strategy and its impact model developed by the evaluation team as part of the multi-country evaluation of IMCI (discussed in the previous section) (Bryce et al., 2005; Bryce et al., 2004). Tools are now available to facilitate the mechanics of developing, revising, and documenting versions of the impact model (for example, the Evaluation Planning Tool [hframe.io]).

In the Tanzania ITN evaluation (Exhibit 18-3), a detailed model was designed that included several necessary steps for the voucher scheme processes to translate into effective coverage: Vouchers needed to be in stock; women needed to attend antenatal services; women had to receive and redeem their voucher; and women needed to sleep under the voucher net. Evidence from three sequential surveys was used to assess intermediate steps in the program pathway so as to inform judgments about its effects (Hanson et al., 2009).

Impact models are essential for several reasons. For instance, they help clarify the expectations of program planners and implementers, by laying out these anticipated outcomes clearly. They help ensure that program implementers and evaluators have the same understanding of program activities and the pathways by which these activities are hypothesized to lead to specific impacts. They help estimate sample sizes, by defining what needs to be measured and what the magnitude of effects is likely to be. Most importantly, models contribute to the development of the evaluation proposal. For example, each box in Figure 18-1 generated relevant evaluation questions, indicators, and data collection strategies. The need to measure improvements in health worker performance, for instance, led to the development of health facility surveys based on the IMCI clinical guidelines, which were then implemented in several countries participating in the evaluation. Also, impact models help guide the analyses and attribution of the results. For example, if the evaluation finds a reduction in mortality in the absence of changes in the intermediate outcomes laid out in the model, it is unlikely that the observed impact can be attributed to the program.

Two other reasons for building impact models upfront can be cited. First, in a dynamic evaluation setting with feedback to implementers (described later in this chapter), models can help track changes in assumptions as these evolve in response to early evaluation findings. Second, models force implementers and evaluators to stay honest about what was expected. Unfortunately, program managers may be tempted to rewrite history by changing expectations as programs are rolled out and initial expectations are shown to be unrealistic.

EXHIBIT 18-5 The IMCI Impact Model

FIGURE 18-1 shows a simplified model of the pathways through which the developers of the strategy believed that IMCI would improve child health and nutrition. This model was originally developed by the evaluation team and refined through consultations with IMCI developers. For each box in the model, the evaluation team developed appropriate indicators and data collection procedures. The evaluation questions addressed the assumptions underlying this model, shown by the arrows in the figure. The impact model formed the backbone of the evaluation, serving as a common frame of reference for the evaluation team and program implementers, supporting estimates of needed sample sizes for various evaluation components, and providing a map for the data analysis that showed clearly the expected associations to be tested.

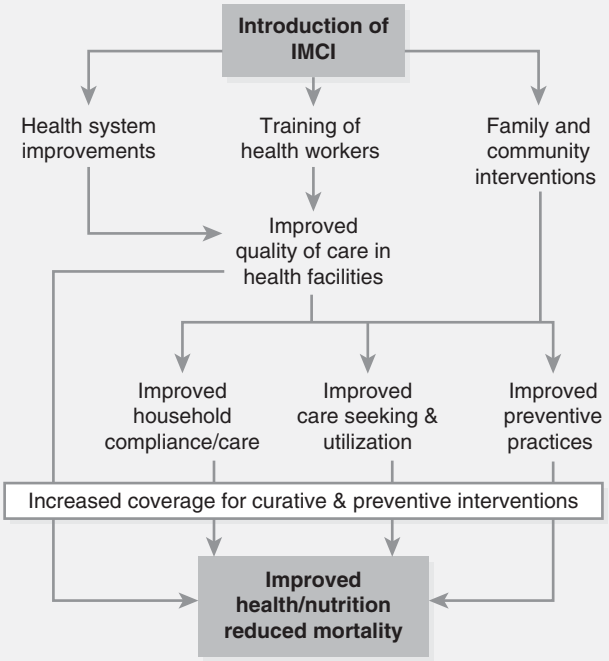

FIGURE 18-1 Example of an impact model: The multi-country evaluation of IMCI.

Reproduced from Bryce, J., Cesar, V. G., Habicht, J-P., Black, R. E., & Scherpbier R. W., on behalf of the MCE-IMCI Technical Advisors. (2005). Programmatic pathways to child survival: Results of a multi-country evaluation of Integrated Management of Childhood. Illness (Figure 2, pp. 4). *Health Policy and Planning, 20*(suppl 1).

The steps involved in developing and checking an impact model are summarized in **TABLE 18-1**. In essence, an impact model describes how a given program is expected to affect health. A later section of this chapter discusses how such models fit within the broader conceptual framework of factors influencing health status, which go beyond any given program or specific attempt to capture other determinants of health.

Stepwise Approach to Impact Evaluations

FIGURE 18-2 summarizes the basic stepwise approach to conducting an impact evaluation. Use of a stepwise approach allows evaluators to provide early feedback to program implementers and to halt the evaluation at midcourse if the implementation is not sufficiently strong to produce a measurable impact, thereby avoiding the costly surveys needed for assessing coverage and impact. The six steps are summarized next.

1. *Assess the technical soundness of implementation plans in light of local epidemiologic and health services characteristics.* It is not unusual for programs to be imported into a country without a proper assessment of whether they address the leading causes of morbidity and mortality, or without a realistic evaluation of the health system characteristics required for making the program work. When considering whether to evaluate a health facility–based program in Niger in the late 1990s, for example, the proposed study was dismissed when a desk review showed an average of 0.5 annual visit per under-5 child in the country, suggesting that the health systems were not strong enough to deliver the program in a short time frame. In recent years, a variety

TABLE 18-1 Steps in the Development of an Impact Model

Step	Details
Learn about the program	Read documents. Interview planners and implementers. Carry out field visits to future implementation areas. Use special techniques as needed: ■ Card-sorting exercise
Develop drafts of the model	Focus on intentions and assumptions. Document responses from implementers. Record iterations and changes as model develops.
Quantify and check assumptions	Review existing evidence and literature. Identify early results from the evaluation: ■ Documentation: What was actually done? ■ Outcomes: Are assumptions confirmed?
Use and evaluate the model	Develop an evaluation design, testing each assumption if possible. Plan for analysis, including contextual factors. Analyze the results. Interpret the results with participation by the implementers.

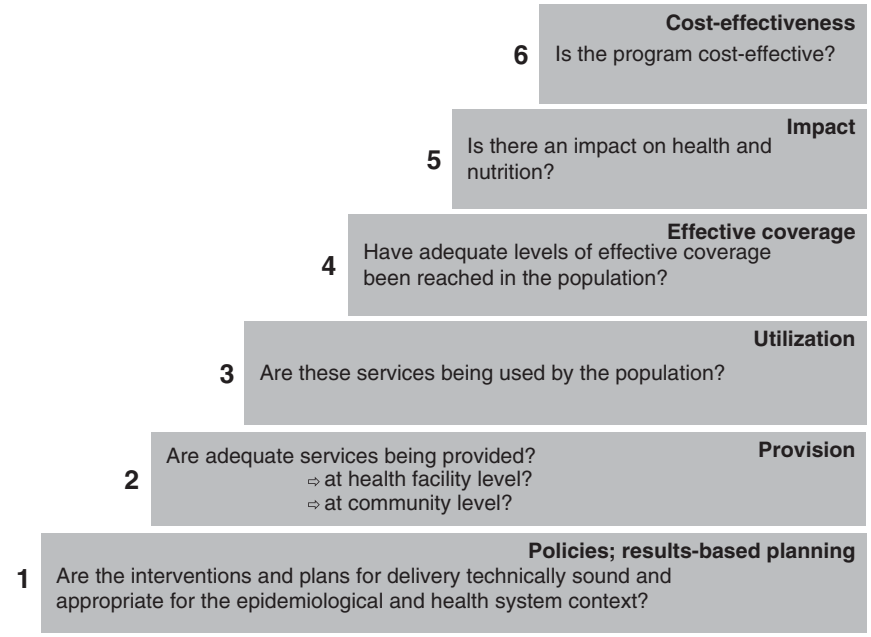

FIGURE 18-2 A stepwise approach to large-scale impact evaluations.

of tools for estimating the impact of interventions in different epidemiologic contexts have been developed. One of those instruments, the Lives Saved Tool (LiST), which is described in detail later in this chapter, can contribute to this kind of initial assessment (Johns Hopkins Bloomberg School of Public Health, n.d.a).

2. *Investigate whether the quantity and quality of the program being provided are compatible with a potential impact*. The evaluation team makes this judgment using the documentation of program activities, combined—if applicable—with surveys assessing the quality of care being provided. For example, in the iCCM evaluation in Burkina Faso, a

survey of CHWs found widespread stockouts of essential drugs and poor quality of care among trained CHWs. Based on these results (and low CHW utilization), it seemed that the program might not achieve an impact, and the endline coverage survey confirmed that the program did not lead to improvements in intervention coverage (Munos et al., 2016). A mortality survey was not deemed necessary to confirm the lack of impact.

3. *Assess whether data on outputs or utilization suggest that an impact is likely*. Even if the program inputs seem sufficient in terms of quantity and quality, uptake by the population may be limited. For example, if the number of insecticide-treated nets effectively distributed in a country is much smaller than the number necessary to achieve adequate coverage in the target population, continuing the study to measure health impact would be unwarranted. This step is usually assessed through documentation of program outputs and/or provider surveys; it does not require household surveys. For example, in the iCCM evaluation in Ethiopia, a survey of health extension workers (HEWs) showed low levels of utilization of such workers by sick children, despite finding that the HEWs provided high quality of care (Miller et al., 2014). As a result, it seemed unlikely that the program would have a population-level impact on mortality, and this suspicion was confirmed by the mortality survey conducted at endline (Amouzou et al., 2016).
4. *Check whether adequate intervention coverage has been reached*. Even if outputs appear to be adequate, it is necessary to check whether they have effectively reached the population and are being used by the target groups. Making this determination usually requires a population survey, which will cost much more than assessing the preceding steps on the basis of documentation. In the ITN voucher evaluation, for example, the nets that were distributed may have been sold to persons who did not reside in the intervention area, or they may have been used by the heads of households instead of by the pregnant women and young children who constituted the primary targets of the program. Assessment of coverage applies not only to interventions based on commodities such as ITNs or vaccines, but also to health-related behaviors—for example, condom use, breastfeeding, or care seeking.
5. *Assess the impact on health*. Measuring health impact often requires costly surveys, and the stepwise approach may reveal shortcomings in the preceding steps that suggest an impact is unlikely. For cost, timing, and logistical reasons, impact is often measured in the same household survey as coverage. However, the inclusion of impact measures—particularly mortality—can greatly increase the sample size and cost of the survey. If evaluators have identified shortcomings related to the program plan, implementation, or utilization and do not expect to see an impact on health status, they may decide to measure only coverage in the endline survey, as was the case in the Burkina Faso iCCM evaluation. Impact attribution also requires ruling out alternative explanations for the observed findings. This may prove to be difficult, or even impossible, no matter how much funders and implementers would like to produce an unequivocal statement. These issues are discussed in greater detail later in this chapter.
6. *Measure cost-effectiveness*. If there is evidence of an impact, the next question relates to cost-effectiveness. Measurement of program costs is discussed in subsequent sections of this chapter.

Types of Inference and Choice of Design

There is no single "best" design for evaluations of large-scale programs, as different types of decisions require different degrees of certainty to support their decisions. Whereas some decisions require randomized trials, other decisions may be adequately taken with observational studies. Also, the manner in which programs are rolled out often limits the scope of possible approaches to evaluation.

In real-world evaluations, the program of interest often accounts for a small part of the variability in the outcomes. **FIGURE 18-3** presents a simplified framework showing that health outcomes may be also influenced by socioeconomic factors, by changes in existing health services in the public and private sectors (which are outside the scope of the program of interest), and by other programs in the health and other sectors present in the same geographic areas.

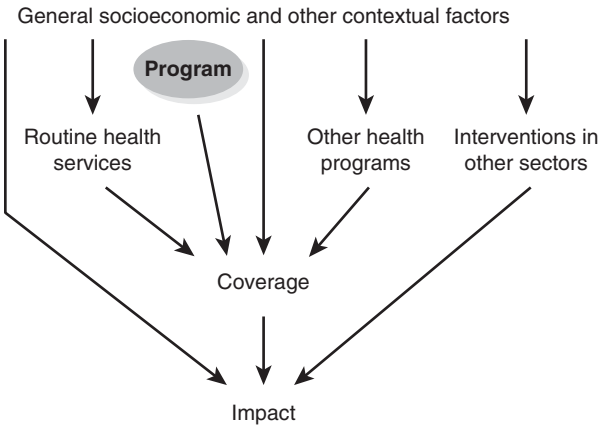

FIGURE 18-3 Simplified conceptual framework of factors affecting health, from the standpoint of evaluation design.

We will refer to this framework when describing different evaluation designs.

Habicht et al. (1999) proposed that evaluations can be classified as one of three types in terms of strength of inference, according to the ways in which the factors described in Figure 18-3 are handled. These types of inference are discussed next in relation to possible evaluation designs.

Adequacy Evaluations

Adequacy evaluations assess whether initial targets were met in the program areas or, at the very least, whether trends moved in the expected direction in terms of coverage or impact measures. For example, for a health manager it may be sufficient to establish that 80% coverage with an intervention (e.g., a vaccine) has been reached in the district; this evidence may be enough to support the continuation of the strategy for delivering this intervention.

Adequacy evaluations are often based on before-and-after studies in the program areas only, aimed at measuring progress in coverage or impact indicators. If the intervention included in the program is new to the geographic area, however, adequacy evaluations may be limited to an endline survey. Such a design is particularly well suited to studies of coverage, in which a direct link exists between the program and the frequency of the intervention's use in the population.

Adequacy evaluations assess whether targets were met or whether trends for outcome or impact measures moved in the expected direction. In contrast, use of adequacy evaluations to attribute changes in coverage or health status to a specific program is more complex. Adequacy evaluations do not include a concurrent comparison group and do not attempt to rule out other explanations for changes in coverage or health status; as a result, in most cases they cannot be used to attribute observed changes in outcomes or impact to a specific program. Even so, adequacy evaluations may produce valid inferences about the effects of a program if the following criteria are met: (1) the causal pathway from program to impact is relatively short and simple; (2) the expected effect is large; and (3) confounding is unlikely—that is, other factors in Figure 18-3 are either unchanged or are unrelated to the impact measure. For example, introduction of the *Haemophilus influenzae* type b (Hib) vaccine in Uruguay was associated with virtual disappearance of Hib disease (Pan American Health Organization [PAHO], 1996). In this example, (1) administration of Hib vaccine to the target population would be expected to lead directly to a reduction in incidence; (2) the vaccine is effective and, therefore, the expected effect was large; and (3) there were no other known factors that could lead to a large drop in Hib incidence. For most health programs and interventions, however, these conditions do not hold, and more complex evaluation designs are needed.

Nevertheless, adequacy evaluations are often the only alternative for programs that are scaled up rapidly and reach whole populations. Also, adequacy evaluations are often the only approach available to estimate the impact on health of policy changes effected through legislation—for example, salt iodization or changes in antimalarial drug regimens. These evaluation designs are also typically less expensive and complex to implement, so they may be used in situations where the program or donor does not require inferences about the effect of the program on coverage or health status.

Even if more complex analyses are being planned, adequacy of program coverage should always be reported. For example, in the Tanzania voucher evaluation (Exhibit 18-3), steady increases in national coverage of any type of net and ITNs were observed over the study period. ITN use among infants increased from 16% in the baseline survey to 34% in the endline survey (Hanson et al., 2009), showing important progress in this area but also revealing considerable room for improvement. Subsequent analyses determined that increases were significantly stronger in early-implementation districts.

In summary, adequacy evaluations are useful for assessing coverage outcomes, but more often than not they are insufficient for attributing these outcomes to the program or for establishing the health impact of a specific intervention.

Plausibility Evaluations

Plausibility evaluation designs aim to document the health impact of an intervention and to rule out alternative explanations by including a comparison

group and addressing confounding variables. Such evaluations are particularly useful when randomized allocation of the program is not possible for ethical, practical, or political reasons—situations that in real-life evaluations constitute the norm, rather than the exception. Plausibility evaluations are also useful to demonstrate the large-scale effectiveness of programs or interventions whose efficacy has already been demonstrated in smaller-scale studies. These evaluations may avoid some of the artificiality of randomized controlled trials (RCTs), which often address efficacy, by studying health impacts under real-life, less-than-perfect implementation conditions. For this reason, the external validity of plausibility evaluations is likely to be greater than that for tightly controlled trials (Victora, Habicht, & Bryce, 2004).

Several types of design may be used in a plausibility evaluation, some of which are described next.

Before-and-After Study in Program and Comparison Areas

A commonly used type of study design is the before-and-after program–comparison design. In this design, one or more areas—say, districts—that received the program being evaluated are compared with districts that did not receive the program (**FIGURE 18-4**). Because health impact indicators may be affected by factors other than the program, it is essential to document changes on the nonprogram factors depicted in Figure 18-4, in both the program and the comparison districts. If these factors differ at baseline from one set of districts to the other, or if they evolve over time in different ways, they may bias the results of the evaluation.

A detailed discussion of design issues with this type of evaluation is outside the scope of this chapter, but some common recommendations are as follows:

- Select as many districts as possible with and without the programs. Detailed sample size calculations are needed, but ideally aim for 10 or more districts in each group.
- In the data analyses, treat the districts as the units, rather than the individuals living in the districts. Thus, the sample size will be, for example, 10 districts in the program group, rather than the number of individuals surveyed.
- When the number of districts with the program is small, select comparison districts from the larger pool of districts without the program by matching them to the program districts according to key characteristics—the most important of which are baseline levels of the main impact indicator. If data on the impact or outcome indicators of interest are not available at the district level, districts can be matched on health systems, poverty, or education indicators, which are more commonly available at district level (see the later discussion of propensity score matching).
- In some cases, when the number of districts with the program is small, the districts receiving the intervention may be selected based on observable criteria, such as the need for the intervention. For example, districts with the highest levels of child mortality may be selected for the intervention, such that no districts with similar levels of child mortality remain in the pool of possible comparison districts. However, if a sufficient number of districts have child mortality levels that are close to those districts where the intervention is to be implemented, these districts should be selected as the comparison districts. This type of selection, which is known as nonrandom quantitative assignment of treatment, can be assessed using regression discontinuity analysis (West et al., 2008).

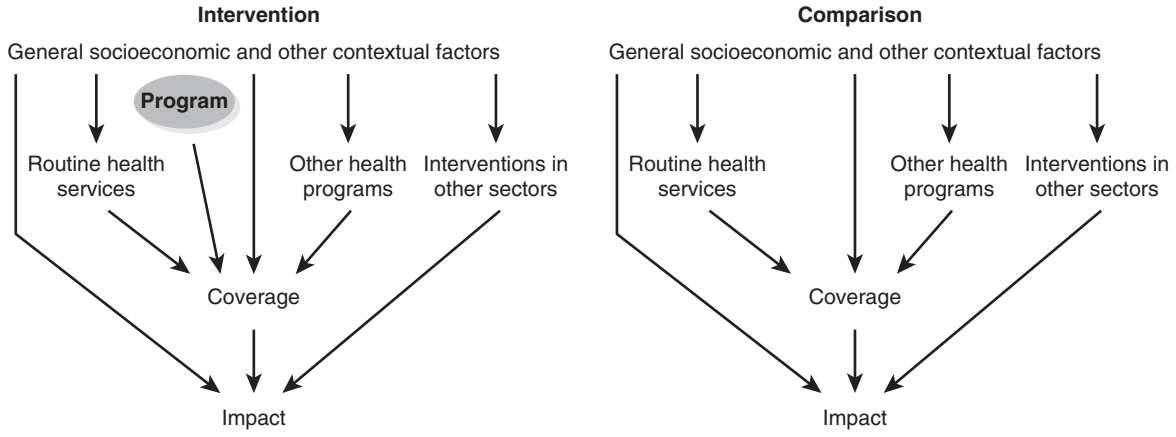

FIGURE 18-4 Schematic program–comparison design.

- Collect detailed information on all nonprogram factors listed in Figures 18-3 and 18-4.
- Take nonprogram factors into account in the data analyses by treating them as potential confounding factors and considering them in the interpretation of results (Cousens et al., 2009).

The before-and-after program–comparison design is well suited to evaluate the introduction of large-scale programs delivering interventions whose efficacy has already been demonstrated under experimental conditions, but that have yet to be scaled up. In this case, the comparison areas are completely devoid of the program's interventions—hence evaluators often refer to them as "virgin" or "untouched" comparison areas.

Many other large-scale evaluations address new strategies for accelerating the delivery of biological or behavioral interventions that are already being implemented, to a greater or lesser extent, in other districts in the same country. An example is the ACSD initiative in West Africa (Exhibit 18-2). This program represented a renewed effort to intensify the delivery of vaccines, ITNs, vitamin A, antenatal care, breastfeeding promotion, and case management of pneumonia, diarrhea, and malaria. An evaluation of ACSD showed that, paradoxically, some of these interventions had higher coverage in districts without ACSD than in districts with ACSD (Bryce et al., 2010). In such cases, the program–comparison design does not make much sense, and other design alternatives are required.

Observational before-and-after designs can be strengthened when sufficient data are available. For example, if outcome or impact data for some years before the start of a program are available, time-series or interrupted time-series designs can help control for confounders that do not change over time (Gertler et al., 2016). Evaluators need to provide an explicit rationale for assuming that important confounders do not change over long periods of time.

In recent years, more attention has been paid to the use of propensity-score matching at the individual level to evaluate large-scale programs using large survey data sets (Axelson, Bales, Minh, Ekman, & Gerdtham, 2009; Jalan & Ravallion, 2003; Mensah, Oppong, & Schmidt, 2010). These methods control for *observed* differences between individuals who received treatment and individuals who did not. Evaluators need to discuss the possibility of unobserved confounders that may lead individuals to receive or not receive treatment, and address how these factors may threaten the validity of the results.

In some cases, different approaches may be combined (Gertler et al., 2016). As mentioned earlier, districts may be matched before the start of implementation, and data across several years may be collected. While these approaches strengthen the overall evaluation design and the plausibility of the results, they are also complex and analytically challenging.

The Ecological Dose–Response Design

When a program includes biological or behavioral interventions that are being promoted throughout a country, a dose–response design may be the most appropriate evaluation approach. For example, in the Malawi iCCM evaluation, every district in the country was implementing iCCM delivered by health surveillance assistants (HSAs), and the evaluation assessed the association between the density of iCCM-trained HSAs and care seeking and under-5 mortality reduction at the district level. **FIGURE 18-5** shows the correlation between density of trained workers and changes in care seeking and mortality; no correlation was observed and no significant associations were found after adjusting for potential confounders.

In light of widespread scaling-up of health interventions in many countries, dose–response designs may become increasingly useful in the future. **EXHIBIT 18-6** proposes an approach to such studies.

Randomized (Probability) Evaluation Designs

Randomized designs are the gold standard for achieving internal validity. Because health programs are delivered to groups rather than individuals, cluster-randomized trials are appropriate for their evaluation (Donner & Klar, 2000). Random allocation of clusters of individuals—for example, districts—to receive or not to receive the program or intervention increases the likelihood that the two study arms will be highly comparable in terms of confounding variables, including those that cannot be measured directly.

This situation is particularly likely to hold when the number of clusters available for randomization is large. If the number is small—as is often the case for large-scale programs delivered at the district level—the program and comparison groups may still differ substantially in terms of baseline confounding factors, in spite of randomization. In these cases, constrained randomization may be used to improve comparability of the two study arms (Hayes & Moulton, 2009).

Even programs that consist of packages of proven interventions may be evaluated through randomized trials. Certain programs, such as provision of vouchers, provision of health insurance, or exemptions from user fees, may be unaffordable if the entire

Independent evaluation of the integrated Community Case Management of childhood illness strategy in Malawi using a National Evaluation Platform design. *The American Journal of Tropical Medicine and Hygiene, 94*(3), 574–583.

EXHIBIT 18-6 The Evaluation Platform Design

The prevailing evaluation paradigm assumes that programs are implemented in a few districts and not in the rest of the country. Changes in service provision, utilization, coverage, and sometimes health impact are documented over time, and gains in the intervention districts relative to comparison areas are attributed to the program, reflecting the assumption that any improvement is a direct result of program inputs. The counterfactual supposition is that in the absence of the program, outcomes in the target districts would have shown trends similar to those in the comparison areas. Several types of bias may compromise this comparison, including selection biases (e.g., districts chosen for the program may have special characteristics that favor implementation) and confounding factors. This traditional evaluation design remains popular despite its limitations because no feasible alternatives may exist to it; if properly conducted and analyzed, such evaluations often provide valuable information.

Recent experience in evaluating large-scale programs and initiatives suggests that this traditional design has important limitations in the current development context. "Untouched" comparison areas are seldom available because similar biological or behavioral interventions are often being scaled up by other programs or initiatives—with greater or lesser success—in different geographic areas. As a consequence, populations in the comparison area are often exposed to interventions that are similar to those promoted in the program area. For example, in the ACSD evaluation (Exhibit 18-2) in Mali and the iCCM evaluation (Exhibit 18-1) in Malawi, several of the comparison districts were receiving virtually the same interventions as the program districts, with support from other donors. Even in situations where a program is planned to be scaled up in several districts, the reality is that implementation speed tends to vary from district to district, as was the case in the Tanzania ITN voucher study. Therefore, in many circumstances dose–response analyses relating implementation strength to coverage and health impact make more sense than comparisons of program and nonprogram districts.

To further complicate the issue of attribution, health status is influenced by a myriad of factors other than an individual program. At least four categories of contextual factors must be considered (Victora et al., 2005), as suggested in Figure 18-3: (1) preexisting health services, whether public or private; (2) the presence of new health programs other than the one being evaluated; (3) the presence of interventions in other sectors that may affect health (e.g., water, sanitation, or education); and (4) overall socioeconomic and environmental conditions. This broad framework of determinants of health requires that evaluations go well beyond the health sector. In turn, evaluations of all health programs require careful documentation of contextual factors and their incorporation in data analyses and interpretation.

For all these reasons, instead of the current practice of evaluating one program at a time, it makes much more sense to develop a broad evaluation platform to assess all of the multiple programs that are in place within a country. For example, partners can work with national and local governments to support nationwide assessments of programs in different

(continues)

EXHIBIT 18-6 The Evaluation Platform Design *(continued)*

areas: maternal and child health; reproductive health; disease-specific control programs, including those for malaria and HIV/AIDS; and efforts aimed at strengthening health systems (Global Initiative to Strengthen Country Health Systems Surveillance [CHeSS], 2008).

From 2013 to 2017, the National Evaluation Platform (NEP) project implemented NEPs in Malawi, Mali, Mozambique, and Tanzania with funding from Global Affairs Canada and technical assistance from the Institute for International Programs–Johns Hopkins University (IIP-JHU) (Johns Hopkins Bloomberg School of Public Health, n.d.b). The project aimed to implement country-owned and -led NEPs, with a focus on building country capacity to manage, assess, and use existing data to answer evaluation questions as defined by country governments. These country NEPs mapped sources of population and health data along the pathway to impact, as well as other contextual factors; assessed their quality; and worked with governments to identify and respond to priority questions.

In Mali, for example, the Ministry of Health wanted to understand why key maternal, newborn and child health (MNCH) indicators were poorer in one region of the country than in other regions. In response, the Mali NEP partners, including the Center for Research, Study, and Documentation on Child Survival (CREDOS), the National Institute of Public Health (INRSP), the National Institute of Statistics (INSTAT), the National Directorate of Health (DNS), and the MoH Unit for Planning and Statistics (CPS) brought together district-level data from population surveys, from routine health information systems, and on contextual factors to try to understand the factors associated with disparities in district- and regional-level indicator trends over time. IIP-JHU provided technical assistance and capacity building in evaluation question design, data quality assessment, indicator calculation, and multiple approaches to analysis (cross-group comparisons, trend, and regression analyses) to support the work done by the Mali NEP team.

The NEP project was inspired by the evaluation platform approach proposed by Victora and others (2009), which included the following steps:

1. Develop and regularly update a district database that includes existing demographic, epidemiologic, socioeconomic, and health infrastructure variables, derived from sources such as censuses, economic surveys, poverty maps, and service availability censuses. All districts in a country—or in a subnational region—would be included.
2. Conduct an initial survey (or build on existing and future household surveys), to be repeated every three years or so, to measure coverage levels for proven interventions and health status. Ideally this survey would also allow estimation of mortality and prevalence of biomarkers.
3. Establish a continuous monitoring system for documenting provision, utilization, and ideally quality of interventions at the district level, with mechanisms for prompt reporting to local, national, and international audiences.

The experience of the NEP project has shown the potential value of this approach, but also highlighted the challenges in implementing evaluation platforms in a sustainable, country-led way. Development of a comprehensive set of data alone is not sufficient. Statistical and health institutions in many countries do not have the capacity to analyze much of the data that they collect, so a key task for many evaluation platforms will be to build country capacity in evaluation principles; core data concepts; data management, analysis, visualization, and interpretation; and audience-appropriate communication of results. Other challenges include sharing data across institutions and sectors, building ownership and understanding of the platform at senior levels of government (see the *Public Health Infrastructure* chapter for more on data sharing), and ensuring adequate staffing in country institutions to collect, compile, assess, and analyze data to answer evaluation questions.

target population must be covered. In such cases, randomization of individual participants or geographic regions may be possible (Powell-Jackson, Hanson, Whitty, & Ansah, 2014). To perform this type of study, all districts in a country would be listed, possibly stratified into categories of risk (e.g., high, medium, or low frequency of the main study outcome), and then allocated randomly within each stratum either to receive the program under routine conditions of implementation or to not receive it. Politicians and managers—as well as members of the population—need to agree with the process of randomization, as do all involved district authorities and implementation partners.

In practice, a variety of ethical, political, and practical barriers to randomizing districts to receive or not to receive a program may exist (Black, 1996; Victora et al., 2004). For instance, large-scale programs usually encompass biological and behavioral interventions whose efficacy has already been established in RCTs in smaller populations, so that withholding them from population groups for the purpose of evaluation is difficult to justify. Political barriers may arise

from a similar source: Policy makers are understandably reluctant to withhold proven interventions from the population for the purpose of research. Practical barriers include the assumptions within an RCT that the researcher controls the pace and quality of intervention delivery and that the intervention does not change over time—criteria that cannot be met when evaluating strategies or programs that are being scaled up by governments and their partners and often are undergoing fine-tuning in response to early experience or intermediate results from the evaluation.

These barriers to RCTs tend to counterbalance the increased internal validity associated with their use. Thus, it is not surprising that randomized designs are rare in large-scale effectiveness evaluations. In addition, evaluators are often called in when it has already been decided which areas will receive—or are already receiving—the program and, therefore, cannot influence its deployment.

Among the few examples of RCTs used for evaluation programs affecting health outcomes are two Mexican studies, which are summarized in **EXHIBIT 18-7**.

EXHIBIT 18-7 Large-Scale RCTs: The Progresa and Seguro Popular Evaluations in Mexico

Mexican policy makers and researchers have pioneered the use of RCTs for large-scale program evaluation in LMICs. Two large studies have attracted special attention: the evaluation of Progresa, a program that included conditional cash transfers (Rivera, Sotres-Alvarez, Habicht, Shamah, & Villalpando, 2004), and the evaluation of Seguro Popular, a health insurance initiative (King et al., 2009).

Progresa was a large-scale, incentive-based development program with a built-in nutritional intervention. Taking advantage of the lack of resources for covering all eligible families in the country at the same time, the evaluators designed a two-wave, stepped-wedge trial. Of 347 poor rural communities in 6 central Mexican states, 205 were randomly assigned to immediate launch of the program in 1998; another 142 were slated to initiate the program 2 years later (Rivera et al., 2004). Random samples of children in those communities were surveyed at baseline, and again at 1 and 2 years afterward. Participants, all of whom came from low-income households within each community, were selected on the basis of an index of household assets.

Progresa provided micronutrient-fortified foods for women and children as well as health services and cash transfers for the family. The original design sought to provide a 2-year window during which Progresa would be implemented in the intervention communities but not in the comparison communities, but political pressure to accelerate the program led the comparison communities to start receiving the program more than 1 year earlier than originally planned, in late 1999 rather than in early 2001. In addition, nearly half of all young children (younger than 6 months) were lost to follow-up by the time of the 2-year follow-up. Progresa was associated with better growth in height among the poorest and younger infants, but not in the sample as a whole. After 1 year, mean hemoglobin values were higher in the intervention group than in the comparison group, but there were no differences in hemoglobin levels between the two groups at year 2, after both groups were receiving the intervention.

The second evaluation involved an innovative cluster trial of health insurance—Seguro Popular—in Mexico, one of the largest randomized health policy experiments ever carried out. Policy makers in 13 of the 32 Mexican states agreed to join the study. From more than 7,000 clusters (health facility catchment areas) in these 13 states, the evaluators "negotiated access to 74 cluster pairs in seven states, with inclusion based on necessary administrative, political, and other criteria" and then randomly assigned one health cluster from each pair to receive the Seguro Popular program. The main finding was a reduction in catastrophic expenditures in health of 1.9 percentage points. Although program resources reached the poor, contrary to expectations, they did not have any effects on medication spending, utilization of health services, or health outcomes after 10 months of follow-up. The authors of the evaluation (King et al., 2009) recognize that the short implementation period may have precluded documenting an impact on outcomes that are unlikely to change rapidly. They also note that the program varied considerably across areas.

These two Mexican trials make an important contribution to the literature on the evaluation of large-scale programs, but they also reveal that RCTs are not a panacea for all evaluation ills. First, obtaining agreement of policy makers at all levels—from national to local—is not a trivial matter. Moreover, external validity may be affected because of low compliance with randomization at local level. That may have been the case in the Seguro Popular trial, in which 74 cluster pairs were nonrandomly selected from more than 7,000 clusters.

Second, both trials show that getting policy makers and managers to accept randomization is a major achievement, but ensuring their continued support during the trials is also essential. In both studies, the patience of decision makers proved shorter than what would be required for a full assessment of the intervention's impact. Both trials demonstrated that, when taken out of their traditional context—that is, efficacy studies that are completely under the control of researchers—RCTs do not perform well for the evaluation of large-scale, real-life programs.

Stepped Wedge Design

An attractive alternative to the RCT is the stepped wedge design, a variation of randomized cluster trials (Brown & Lilford, 2006). This strategy should not be confused with the stepwise approach to evaluation described in Figure 18-2. A stepped wedge design makes use of implementation timetables that specify introduction of the program or strategy earlier in some geographical areas than in others. This phased rollout allows evaluators to use the later-implementation areas as comparison groups for the earlier-implementation areas.

A hypothetical example of a randomized stepped wedge design follows. Suppose the capacity to train health workers or to procure a commodity is limited, so that only a few districts can be covered in the first year of the program. These areas are selected randomly from all districts in the country, and start to receive the program. In the following year, another wave of districts is selected from those without the program, and so forth, until all districts are covered. At any given time until the last implementation wave is complete, there will be districts with the program and districts without the program; the latter provide a randomized comparison group.

This design has advantages from an ethical standpoint, because it would not have been possible to implement the program in all districts at the same time, and selection of program districts is random. Nevertheless, fewer than 20 such trials have been published in the literature (Brown & Lilford, 2006), and none of these reports have dealt with large study units such as districts. Instead, the study units in most cases were health facilities, vaccination teams, or small communities.

As with standard RCTs, practical constraints to implementing stepped-wedge trials at the district level in LMICs exist:

- It may be difficult to explain the randomization process to district authorities and convince them that there are no hidden allocation biases.
- National governments are often reluctant to leave any district completely devoid of a program. Instead, they may attempt to be "equitable" by allocating some amount of resources to all districts.
- Other bilateral or international organizations delivering health programs in the country already have their favorite districts, and may continue to implement activities that are similar to the program.
- Many infectious diseases demonstrate marked seasonal or cyclical patterns, and it may be difficult to distribute program-implementation waves of districts over time so that temporal patterns do not affect the interpretation of results.
- Implementation timetables are subject to many influences, and often change over time, which may weaken the design.
- This design can be used only for programs or strategies that are unlikely to have effects beyond the border of a district. It would not be appropriate, for example, in evaluations of mass-media campaigns.
- The analysis of this design is particularly complex, and requires strong statistical support during both the design and analysis stages.

These reasons may explain why stepped wedge designs, although available since the 1980s, have never enjoyed great popularity despite their theoretical advantages (Brown & Lilford, 2006).

Occasionally, programs will be implemented in only selected areas of a province or district, due to budgetary or other constraints. In these cases, it may be possible to exploit the employment of a nonrandomized phased implementation (stepped wedge) or arbitrary break in implementation along the borders of districts (Sood et al., 2014). These types of designs, which are called regression discontinuity designs or geographic discontinuity designs, fall into the "plausibility evaluation" category, although they are considered some of the stronger methods for observational studies, and have in some cases closely replicated random designs (Buddelmeyer & Skoufias, 2004).

Defining the Indicators and Obtaining the Data

Documentation of Program Implementation

In terms of the stepwise design described in Figure 18-2, documentation is essential for assessing the first question: Are the interventions and plans for delivery technically sound and appropriate for the epidemiologic and health system context? Documentation will also contribute quantitative information on implementation activities that can help address the second question: Are adequate services being provided at the facility and community level? The ultimate objective of documentation is to go beyond program objectives and goals to understand what actually took place at the population level. Systematic documentation is essential for understanding why a program achieved—or failed to achieve—its intended

effect. Qualitative studies are often a useful adjunct to documentation.

Obtaining detailed data on program implementation is essential because—unlike what happens in tightly controlled, small-scale trials—large-scale programs often fail to deliver what was originally proposed. The ACSD evaluation showed, for example, that whereas vaccines and vitamin A supplements reached high coverage in the target districts, other equally important parts of the ACSD package, such as insecticide-treated nets, were affected by unforeseen stock-outs that resulted in insufficient distribution of these items to the population.

It is often assumed that data on program implementation are readily available from those parties involved in delivering the program. Our experience, however, shows that this is rarely the case. In the Malawi iCCM evaluation, information about the hard-to-reach areas that were supposed to be covered by iCCM-trained CHWs was not possible to obtain. In Burkina Faso, data on drug stock-outs at the CHW and facility level were not available. In the retrospective ACSD evaluation, obtaining data on the early stages of the program proved difficult because records were often incomplete, and some key staff involved in setting up the program were no longer available to be interviewed.

Documentation efforts should strive to cover the following topics, which are drawn from the conceptual framework for the program (Figure 18-1) and reflect the stepwise approach (Figure 18-2):

- Describe the original program proposal—development, adaptation, program strategies and activities, associated policies, and delivery strategies.
- Describe how the original proposal changed over time, and why—for example, whether a result of internal decisions or due to feedback by the evaluation team.
- Quantify the program inputs, processes, and outputs—for example, the number of health workers who were trained, the types of commodities that were procured and distributed, the frequency and duration of stock-outs, the type and frequency of supervision activities, utilization by the target population of the services being provided, and the frequency and nature of community-level activities.
- Describe contextual factors that may affect the program's impact—for example, epidemiologic, health systems, demographic, or sociocultural characteristics.

Methods for documentation include desk reviews of program and policy documents, training materials, workshop and supervision reports, and administrative records related to program inputs and outputs. This step may also require talking to implementers, conducting in-depth interviews, and conducting focus-group discussions.

Where key data on program implementation are not available from program documents, or where interviews with implementers contradict the quantitative program data, primary data collection to describe the state of program implementation may be needed. In the Burkina Faso iCCM evaluation, for example, data provided by health districts showed that the number of iCCM-trained CHWs remained constant over time, following the initial iCCM training. In contrast, interviews with district staff reported substantial turnover among CHWs. To better understand the staffing situation, and to fill gaps in program data with respect to utilization and drug stock-outs, the evaluation team conducted a survey of CHWs in the regions that received the program (Munos et al., 2016). CHWs were asked about their selection, training, and supervision, and data collectors observed their drug stocks and abstracted information from their consultation registers. In addition, in-depth interviews were conducted with a subset of CHWs as well as with caregivers of young children and with the nurses who supervised the CHWs.

Similar assessments of implementation, sometimes referred to as implementation strength assessments or implementation snapshots, are increasingly being conducted during program evaluations to provide high-quality data on program processes and outputs (Hargreaves et al., 2016). These assessments are generally surveys of the front-line providers who are delivering the program interventions. Survey methods are available for this purpose. Typically, a multistage sampling scheme is used to select units within the program areas—for example, health facilities or communities. Within these units, health workers involved in service delivery are then sampled. The content of the assessment will vary somewhat depending on the program activities, interventions, and modes of delivery. For programs delivering health services to populations, key domains may include training, supervision, availability of drugs and commodities, availability of guidelines and other job aids, and utilization of services. In addition to the quantitative assessment, qualitative interviews may be conducted with providers, their supervisors, and program beneficiaries or other community members to better understand challenges in implementing the program or delivering interventions. As discussed in the next section, assessments of the quality of service provision may also be added to the implementation strength assessment.

Measurement of Intervention Quality

Most health programs include interactions between health workers and the target population, with or without the provision of commodities. A behavioral change and communications intervention may include individual or group sessions; a vaccination program will include delivery of the vaccine to the target population; and case management interventions will include interaction between a community- or facility-based provider and a patient, often followed by provision of treatment. While documentation will provide quantitative information on these interactions, it is also important to assess their quality.

Assessments of the quality of service provision are generally conducted in a sample of health workers or health facilities, using the same sampling approach described earlier for implementation strength assessments. For each sampled provider, data collectors typically observe the interactions between the health worker and members of the population. Many survey tools also include a description of the facilities where health workers operate (e.g., the physical space, drug supply, equipment) and incorporate exit interviews to assess user satisfaction. For case management surveys, a second examination of the same patient by a gold-standard examiner is often included, which is then compared with the original conduct of the health worker. The quality of case management for rarely occurring events is sometimes assessed through the use of written or oral scenarios. Further details on how to conduct these surveys, and standard indicators to be used, are available elsewhere (Gouws et al., 2005).

Measuring Coverage

Although population coverage of interventions can sometimes be estimated from routine health system data such as utilization statistics (e.g., dividing the number of births reported by skilled attendants by the estimated number of births in the population), in most instances coverage measurement requires household surveys. This technique is necessary because population movements may occur—for example, mothers from a neighboring district coming to the focus district to give birth—and because the availability of simple data on commodities disbursed (e.g., antibiotics, oral rehydration solution [ORS] packets, or ITNs) does not guarantee that those items reached, and were used by, those in need. In addition, in many LMIC settings, routine health system information on the numerators (services delivered) and the denominators (individuals in need) for coverage indicators can be biased upward or downward due to incomplete records, incentives for over-reporting, or inaccurate census projections that contribute to the denominator. Even with these potential biases, coverage data from routine sources may still be useful for local planning, although their use in an effectiveness evaluation requires a robust assessment of data quality to avoid invalid inferences.

Many LMICs now have regular surveys on maternal and child health, such as Demographic and Health Surveys (DHS; The DHS Program, n.d.b) or UNICEF's (n.d.) Multiple Indicator Cluster Surveys (MICS) that are carried out every three to five years in a given country. In addition, surveys may assess coverage of disease-specific programs, such as malaria indicator surveys (MIS; The DHS Program, n.d.c) and HIV/AIDS indicators surveys (The DHS Program, n.d.a).

These types of surveys include standard indicators, usually defined by multi-institutional or interagency working groups. It is essential that program evaluations comply with agreed-upon indicators, so that the results can be compared with those from other evaluations and studies.

Surveys may be used as part of evaluations in several types of scenarios:

- A national survey (e.g., DHS or MICS) is carried out at a suitable time for the evaluation, and the number of households sampled in the program and comparison areas is sufficiently large to yield precise estimates. This was the case in the Malawi iCCM evaluation, for which DHS data were used as the baseline, and an "MDG survey" conducted by MICS was used as the endline (Amouzou et al., 2016).
- A national survey as described previously is planned, but needs to be oversampled in program and/or comparison areas. This was done in the ACSD evaluation in West Africa (Bryce et al., 2010).
- No suitable surveys are planned, and the evaluation team has to carry out its own survey in program and comparison areas. This was the case in the Burkina Faso iCCM evaluation; while a DHS was available to use as the baseline, the sample size at the district level was insufficient and oversampling in the evaluation districts was not an option (Munos et al., 2016).

Survey samples are usually insufficient for providing precise coverage estimates at the district level. Some exceptions do exist, however, such as the Malawi 2010 DHS and 2014 MDG survey, which sampled 1,000 households per district, and the India National

Family Health Survey, which had a total sample of more than 600,000 households in 2015–2016 (DHS, 2010; National Statistical Office, 2015; India Ministry of Health and Family Welfare, 2017).

Even if the number of sampled households per district is small and few programs are implemented in a single district, pooling across several districts may result in sufficient numbers of individuals to assess coverage. It is often argued that survey results should not be pooled, because few national surveys are designed to provide probability samples at the district level. Nevertheless, these surveys systematically present tables stratified by age, socioeconomic, and ethnic categories, even though the sample was not designed to be strictly representative of such subgroups. In practice, most nationally representative surveys employ implicit stratification within each district by listing enumeration areas in a geographic sequence and systematically sampling these areas; as a result, households included in the sample tend to be spread throughout the districts. By giving due attention to sampling weights, groups of districts where a program was implemented may be separated from a national survey for the purposes of assessing coverage (Rao, 2003; West, Berglund, & Heeringa, 2008).

Surveys can be disaggregated to the district level using either district identifiers in the data sets (which are infrequently available in MICS and DHS and usually provided only in surveys explicitly stratified by district) or geolocation information on clusters. Cluster geocodes are now routinely collected for DHS surveys, with a few exceptions, and are increasingly collected for MICS. To protect the anonymity of respondents, DHS randomly displaces cluster locations by as much as 5 km in rural areas and as much as 2 km in urban areas, with 1% of rural clusters displaced by as much as 10 km (Burgert, Colston, Roy, & Zachary, 2013). In earlier surveys, this displacement made disaggregation by districts problematic; starting in 2009, however, DHS changed the displacement protocol to respect district boundaries, making it possible to disaggregate DHS data to the district level and to regroup districts as needed.

Due to the high cost of surveys, other alternatives for data collection are worth exploring, such as using National Immunization Days (NID) to collect information on coverage or health outcomes related to other programs than those delivered at the NID—for example, breastfeeding promotion or nutritional status (Santos, Paes-Sousa, Silva, & Victora, 2008). As long as coverage of NID attendance is high (say, 90% or so), coverage of other programs can be estimated with little bias.

Measuring or Modeling Impact

Some programs express their main goals in terms of coverage indicators, so impact measurement is not strictly necessary. This is the case, for example, with a vaccination program that seeks to reach high coverage with a vaccine (e.g., rotavirus vaccine) whose efficacy is well established. For such an evaluation, if high coverage is documented, there is no need for expensive and complex assessments of the incidence of diarrhea due to rotavirus.

Even so, many funders wish to go back to their constituencies armed with hard data on the health impact of the intervention—for example, the number of lives saved by their actions. Some initiatives, such as the Catalytic Initiative to Save a Million Lives (UNICEF Canada, n.d.), have actually incorporated their quantitative goals into the program title.

Impact measurement is often included in surveys that also measure coverage. Nevertheless, assessing impact indicators usually makes coverage surveys much more complex. Issues that influence the measurement of impact in program evaluations include the following:

- *How difficult is the measurement?* For example, will impact be assessed through interviews (e.g., full birth histories of women of reproductive age, aimed at assessing child mortality; infant feeding practices), or is there a need for measurements or collection of biological specimens? Measuring child underweight with a weighing scale is easier than measuring stunting, which requires substantial training of interviewers and use of more sophisticated equipment. Drawing blood samples adds another level of logistical complications, including equipment requirements, interviewer safety concerns, and issues related to processing, transportation, storage, and analysis of samples. If data on causes of death are needed—often an important consideration for attributing success to a program—additional requirements will arise in terms of interviewer training and sample size.
- *How rare is the event being measured?* The frequency of the impact measure in the population is key for determining sample sizes. Rare events (e.g., mortality or, even worse, cause-specific mortality) require larger sample sizes than more frequent events (e.g., stunting or malaria parasitemia in an endemic area). Some events (e.g., maternal mortality) are so infrequent that the samples required are prohibitively large, leading evaluators to rely on proxy measures such as coverage

of interventions known to reduce mortality. In the case of cluster surveys, evaluators also need to take into account the "design effect" (Cochran, 1977): Events that are evenly spread throughout the population require samples that are smaller than events that are highly clustered, as is the case for some transmissible diseases. For impact measures such as mortality rates, sample sizes may be reduced by using deaths in the last two or three years before the survey, rather than deaths in the last year. This approach requires full implementation of the program throughout the mortality measurement period, as otherwise its full effect will not be picked up.

- *How large is the effect to be detected?* Picking up large effects requires smaller samples than detecting small effects. For example, detecting a 25% reduction in under-5 mortality over a certain period, relative to baseline levels, will require much smaller samples than detecting a 15% decline in this metric. Even larger sample sizes are needed to detect a 25% difference between the annual rates of mortality decline in program and comparison areas—for example, 10% and 8% per year, respectively.

Given the complexities of estimating impact through household surveys, evaluators or donors may propose the use of routine health systems data or civil registration and vital statistics data to assess impact. In principle, these routine data have a number of advantages over household surveys: They are often available at the district level, on at least an annual basis, and at little to no cost. The greater availability of data can facilitate more complex plausibility evaluation designs and increase the power of an evaluation to detect an effect. Nevertheless, as with routine coverage data, routine data on mortality, morbidity, and nutritional status in LMICs often suffer from important quality limitations that can threaten the validity of an evaluation. Routine mortality or morbidity data can be, and have been, used for high-quality impact evaluations (Rasella, Aquino, Santos, Paes-Sousa, & Barreto, 2013), but a thorough assessment of the quality of these data, including their completeness, internal validity, and external validity, is essential before using them in an evaluation (see, for example, Willey et al., 2011).

Recent advances have led to the development of modeling tools that allow the estimation of under-5 mortality trends based on measured changes in coverage. **EXHIBIT 18-8** describes the Lives Saved Tool

EXHIBIT 18-8 The Lives Saved Tool: An Example of Mortality Modeling Software

Modeling approaches are increasingly recognized as valuable for planning and evaluation in public health (Garnett, Cousens, Hallett, Steketee, & Walker, 2011). The Lives Saved Tool (LiST) is a model that estimates changes in mortality on the basis of intervention coverage data. LiST allows users to estimate the impact of scaling up proven interventions by defining and running multiple country-, state-, or district-specific scenarios (Walker, Tam, & Friberg, 2013). LiST was designed for a range of MNCH stakeholders, including ministry of health personnel, program managers, and NGO partners; the intent was to enable them to combine the best scientific evidence on the effectiveness of interventions with information about the causes of death and current coverage of key interventions to inform their planning and decision making. This evidence-based platform has been widely used to help prioritize investments and evaluate existing programs (Boschi-Pinto, Young, & Black, 2010).

LiST uses data on baseline mortality rates, causes of death, and intervention coverage, together with demographic data and intervention effectiveness, to estimate the number of maternal, under-5, and neonatal deaths that can be averted, both by cause of death and by intervention, as intervention coverage increases. It also estimates levels and changes in mortality rates, disease incidence, and the prevalence of risk factors such as undernutrition (stunting and wasting), by cause and by intervention. LiST is programmed as part of a larger software package called Spectrum, which has been widely used for 25 years and is designed to predict population changes over time by age and sex (Stover, McKinnon, & Winfrey, 2010). Spectrum uses the population projections developed by the United Nations Population Division, which facilitate estimates of population growth through 2050. Through Spectrum, LiST is linked to other modules such as the AIDS Impact Module (AIM), which models UNAIDS data for each country, and FamPlan, which estimates the impact of family planning parameters on outcomes such as the number of births.

LiST and other software can be applied in two ways for the evaluation of large-scale programs. First, they can be used to model or assess whether the interventions being promoted by the program are appropriate given the cause of death profile in the program area. For example, LiST modeling can estimate the potential change in mortality and health status if scale-up efforts are successful. This information helps evaluators answer the first question asked in the stepwise model described in Figure 18-2: Are the interventions relevant to the epidemiologic context? This approach was used at the beginning of the iCCM evaluations conducted in Burkina Faso and Malawi (Bryce et al., 2010).

The second, and more important, use of LiST and similar software is to translate changes in coverage measured through surveys into expected mortality impact. When direct impact measurement is not feasible or too expensive under given conditions, LiST can provide a reasonable estimate of the expected decline in mortality based on the measured coverage gains. This approach was used in the Burkina Faso iCCM evaluation (Munos et al., 2016).

The LiST website (http://livessavedtool.org/) provides access to the most updated version of the software. In addition to links for downloading the tool, other resources and technical documentation are posted to guide users. An embedded manual provides instructions on the software's use, as well as citations for intervention reviews and validation studies.

(LiST), which is becoming widely used for this purpose (Bryce et al., 2010).

Describing Contextual Factors

In impact evaluations, contextual factors are variables external to the program that can confound or modify its observed effect (Victora et al., 2005). Confounding occurs when changes in these external variables differ in program and comparison areas. For example, crop failures, natural disasters, or establishment of new health facilities (or presence of other programs) may occur in one area, but not in others. The ACSD evaluation showed an apparent impact of the intervention on undernutrition prevalence, but documentation of contextual factors identified a famine in some of the comparison districts; once these effects were excluded from the comparison group, there was no longer any evidence of a positive impact of the program (Bryce et al., 2010). Control of confounding factors is essential for improving the internal validity of the evaluation.

Effect modification occurs when certain baseline conditions—for example, the level and causes of mortality, or the strength of health systems—either contribute to or detract from the observed impact of the program. Effect modification is particularly relevant to external validity, or the ability to generalize from the evaluation findings. In the iCCM evaluation in Malawi, high levels of care seeking for sick children from health facilities may have limited the potential impact of the intervention, and partially explained the finding that the program was not associated with a reduction in under-5 mortality (Amouzou et al., 2016). Given that the program was reasonably strongly implemented, we might expect to see a much greater impact on mortality if it were implemented in a setting with lower levels of facility care seeking.

Data on contextual factors may come from a variety of sources. Most LMICs already have a number of databases maintained by governmental, international, or partner institutions, with information disaggregated at the provincial or district level. **TABLE 18-2** identifies sources of information on a variety of contextual factors; this listing was prepared for an evaluation of the Catalytic Initiative to Save a Million Lives in Mozambique.

If quantitative information is available for all geographic areas included in the evaluation, contextual factors may be formally included in the statistical analyses models as covariates. Even if information is incomplete or unquantifiable, contextual factors may help interpret the evaluation findings.

The process of obtaining information on contextual factors is part of the documentation exercise described previously. It can be often done by the same team that is collecting data on program implementation.

Measuring Costs

Cost data can be used in many different ways to inform decisions about public health programming, and are a key component of large-scale program evaluations. They contribute to understanding the budgetary implications of health programs and are needed to perform economic analyses such as those assessing cost-effectiveness. Cost data can help answer questions not only about how much money programs cost, but also about where the costs are incurred (e.g., by patients, at a particular service level, at higher levels), how programs operate, and which factors are hindering program scale-up. Moreover, such data can help answer questions about the relationship between costs and other aspects of health care, such as the quality of services, that are public health goals in their own right (Bishai, Mirchandani, Pariyo, Burnham, & Black, 2008). Finally, cost data can be used in conjunction with data on utilization and household socioeconomic status to understand the equity implications of a program.

FIGURE 18-6 presents a conceptual diagram of the total costs involved in the scale-up of health programs. The *x*-axis represents the time from before the start of the scale-up program until the target levels of coverage (or mortality reduction) have been achieved, or until the end of the evaluation. The *y*-axis represents the total costs of health services, where higher levels of coverage are associated with higher levels of total costs.

TABLE 18-2 Examples of Data Available from Existing Databases at the District and Provincial Levels in Mozambique and Sources of Information

Category	Examples	Source
Socioeconomic factors	Household assets Family income and poverty Parental education and occupation Unemployment Land tenure Economic crises (inflation rates, crop failures, floods)	2007 census Economic censuses and surveys National Institute of Statistics
Demographic factors	Population density Fertility patterns Family size Ethnic groups	2007 census
Environmental characteristics	Water supply Sanitation Urbanization Housing Rainfall Altitude	2007 census National Meteorological Institute
Baseline health conditions	Under-5 mortality Prevalence of malnutrition HIV prevalence Malaria transmission patterns	2007 census 2008 MICS Malaria and HIV surveys
Health services characteristics	Availability of health services (e.g., hospitals, clinics) in public and private sectors Population/facility ratio Health worker staffing patterns Health worker pay Drug supply Baseline utilization rates Availability of referral services Strength of district health management team District health budget (overall and for child health)	Health Metrics Network Ministry of Health Information Systems UNFPA Needs Assessment Survey WHO Service Availability Mapping
Presence of other projects and programs that may affect health status	Micronutrients Indoor residual spraying Immunizations HIV programs Others	UNICEF World Health Organization Network of Organizations Working in Health and HIV/AIDS (NAIMA) Official Development Assistance to Mozambique Database (ODAMOZ)

Five cost categories are incorporated in the framework depicted in Figure 18-6. *Area A*, the rectangular region above the *x*-axis, represents the total amount of resources used for health services at the beginning of the observation period.

Area B represents the change in costs normally associated with secular trends in most health systems. It can also be thought of as the change in area A over time due to changes in the population, inflationary pressures, and the introduction of new

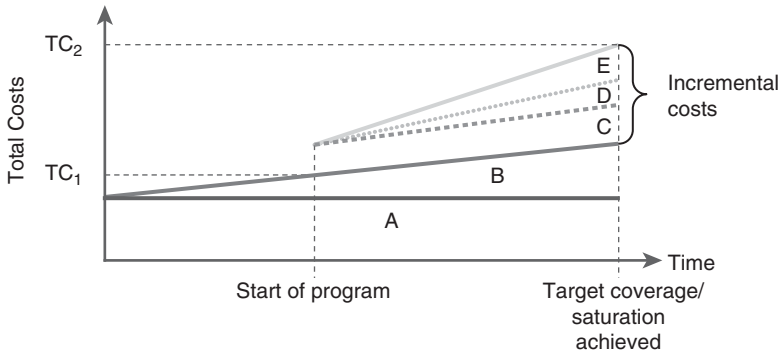

FIGURE 18-6 Conceptual framework for assessing the cost of rapid scale-up.

Reproduced from Johns, B., Opuni-Akuamoa, M., Walker, D. (n.d.). Assessing the costs and cost-effectiveness of rapid-scale up for the maternal, neonatal, and child health: The economic component of the impact evaluation strategy for the Catalytic Initiative. Retrieved from: http://www.jhsph.edu/research/centers-and-institutes/institute-for-international-programs/_documents/rapid_scaleup/CI_costeffectiveness.pdf. With permission of the author.

technologies, among other factors. In Figure 18-6, secular trends are seen as increasing total costs, which is normally—albeit not universally—the case. This relationship does not conceptually imply that the cost per patient or per visit is necessarily increasing, nor is there any particular reason to believe that secular trends will affect costs in a linear way as shown in the diagram; this depiction is provided here for simplicity's sake. Note that secular trends will affect the costs of a health program both before and after its implementation.

The costs in Areas A and B represent multiple kinds of costs:

- **Service delivery level costs:** These costs are incurred in the direct delivery of health services. They include costs incurred at health facilities, but may also include any activity that involves direct contact with patients or the population, such as indoor residual spraying or other "campaign"-type interventions, community delivery of interventions, and so on.
- **Above service delivery level costs:** These costs are not directly linked to the delivery of health services, but rather support the delivery of health services. They may include activities such as training and mentoring, media messages, supervision, demand generation, advocacy, policy development, monitoring, and central laboratory services. Studies suggests that above service delivery level costs can be a substantial proportion of the costs for many programs, even those focused on treatment of diseases (Marseille et al., 2012).
- **Recurrent costs:** Costs that are incurred on a regular basis, defined as at least once a year, are considered recurrent costs. Recurrent costs are typically incurred for items that are consumed after one use (such as medicines, supplies, gasoline, and laboratory reagents) or that need regular payment (such as staff salaries and utilities).
- **Capital costs:** Costs for items that are durable—that can be used multiple times and over multiple years—are considered capital costs. Examples include buildings, medical and office equipment, furniture, and laboratory machines. For most cost assessments that are not directly tied to budgetary expenditures, capital items are *annualized*—that is, the cost of the capital is averaged (in some way) over its expected useful life to determine the equivalent cost of the capital item if it were paid for every year (rather than once).

Both service delivery and above service delivery costs may be recurrent or capital costs. Summing the different kinds of costs gives the **total costs** of the intervention or program (TC_1), encompassing all of the costs incurred in association with a program, before the start of the program's scale-up or the introduction of a new intervention.

Area C in Figure 18-6 represents the **start-up costs** associated with the scale-up; these costs are specific to the scale-up/new program and, therefore, are added to the costs represented in areas A and B. Start-up costs include costs for activities that are incurred once, or infrequently, during a program. Examples include intensive training or policy development. Start-up costs can be thought of as capital items, albeit with start-up costs generally being incurred for activities instead of for tangible items. Like capital costs, start-up costs are typically annualized; thus, they are shown in Figure 18-6 as remaining constant over time, although this again may not necessarily be the case.

Area D represents the above service delivery level costs associated with the scale-up. These costs are specific to the scale-up program and, therefore, are added to the costs represented in areas A and B. Again, there is no predetermined pattern for how these costs will change over time; for convenience, they are depicted in Figure 18-6 as increasing with the expansion of scale-up activities.

Area E represents the additional service delivery level costs due to the increased service utilization associated with the scale-up/new program. Again, if the scale-up/new program increases coverage, total costs should increase. An exception may occur with programs aimed at preventing diseases. In these cases, the decreased need for treatment may decrease service delivery level costs.

The costs associated with areas C and D may be estimated using four different designs:

- **Documentation approach:** Costs are estimated by documenting the costs of activities and then identifying which costs are unique to the scale-up. This process is similar to the process discussed in the section on documentation.
- **First difference approach:** The costs for areas C and D are estimated by first calculating start-up and above service delivery level costs at baseline and then subtracting these baseline costs from the total start-up and above service delivery level costs observed after implementation. This approach ignores secular trends.
- **Aggregate difference approach:** Costs are estimated by subtracting the start-up and above service delivery level costs in comparison districts (if there are any) from these costs in the scale-up districts after scale-up has occurred. This approach assumes that the baseline costs in the comparison and rapid-scale up areas are the same, and is essentially the same as a plausibility design.
- **Before-and-after comparison design:** The two previous methods can be combined to control for secular trends. With this approach, start-up and above service delivery level costs are collected before and after rapid scale-up in both the comparison (if there are any) and implementation districts. The difference in costs in the comparison districts is interpreted as the secular trend in start-up and above service delivery level costs, and subsequently taken out of the difference in costs between the two time points in the scale-up districts (Adam, Bishai, Kahn, & Evans, 2004).

Similar methods are used to estimate the costs that make up area E, although further adjustments may be necessary. Tracking time-series cost data by activity may allow for the calculation of total, incremental, and unit costs in both the scale-up and comparison areas and by different levels of coverage, because data on changes in the utilization, population, and the unit costs will be available.

Incremental costs (the sum of areas C + D + E) are the new costs associated with the program being evaluated. In some cases, separating the incremental costs from the total cost is relatively straightforward. For example, training associated with the new program can be attributed directly to the program. In other cases, separating incremental costs from the total cost is considerably more complex. For example, the new program may increase the utilization of health facilities. In this case, items that existed before the new program (such as health facility staff and infrastructure) are utilized for the delivery of services associated with the new program. Similar to total costs, incremental costs are usually positive, except for some preventive programs, where incremental costs may be negative ("cost-saving").

Unit costs (sometimes referred to as average costs) are variously defined, but can be thought of as the cost per service provided (e.g., cost per outpatient visit) or the cost per beneficiary (e.g., cost per child). Unit costs can be derived from both the total cost and incremental costs. In either case, data on the total or incremental costs and the number of services provided, people reached, or population are needed to calculate the unit costs. While total costs for non-preventive interventions will usually be greater after the implementation of a program than before the program's introduction, unit costs at health facilities may be lower after program implementation than before program launch (even if total costs increase). This will happen if, for example, health facilities existed but were relatively underutilized before a program. In these cases, health staff and infrastructure were serving relatively few patients, and the cost per patient at health facilities would be relatively high. The new program may increase utilization, without necessarily incurring the need for more staff or infrastructure. In such a case, the costs of health staff and infrastructure are now spread over relatively more patients, which lowers the cost per patient. If this lower unit cost is not fully offset by the incremental cost per patient associated with the new program, then the total unit cost will be lower after the program compared to before the program.

Using the full change (comparing the baseline to full implementation—that is, the first difference approach) in unit cost in the intervention areas would assume that all changes in the unit cost of service delivery and the utilization rate are attributable to the intervention, which ignores the influence of secular trends. Secular trends may be controlled for using comparison areas (i.e., via the aggregate or difference-in-difference approaches described earlier).

Thus, costs, like the outcomes or impact of a program, are subject to confounding by secular trends and contextual variables, and similar study designs should be considered for costs as for other aspects of

the evaluation. Sometimes, however, policy makers may demand less rigor in the evaluation of costs than for other aspects of the evaluation; for example, they may accept a plausibility design for evaluating costs, but not accept this approach for assessing impact.

Different research questions and designs will determine which categories of cost data need to be collected. Generally speaking, the incremental unit cost of an intervention is the metric required for a cost-effectiveness analysis, but may not be sufficient for an affordability analysis. On the one hand, when assessing the costs of a new technology, such as a new vaccine or diagnostic test, it may be sufficient and feasible to collect only the incremental costs associated with the technology; it may suffice to use a mathematical model to estimate the cost savings associated with the new technology. On the other hand, interventions with more complicated causal pathways, or that influence demand for health services, may require collection of total costs in intervention and comparison areas.

Given the concerns related to estimating area E in Figure 18-6, it is important to clarify which factors may influence costs apart from the program of interest. Three kinds of variables may potentially affect costs: patient-level variables, service delivery characteristics, and contextual variables (Hussey et al., 2009). In the next subsections, we describe considerations for contextual factors that are specific to costs.

Patient-Level Costs

A great deal of the existing cost-effectiveness literature has been devoted to controlling for differences in costs due to variation in patient-level characteristics; most of this work has been conducted in high-income countries. Variables that have been found to be important include case mix or severity of illness (Hofer et al., 1999; Powell & Hampers, 2003; Tucker, Weiner, Honigfeld, & Parton, 1996), sex, age, living conditions, race/ethnicity, and other socioeconomic variables (Grieve, Nixon, Thompson, & Normand, 2005; Hussey et al., 2009).

Service Delivery Characteristics

Facility-level variables encompass factors that affect costs at the provider level. Quality is one frequently cited example (Amorin et al., 2008; Bishai et al., 2008), although one review found that many authors fail to control for it when examining efficiency measurement (Hussey et al., 2009). The scale of services (e.g., the number of patients seen) and the number and types of outputs for a particular health service provider (i.e., the scope of service provision) may influence the unit costs and total costs of delivering those services (Jacobs, Smith, & Street, 2006). Technical efficiency—the ability to maximize outputs for a given set of inputs or to minimize inputs for a given set of outputs—may also influence unit costs at the facility level (Adam, Ebener, Johns, & Evans, 2008; Adam et al., 2005; Baltussen et al., 2003; Bryce et al., 2005; Jacobs et al., 2006). Other variables that have been used to control for costs include the way in which a health provider is reimbursed (Grieve et al., 2005) and the type of ownership (Hollingsworth, 2003), although the latter consideration really reflects technical efficiency.

The effect of economies of scale on unit costs has been shown to be important for primary health care in LMICs (Berman, Brotowasisto, Nadjib, Sakai, & Gani, 1989). It has also been increasingly studied in disease-specific contexts, where this factor has been shown to influence costs (Guinness et al., 2005; Kumaranayake, 2008; Marseille et al., 2004; Menzies, Berruti, & Blandford, 2012; Valdmanis, Walker, & Fox-Rushby, 2003). Technical efficiency has been less frequently studied, although at least one study from an LMIC indicates that health centers may have different costs due to different levels of technical efficiency (Masiye et al., 2006). Quality may either increase costs or lower costs. All three of these factors—economies of scale, technical efficiency, and quality—may influence the costs of health services.

Contextual Variables

Variables that are outside the control of the health provider, yet reflect the environment in which the provider operates, may also influence the costs of services. In many cases, these variables are similar to those for outcome and impact evaluations. For example, income and other socioeconomic factors may affect utilization of services (Adam et al., 2009) and the costs of staff salaries (Jacobs et al., 2006), while the geographic features of an area may influence the cost of transport, supervision, and training as well as patients' ability to access care due to the need to travel for greater distances and over difficult terrain (Johns & Torres, 2005; Over, 1986). The degree of competition between providers within an area may also influence efficiency and therefore costs, yet be outside the control of an individual provider (Jacobs et al., 2006). Thus, data on factors that may influence costs, as well as data on the costs themselves, need to be collected and analyzed at baseline to establish the extent to which they influence costs, or may result in differences in costs after the program has been implemented.

Best practice is to collect both service delivery and above-service delivery level costs, as well as capital and start-up costs. Of course, collecting comprehensive,

accurate, and precise cost data can itself be a costly activity, and the cost of data collection and analysis should be taken into account when planning the evaluation (Wilson, Mugford, Barton, & Shepstone, 2016). Fully describing the strengths and weaknesses of different study designs, as well as the costs of collecting the data necessary for the different study designs, up front to the funders of the study and other target audiences is a necessary part of deciding the approach to assessing costs.

Previous studies of the costs of large-scale child health interventions in LMICs have, by and large, relied on cross-sectional data collection after the program was implemented, as was the case in three of the four countries participating in the IMCI evaluation (**EXHIBIT 18-9**). Although these studies plausibly established that IMCI did not increase the cost of child health programs by a great deal in comparison with areas that did not implement IMCI, they did not ascertain the costs of the IMCI program.

Data Collection Methods

Three principal methods are used to estimate costs: modeled costing, top-down costing, and bottom-up costing. Within each of these methods, multiple sources or ways of collecting data may be employed. These techniques are complementary methods that can be applied simultaneously to obtain a comprehensive collection of cost data, and for cross-checking the results from each strategy. Modeled cost analysis should be done only before or at the start of the

EXHIBIT 18-9 The Cost of Child Health Services: The Multi-Country IMCI Evaluation

The cost of child health services delivery has been most recently and notably studied in conjunction with the evaluation of the IMCI program in Bangladesh, Brazil, Tanzania, and Uganda (Adam et al., 2005; Adam et al., 2009; Amorim et al., 2008; Bishai et al., 2008). In this assessment, costs were estimated from the societal perspective (providers and households).

Standard MCE cost questionnaires were developed and adapted for use in each country. They consisted of four questionnaires to collect data at the national, district, facility, and community levels, respectively. At national level, data on the following IMCI-related activities were collected: planning and orientation meetings, preparation of IMCI training materials (including translation, adaptation, and printing of guidelines and training materials) and training of national trainers, and administration. Data collection at the district level included training of trainers related to IMCI, supervision for IMCI activities related to under-5 children, and administrative costs of under-5 care. The cost questionnaire at the first-level health facility collected data on personnel (including volunteer labor, if any), drugs, capital items, number of patient visits by type, and staff time allocation based on a time-and-motion study. Data collection of household costs was based on a two-week morbidity module in a household survey. Information on costs incurred during under-5 illness episodes in the two weeks prior to the survey were collected for each child in the household.

In Brazil, Tanzania, and Uganda, no baseline cost data were collected because the evaluations were commissioned after implementation of the program was already underway, when it was no longer possible to collect baseline costs. Therefore, costs were collected after the implementation of IMCI had occurred in the intervention districts, and other matched districts without IMCI were used as comparison districts (Adam et al., 2005; Adam et al., 2009; Amorim et al., 2008; Bishai et al., 2008). Only in Bangladesh, where a fully prospective IMCI evaluation was carried out, were baseline costs collected (S. Arifeen, personal communication). The need to collect baseline costs is another strong reason for undertaking prospective assessment, rather than ambispective or retrospective evaluations.

Given the fact that the evaluations from Brazil, Tanzania, and Uganda were not prospective and, therefore, lacked baseline data, the results proved somewhat difficult to interpret. For example, the study from Tanzania found that the costs at the household and the health center levels (primary healthcare level) were almost the same between the IMCI and comparison areas, while costs at the hospital level and at the district level were higher in the comparison areas than in the IMCI districts. Given the nature of the data collection, the reasons for this difference could not be explained; the authors concluded it could be due to decreased referrals after IMCI training, or to factors not related to IMCI (Adam et al., 2005). Without baseline data, it is difficult to know, from this study, what the costs of IMCI were, and to what extent they increased (or decreased) the costs of providing child health care.

A similar analysis done in Brazil found that costs were higher at the hospital and municipal levels in the IMCI areas than in the comparison areas, but lower at primary healthcare levels, although the authors did not find a statistically significant ($p < 0.05$) difference between the two areas in terms of the total costs (Adam et al., 2009). The study in Brazil tried to control for other differences between IMCI and control areas by including variables for facility location and population in the catchment areas of the health centers. This construction suggested that IMCI is endogenously related to total costs via the number of visits per child. That is, IMCI may improve quality, so that people become more likely to attend the clinic; this greater volume of patients then increases total costs but also alters the unit costs of delivering services (Adam et al., 2009).

scale-up program. Top-down costing is usually done retrospectively—frequently for the last year of the intervention, although it could be carried out on a repeated basis (or even before the start of the program being evaluated, so as to establish baseline costs). Bottom-up costing is usually cross-sectional, so it could also be performed on a repeated basis.

Model-Based Cost Estimates Using Existing Data

Models such as WHO's OneHealth Tool (http://www.who.int/choice/onehealthtool/en/) can be used to derive an ex ante cost-effectiveness ratio to inform policy makers of an expected level of cost-effectiveness for their planned activities. Both the unit costs of delivering services and the program-level costs of operating the scale-up effort need to be estimated to carry out model-based cost or cost-effectiveness analyses. Full provider- and patient-perspective analyses may not be feasible given the available data. Any comparison with later results should be adjusted to account for the perspective used in the initial analysis.

Modeled unit costs can be estimated based on any of the following methods. The preferred methods, which reflect the most context-specific data, are listed first. Nevertheless, different methods can be used to derive unit costs, to the extent possible, so as to perform sensitivity analysis.

1. Unit costs can be collected during a baseline survey of health services providers (e.g., health centers, hospitals, and minimally trained health workers in the community). If such data are collected during the evaluation or are available from another study recently undertaken in the country, they can be used either directly or with adjustments due to anticipated changes in utilization.
2. Unit costs can be based on estimates made in previously undertaken econometric studies. It is recommended that WHO-CHOICE (http://www.who.int/choice/costs/en/) unit costs be used because they are available on a country-by-country basis. WHO-CHOICE unit costs include human resources but exclude drug items; thus, excluded costs must be estimated using method 3.
3. Unit costs can be estimated based on treatment protocols (and estimated staff time if methods 1 and 2 are not used). Although this method suffers from the bias that medical personnel rarely have 100% adherence to treatment protocols, it does allow for a relatively quick assessment of the potential costs of delivery of the program. An alternative, and more desirable, approach is to elicit resource usage from providers using vignettes; this approach requires additional time and resources, however.

Two principal methods of measuring costs are used: top-down costing and bottom-up costing. These methods are seen as complementary methods that can be used to obtain a complete collection of cost data and for cross-checking each other.

Bottom-Up Cost Analysis

Bottom-up costing involves three aspects:

1. An ingredients approach, in which the total quantities of goods and services employed in delivering health care are measured, and multiplied by their respective input prices.
2. Surveys of patients and/or caregivers to collect information on the costs associated with accessing and receiving care. Costs at this level reflect both out-of-pocket payments made to access and receive care and the opportunity costs of patients' and caregivers' time.
3. Detailed review of program accounting and expenditure reports to estimate above service delivery level costs.

Top-Down Cost Analysis

The top-down approach focuses on financial expenditures data, linking these data to other resources such as staff and services and population data. Data are collected by reviewing records and conducting interviews at pertinent governmental levels about the financial flows and costs of health services. The starting point for top-down cost analysis is the total cost (e.g., of a health center, hospital, or health program), which is then parsed and allocated to particular services.

Top-down and bottom-up costing approaches often produce different results due to differences in what is included and different methods of measurement (Cunnama et al., 2016). Some evidence indicates that increased funding, by itself, does not always result in more or better services. Notably, various barriers to the effective usage of funds—such as leakage, corruption, and poor incentive structures—can have a detrimental impact on the effective use of funds (International Institute for Population Sciences [IIPS] and Macro International, 2007). Further, use of some resources, such as electricity, is difficult to directly observe using bottom-up methods. Thus, the costs collected using the bottom-up approach may "miss"

some expenditures and provide an unrealistic estimate of the true costs of services. Conversely, bottom-up approaches provide more details on how services are being delivered. In cases where the costs for the treatment of specific diseases are needed for an evaluation, employing at least some bottom-up cost methods in combination with top-down approaches is necessary (Hendriks et al., 2014). The top-down and bottom-up approaches provide different bases from which to estimate total costs; thus, they represent complementary means of assessing the accuracy of the data collected.

Allocation Methods

Some resources (e.g., staff, facility space, transportation) may be fully dedicated to the program being evaluated, in which case their full costs should be included in the estimation. In contrast, overhead (capital and administrative) costs may need to be separated between the program being evaluated and other health or development activities. For example, structural overhead costs, such as for staff not involved in direct patient contact, may be allocated according to utilization variables (e.g., the percentage of visits that involve children). In contrast, equipment, facility costs, and staff costs that are shared between different types of patients are usually allocated according to the amount of staff time spent on particular activities.

The gold-standard methodology for determining the proportion of time staff spent on particular activities comprises time-motion studies (Bratt et al., 1999). While provider interviews tend to underestimate nonproductive time (Bratt et al., 1999), this bias may not be as important when assessing relative time spent between activities. Time-motion studies were part of the IMCI evaluations in Tanzania, Brazil, and Bangladesh. Higher standards for accurate allocation of costs, which generally involve more time and effort to collect, should be applied to the largest of cost categories, while less precise methods can be used for more minor costs (Tan et al., 2009).

Incorporating Equity in the Evaluation

There is growing concern that programs and interventions may fail to reach those who need them most, and that overall progress in health indicators can hide important gender, socioeconomic, or ethnic group differences. Assessing the impact of a program on equity, therefore, is becoming increasingly more important.

The focus on equity can start at an early stage in the evaluation, by assessing whether programs are being deployed in those districts where they are most needed (i.e., in those areas with the highest mortality and the lowest standard of living). These analyses require combining data on baseline contextual factors with implementation strength—an approach that is further discussed in the later section on data analysis.

Another step to address equity concerns is to ensure that—within program areas—the evaluation team can document the degree to which different population subgroups (stratified by gender, socioeconomic position, urban versus rural residence, and ethnic group, for example) are benefiting from the interventions being promoted. Similar information should be collected for nonprogram areas. This effort requires ensuring that the data collection tools used for the evaluation incorporate the information required to classify families or individuals according to the stratification variables to be used in the analyses. Simple and reasonably accurate measurement of socioeconomic position is now possible in household surveys, using principal component analyses of household assets to classify families into five equal groups, or wealth quintiles (O'Donnell, Van Doorslaer, Wagstaff, & Lindelow, 2007). Because it is possible to calculate summary indices of inequality that use information from the whole population rather than a single subgroup (see the later section on data analysis), in most cases there is no need to expand the original sample sizes to perform such analyses. The evaluations described in Exhibits 18-2 and 18-3 incorporated equity analyses using these tools (Bryce et al., 2010; Hanson et al., 2009).

Incorporation of the equity dimension in program evaluations is no longer an option, given its importance and the wide availability and simplicity of existing tools. Rather, it is a requirement for public health interventions.

Carrying Out the Evaluation

In prospective evaluations, there is a need for continued interaction between the evaluation and implementation teams.

Starting the Evaluation Clock

In a prospective evaluation, documentation of program implementation will help assess how rapidly the interventions are being rolled out. This information should be used to plan the timing of post-baseline data collection on coverage and impact indicators. If outcomes are measured too early, there is a risk that the full effect of the program may not be captured. This was the case, for example, in a randomized evaluation

of the Mexican Seguro Popular program, in which—for reasons beyond the control of the investigators—the endline survey took place only 10 months after the program was launched (King et al., 2009).

In the IMCI evaluation in Tanzania, formal meetings between the evaluation and implementation teams were held to decide whether the "evaluation clock" should be started—that is, whether data collection for assessing outcomes could be carried out. In the retrospective ACSD evaluation, similar discussions led to the identification of three periods: baseline (prior to the program), phase-in, and endline (program fully implemented); each period lasted 18 to 24 months. The main analyses of program impact included comparisons between the endline and baseline phases.

Feedback to Implementers and Midstream Corrections

In classical efficacy trials, the interventions are defined a priori and remain unchanged during the study. In contrast, for large-scale programs including proven interventions, midstream corrections are commonly undertaken to increase coverage and improve quality. Such corrections may result from the implementation team's own assessment of how the program is performing, based on internal monitoring. Changes may also arise in response to feedback from the evaluation team, as indicated in the earlier discussion of documentation. In prospective program evaluations, it would be unethical for the evaluators not to provide feedback on obvious implementation shortcomings.

Feedback from evaluators may also improve the program. This type of change may affect the external validity of the study findings, but in light of the ethical imperative this difficulty is unavoidable. To minimize this problem, it is essential that feedback should be provided in a structured manner—for example, in one session conducted every three to six months. All feedback and any resulting actions should be carefully documented and reported as part of the final evaluation results. Plans for feedback should be developed and agreed upon with program implementers in advance. In the iCCM evaluations, the process for disseminating feedback varied somewhat across countries, but feedback was provided first at the national level via either annual stakeholder meetings or "validation" workshops conducted for specific data collection activities. These national meetings also provided a venue for discussing the implications of interim results for both the program and the evaluation. Dissemination of this feedback at the district level was led by the Ministry of Health, in some cases with support from the evaluation team.

Ongoing feedback is not relevant to retrospective evaluations. Nevertheless, whatever the design of the evaluation, it is important to provide feedback to implementers and policy makers at the end of the study. This point is discussed further in the section on dissemination of evaluation results.

Linking the Independent Evaluation to Routine Monitoring and Evaluation

All programs must include internal monitoring and evaluation systems. Monitoring typically includes documenting program inputs and outputs—for example, the number of health workers trained, the number of ITN vouchers distributed, or the number of mothers attending breastfeeding promotion activities.

As far as possible, the independent evaluation data collection activities should be integrated with routine monitoring, such as by including the same data sources and indicator definitions. Nevertheless, because the data quality needs for a rigorous evaluation often exceed those required for routine monitoring, it may be necessary to establish a parallel data collection or data quality checks system. This structure should not be viewed as a replacement for routine monitoring activities, which must continue during and after the independent evaluation. It is also important to provide feedback to implementers when shortcomings in the program or the monitoring system are identified through the use of routine monitoring data. For example, if the monitoring system is not documenting key inputs such as stockouts of commodities at the health facility level, evaluators should discuss with implementers why these data are not being collected and explore how the data could be collected and used to improve program performance.

Similarly, the presence of an independent evaluation does not replace the need for focused internal evaluations aimed at fine-tuning the program. As far as possible, these two exercises should be coordinated so that they complement each other.

Data Analyses

Data analyses should be driven by the evaluation questions, and should make full use of the data collected on implementation strength, quality, and outcomes—complemented by data on costs and contextual factors. Integrating data from different sources in a comprehensive and logical plan of analysis is not an easy task, and its success requires careful forward planning from the time the evaluation is being designed. Data analysis plans should be developed alongside the program impact model, objectives, and measurement plan at the start of the evaluation.

In real-world evaluations, evaluators frequently need to change evaluation plans in response to changes made in the program, to account for new programs or interventions that are rolled out in comparison areas, or to address the unavailability of certain data. For example, as happened in the Malawi iCCM evaluation, programs similar to the one being evaluated may be rolled out in comparison districts by other partners, resulting in comparison areas that are no longer valid approximations of the counterfactual. In turn, evaluators may change a quasi-experimental evaluation design into a dose–response design, or may update the types of inferences that can be drawn from the quasi-experimental design. In any case, it is essential to document the initial design and analysis plan and any changes made to them, and to make note of possible biases resulting from these changes.

Issues in the analyses of nonrandomized evaluations are reviewed elsewhere (Cousens et al., 2009), but the following basic concepts should certainly drive the planned analyses:

- The units of analysis should be the same as the geographic units where the program is being implemented (e.g., districts).
- The sample size is the number of districts, not the total number of individuals surveyed in all study districts.
- Detailed analyses of baseline comparability are essential.
- Standard stratification and regression techniques will often be appropriate, but attention must be given to the number of degrees of freedom, which will often be small as a result of the number of districts available for analyses.
- Propensity scores may be useful for summarizing several confounders (Sturmer et al., 2006), particularly when the number of degrees of freedom is small.
- Comparisons between program and nonprogram areas, when baseline data exist, may rely on the difference-in-differences approach. This method focuses on the net change in each set of districts.
- Multilevel analyses may be appropriate if the data structure is hierarchical—for example, districts within the program area, health facilities within each district, providers within each facility, and patients seen by each provider.
- The plan of analysis should ideally examine all assumptions included in the conceptual model (i.e., all the arrows in the model). An example is provided in **TABLE 18-3**.
- The plan of analyses should be flexible, as real-world implementation may follows paths that are not planned ahead of time.

Table 18-3 shows possible research questions for evaluating a hypothetical MNCH program in a country in sub-Saharan Africa. The program includes several MNCH interventions, which will be initially rolled out in a limited number of districts. Although a stated objective of the program is to eventually scale up the program to all districts in the country, this step will depend on further partner and governmental buy-in and additional funding. This somewhat vague implementation plan is typical of many health programs in LMICs. A good example is the ACSD program (Exhibit 18-2), in which the full package was implemented in selected high-impact districts but a smaller set of interventions were scaled up nationally.

The analytical approaches suggested in Table 18-3 encompass the traditional program versus nonprogram districts comparison as well as dose–response analyses, such as those carried out in the context of an evaluation platform (Exhibit 18-6). Of the primary objectives, questions 1–4 may be addressed through a traditional comparison of two groups of districts (with or without the program). As pointed out earlier, such comparisons are often favored by funders, but may make little sense if the same or similar interventions are also present in the comparison areas. Answering questions 5–7 requires dose–response analyses, which go beyond the simple stratification of districts in two groups. If a stepped wedge design is used for the evaluation, these questions can be tailored to this type of analytical approach (Hussey & Hughes, 2007).

Question 8 is fundamental for both approaches: It requires control of confounding factors to address the issue of attribution of an observed impact to a given program. In a context in which multiple programs are being studied simultaneously through an evaluation platform approach, the presence of other programs may also be included as a confounding factor. For example, the Tanzania ITN voucher evaluation showed that the program's effects persisted even after taking into account the large number of free ITNs that were distributed in some districts in 2005 (Hanson et al., 2009).

Questions 9–12 represent secondary objectives of the hypothetical program evaluation. Question 9 assesses whether programs are being deployed where they are most needed. Although implementers often state that they are prioritizing the poorest or highest-mortality districts, studies have shown that this is not always true (Victora et al., 2006). Identification of indicators of baseline mortality, poverty levels, or

TABLE 18-3 Proposed Approaches for Data Analyses, According to Each Objective of a Hypothetical Evaluation of a Maternal, Newborn, and Child Health Program

Research Question/Objective	Analytical Approach
Primary Objectives	
1. Will the program-focus districts implement maternal, newborn, and child health (MNCH) interventions more strongly and at higher levels of quality than other districts in the country?	Comparison of implementation strength in program and non-program districts
2. Will the program-focus districts achieve greater increases in coverage of MNCH interventions than other districts in the country?	Comparison of changes in coverage over time in program and non-program districts
3. Will the program-focus districts achieve greater health impact (i.e., reductions in mortality and undernutrition) than other districts in the country?	Comparison of changes in impact indicators over time in program and non-program districts
4. How much did the program cost compared to other approaches, and how does their cost-effectiveness compare?	Comparison of costs and cost-effectiveness in program and non-program districts
5. Among all districts in the country, will those with stronger implementation of MNCH interventions achieve higher coverage levels than those with weaker implementation?	Dose–response analyses: Regression of changes in coverage over time on implementation score
6. Among all districts in the country, will those with stronger implementation of MNCH interventions achieve greater health impact (i.e., reductions in mortality and undernutrition) than those with weaker implementation?	Dose–response analyses: Regression of changes in impact indicators over time on implementation score
7. How much did the implementation cost, and is it cost effective?	Dose–response analyses relating implementation costs to impact
8. If there is evidence of an impact, can external explanations for these associations be ruled out?	Incorporation of relevant confounding factors in the preceding analyses
Secondary Objectives	
9. Was the program focused on the districts where it was most needed, in terms of baseline health and socioeconomic characteristics?	Stratification of all districts according to baseline characteristics, and comparison of strata in terms of implementation strength
10. Did implementation of the program contribute to reducing socioeconomic and other inequities in MNCH indicators?	Analyses of time trends in inequalities in coverage and impact indicators, according to strength of implementation of the program
11. Are there positive or negative effects of the program in terms of health systems, other health programs, or related indicators?	Comparison of health systems indicators and coverage of other interventions, according to strength of implementation of the program
12. Are changes in program implementation and in intervention coverage compatible with the observed impact on mortality and nutrition?	Comparison of actual changes in impact indicators with those predicted by modeling changes in intervention coverage (e.g., LiST)

health systems strength available in the district database (Exhibit 18-6) will help answer this question.

A related question is number 10, which assesses changes in health inequalities between population subgroups. Earlier in this chapter, we described the importance of collecting information on gender, socioeconomic position, urban versus rural residence, and ethnic group during surveys commissioned by the evaluation. Several approaches may be used to express the magnitude of inequality, and to describe how this level evolves over time in program versus non-program areas. In particular, concentration indices and slope indices of inequality have become increasingly popular means of examining these issues (O'Donnell et al., 2007; PAHO, 1999; Pamuk, 1985; Wagstaff, Paci, & van Doorslaer, 1991).

Question 11 relates to side effects of the program, which are often unintended and overlooked. Evaluators can address this question by collecting relevant information on the implementation and coverage of other health programs, such as through an evaluation platform approach.

Finally, question 12 relies on statistical modeling to check whether the observed impact on health status is compatible with the magnitude of changes in coverage of the interventions being promoted. In the case of maternal, newborn, and child mortality, the LiST software (Exhibit 18-8; Johns Hopkins Bloomberg School of Public Health, n.d.a) may be used to conduct these simulation exercises. Demonstration that the degree of mortality decline can be explained by changes in coverage is a strong argument that reinforces the impact model and increases the ability to attribute the health impact to the program interventions.

For evaluations that do not go as far as measuring mortality impact—which include most evaluations of maternal health and HIV/AIDS programs—use of LiST or similar simulation tools can provide evidence to funders and national policy makers that observed improvements in coverage are most likely contributing to reducing mortality rates.

Analyzing Costs and Cost-Effectiveness

A number of process, intermediate, and outcome indicators are available to be compared with cost; these indicators are summarized in **TABLE 18-4**. To the extent possible, all of these indicators should be used, because each provides useful information. However, the minimum set of recommended indicators includes the following items:

- Cost per beneficiary
- For curative services, the cost per person treated
- For preventive services, the cost per preventive item delivered
- Cost per death averted

Costs should be presented in the currency most relevant for the target audience. In most cases, this means that results should be presented in local currency units (for national policy makers), in U.S. dollars (for donors and program managers in other countries), and in purchasing power parity adjusted dollars (for comparison with other studies and for international policy makers). WHO website (http://www.who.int/choice/costs/ppp/en/index.html) offers more details about purchasing power parity adjusted dollars.

Once the incremental cost has been established, it can be compared with the incremental benefits to determine the *incremental cost-effectiveness ratio* (ICER). At the very least, cost-effectiveness should be calculated using deaths averted as the denominator. Other metrics (e.g., life-years saved, disability-adjusted life-years [DALYs] averted) can be applied if relevant for a particular country, although these metrics also imply different analytic horizons or time frames.

The *ceiling ratio* is the relative cost-effectiveness value against which the acceptability of ICERs is judged. If the value of an ICER is below the ceiling ratio, an intervention is deemed acceptable on grounds of cost-effectiveness. Previous recommendations, based on work by the Commission on Macroeconomics and Health (2001), classified interventions as "highly cost-effective" for a given country if they avert a DALY for less than the per capita national gross national income (GNI) or gross domestic product (GDP), and as "cost-effective" if this value is less than three times the per capita national GNI. The choice of ceiling ratios is affected by the decision maker's valuation of a unit of health gain; it is a particularly crucial and politically sensitive element of economic evaluation. Recently, the utility of the GDP per capita threshold has been questioned (Marseille, Larson, Kazi, Kahn, & Rosen, 2014), and the need for country-specific thresholds and information related to affordability, feasibility, and equity has been highlighted when making decisions about whether to adopt a program (Bertram et al., 2016).

We suggest placing findings in a broader context by comparing them to other economic evaluations that have been undertaken in the same or neighboring countries after adjustments have been made for inflation. Placing results in the context of a ceiling ratio provides a general picture of the program's value for money, but does not address the issue of whether the intervention represents the best

TABLE 18-4 Types of Process, Intermediate, and Outcome Indicators and Data Needed

Type of Indicator	Indicator	What the Indicator Measures	Additional Data Needed for the Indicator
Process	Ex ante cost-effectiveness	Expected costs and value for money	Budget projections, work plans, coverage targets
Process	Incremental/total cost per person treated	Services provided	Utilization rates
Process	Incremental/total cost per preventive item delivered (e.g., bed net or vitamin A capsule)	Services provided	Utilization rates
Process	Incremental/total cost per capita	Services provided, program effort, and sustainability	Population
Intermediate	Incremental/total cost per patient correctly treated	Treatment leading to health gains	Utilization rates adjusted by quality
Intermediate/outcome	[Incremental] cost of quality improvement	Improvements in services due to program	Quantitative measure of quality improvements
Outcome	Incremental cost per death averted	Mortality reduction	Mortality rates
Outcome	Incremental cost per life year gained	Mortality reduction	Mortality rates and age of death (and life expectancy)
Outcome	Incremental cost per disability-adjusted life-year (DALY) averted	Mortality and morbidity reduction	Mortality rates, age of death (and life expectancy), average morbidity associated with diseases, correct treatment by disease

Modified from Johns, B., Opuni-Akuamoa, M., Walker, D. (n.d.). Assessing the costs and cost-effectiveness of rapid-scale up for the maternal, neonatal, and child health: The economic component of the impact evaluation strategy for the Catalytic Initiative. Retrieved from http://www.jhsph.edu/research/centers-and-institutes/institute-for-international-programs/_documents/rapid_scaleup/CI_costeffectiveness.pdf. With permission of the author.

possible use of additional resources. Comparing the results to other studies will partly alleviate this problem. It also informs the decision maker about other options to the program besides "doing nothing," "the status quo," or what is happening in the comparison areas. Note, however, that the methods and assumptions in other studies may be different from those employed here or in comparison with each other, which makes these comparisons problematic. Results need to be interpreted in the full light of these shortcomings.

Interpretation and Attribution

Adequacy evaluations were discussed earlier in this chapter, in the design section. These assessments typically include a before-and-after comparison of outcomes within the program areas, without an external comparison. The conclusion may be that outcome indicators improved, remained unchanged, or worsened. Such evaluations may be useful for assessing changes in coverage and attributing them to a given program, but are rarely sufficient for attributing

impact. As a consequence, adequacy evaluations per se have a limited role in attribution.

Nevertheless, assessment of the adequacy of impact indicators—whether or not they improved over time—is essential, even in more complex plausibility evaluations that also include a comparison group. Because every plausibility evaluation provides the opportunity to assess adequacy, it is possible to interpret these findings jointly. **TABLE 18-5** shows how combining adequacy and plausibility may help the evaluators interpret the results and attribute them to a given program. (Table 18-5 is based on a program- versus non-program areas design, but can be adapted to dose–response and stepped wedge designs.) The plausibility findings are assumed to be not confounded—that is, they are expected to be unaffected by changes in contextual factors.

Our experience with large-scale evaluations is that implementers often concentrate on adequacy findings (e.g., did mortality rates fall in the program area?). Although this understanding is important, the result does not necessarily mean that the program can be held responsible for the observed success, as in some cases the comparison areas may have done just as well. An example is the ACSD evaluation (Bryce et al., 2010).

Table 18-5 also shows situations in which no improvement occurred in the program areas but non-program areas fared worse. This outcome would support a safety net effect in which the program helped offset the deterioration in external factors.

Finally, there is the possibility that the program displaced a more efficient program or strategy. This outcome may have occurred in the ACSD evaluation in Mali (Bryce et al., 2010), where documentation of program implementation and contextual factors showed that other funding agencies were supporting the scale-up of MNCH interventions similar to ACSD in most districts from the comparison area.

Ensuring the internal validity of an evaluation requires several steps that were described earlier in this chapter—namely, taking into account baseline comparability, documenting and adjusting for important confounding factors, ensuring valid measurement of implementation and outcomes, and using appropriate analytical strategies. An equally important consideration is to document changes in the intermediate steps laid out in the impact model, and to show that these outcomes are consistent with the impact findings.

Plausibility that the impact findings can (or cannot) be attributed to the intervention does not depend on a single finding or analysis, but rather on the progressive accumulation of evidence supporting the

TABLE 18-5 Joint Interpretation of Findings from Adequacy and Plausibility Analyses

How Did Program Areas Fare Relative to Non-Program Areas? (Plausibility Assessment)	How Did Impact Indicators Change Over Time in the Program Areas? (Adequacy Assessment)		
	Improved	**No Change**	**Worsened**
Better	Both areas improved, but program led to faster improvement	Program provided a safety net	Program provided a partial safety net
Same	Both areas improved to a similar extent; no evidence of an additional program impact	No change in either area; no evidence of program impact	Indicators worsened in both areas; no evidence of a safety net
Worse	Both areas improved, particularly non-program areas; presence of the program may have precluded the deployment of more effective strategies	Program precluded progress; presence of the program may have hindered the deployment of more effective strategies	Program was detrimental; presence of the program may have hindered the deployment of more effective strategies

hypothesis that the observed impact is due to the program. This type of buildup was noted in the Tanzania ITN voucher evaluation (Hanson et al., 2009).

Attribution is a central issue in evaluation and should be considered prior to deciding on an evaluation design. When multiple agencies or programs are active in the same country promoting similar interventions, as was the case in the Malawi iCCM evaluation, it is difficult, if not impossible, to attribute any observed improvements to a single partner. A more sensible approach in such situations is to adopt a "contributorship" model of attribution, in which all those who contribute to a program are acknowledged and successes or failures are shared among the partners. Doing a good job on the documentation component of the evaluation should make this type of joint attribution possible. If the number of districts is reasonably large (say, 30 or more), a dose–response design may be used to account for differential levels of implementation by different partners and the resulting variability in the effect size.

Evaluators are sometimes requested not only to provide evidence that overall impact can be attributed to a program, but also to assess which of several program components or interventions played the most important role. As mentioned in the description of the ACSD program, it is usually impossible to disentangle these different components, unless there are few interventions, the various interventions address different causes of morbidity and mortality, and little comorbidity exists between these causes. A similar issue arises when different funders support separate interventions that are packaged in the same program, in which case separate attribution of results is seldom possible. Funders and implementers must be made aware early on that these types of attribution are not feasible.

Disseminating Evaluation Findings and Promoting their Uptake

Evaluators have an ethical responsibility to make their findings available so that they can be used to guide program implementation and future evaluations. The provision of feedback to program implementers was addressed earlier in this chapter; the same principles apply to the final results addressing the evaluation questions. Dissemination activities should be planned and carried out with several audiences in mind:

- *Policy makers and program implementers at the country level*. These audiences should be carefully defined, and are likely to include district managers and even communities as well as national-level decision makers. Dissemination channels can take various forms, including face-to-face presentations and print materials. For example, in the Burkina Faso iCCM evaluation, two-page "district profiles," which used basic charts to visualize the evaluation data collected for that district and its performance relative to other districts, were developed for each district by the evaluation team.
- *Global scientific public health communities*. Evaluators have a responsibility to publish their findings in peer-reviewed scientific journals, and especially those likely to reach readers who can make use of the findings. Presentations at professional conferences usually reach a smaller audience but can also be useful. The latter forums offer an opportunity for younger members of the evaluation team to gain visibility and experience in presenting to colleagues.

Our experience indicates that generating interest in and uptake of the results of large-scale program evaluations is an ongoing process, and often requires several attempts using multiple channels. One strategy to enhance dissemination of the results is to ensure that those who can make use of the findings are involved from the start in defining the evaluation questions and are kept informed of the progress of the evaluation and its intermediate results.

Working in Large-Scale Evaluations

Conducting large-scale evaluations is not for the faint-hearted. This chapter has focused on the technical aspects of designing and conducting an evaluation, mentioning only in passing some of the political and personal challenges involved. We close the presentation here by highlighting a selection of these issues, all of which are crucial for designing an evaluation that can produce sound evidence that is widely used to improve public health practice and programs.

First, good evaluations require effective communication. **EXHIBIT 18-10** lists some common misperceptions about evaluation and evaluators from the perspective of those implementing or funding programs, and vice versa.

Second, good evaluations require a broad range of skills and techniques, as well as an interdisciplinary approach. Evaluators should have sufficient experience and a multifaceted "toolbox" to respond to the specific questions posed by stakeholders, rather than

EXHIBIT 18-10 Building Stronger Bridges Between Implementers and Evaluators

TABLE 18-6 lists some of the things implementers say about evaluators, and evaluators say about implementers. In a perfect world, these perceptions would be brought into alignment and both groups would recognize the value of sound evaluation as a contribution to strong programs. Making this synchrony happen is a challenge that must be faced every day, in every evaluation.

TABLE 18- 6 What Are They Saying?

Implementers About Evaluators and Evaluations	Evaluators About Program Implementers and Implementation
■ Not tied to the realities of the field; too academic ■ Interested in publishing rather than saving lives ■ Too slow in producing results ■ Cost too much; resources would be better spent in doing more implementation ■ Can bring only bad news ■ Too focused on impact, rather than on process (black box) ■ Insensitive to the policy process—produce results that are too late, too negative, insufficiently action oriented ■ We could do a better job ourselves, from within the program	■ Don't understand the importance of external, independent evaluations ■ Underestimate the need for data checking and time for analysis before sharing results ■ Need to recognize and act on intermediate results more rapidly ■ Want to "cherry pick" the findings to support their own program ■ Don't understand that evaluation is a technical discipline and requires special training to be done well ■ Need to do more internal monitoring and documentation of their own programs and to cover such costs from their budgets, rather than expect evaluators to do these tasks

just those questions they have been trained to answer. This goal is often best accomplished by establishing an evaluation team, as was done in all of the large-scale evaluations used as examples in this chapter.

Third, good evaluations require sufficient time and funding. Unfortunately, evaluation is often an afterthought, and setting aside funds for evaluation is perceived as "taking money away from beneficiaries." Underfunded and rushed evaluations often lead to poor-quality data, significant design limitations, and invalid results. In situations where sufficient funds truly cannot be set aside for an impact evaluation (say, at least 5% of program costs, and more if the evaluation needs to conduct its own household surveys), it may be preferable to focus instead on conducting a process evaluation, or using evaluation funds to conduct high-quality monitoring. However, if a measure of the program's effectiveness is required, it is essential to allocate adequate funds for the evaluation, and to begin evaluation planning and data collection well before the program is rolled out.

Fourth, good evaluations require patience and flexibility. Large-scale evaluations can move only as fast as implementation, and real-world programs are vulnerable to frequent delays, setbacks, and false starts. Timetables for program implementation often slip or are changed for reasons outside the control of the evaluation team. In-country research partners have many demands on their time, and capacity-building exercises are often needed as a precursor to full analysis of the data. Evaluation results may sit on a shelf until political circumstances or changes in leadership provide an opportunity for them to be incorporated into program plans. Ideal designs (based on the content in texts like this one) must often be modified to reflect what is possible and affordable in specific country contexts.

The authors of this chapter extend an invitation to readers to become engaged in the science of large-scale evaluations, either as evaluators themselves or as informed consumers and supporters of evaluation. Few formal training programs for public health evaluators exist, although the number has increased in recent years. Making a commitment to evaluation often requires seeking out and using resources from a variety of disciplines, and bringing them together into an effective mix of skills. Recent efforts to establish a community of practice—for example, the 3ie initiative—should be continued and expanded to support this emerging culture and to ensure that more and better evaluations of large-scale programs are supported in the future.

Acknowledgments

We thank Jennifer Bryce and Damian Walker for their substantive contributions to the earlier version of this chapter that was published in the third edition of this text.

Discussion Questions

1. Which arguments would you use to convince (1) a donor agency or (2) a ministry of health to allocate funds to conduct impact evaluations of its health programs?
2. What are the major challenges in conducting impact evaluations of health programs in LMICs?
3. Imagine that you are advising an NGO that wants to evaluate one of its health programs implemented in a LMIC. How would you go about determining whether the organization should use an adequacy, plausibility, or probability design for the evaluation? What are the tradeoffs for these designs in terms of feasibility, complexity, and level of inference?
4. How are data about costs obtained and used in program evaluations? Which kinds of questions can these data answer?

CHAPTER 19

Health and "The Economy"

Richard Smith, Jennifer Prah Ruger, Dean T. Jamison, David E. Bloom, and David Canning

Introduction

At the most basic level, being poor is bad for one's health and being ill is bad for one's wealth. Of course, beyond that simple statement, the discussion becomes more complicated. Clearly, though, health and economics have a close, symbiotic relationship. That the health of an individual determines his or her productivity and ability to work, and that having more resources enables better nutrition and better health care, are well known. Although this dynamic is often examined at the individual level, it is less often investigated at the macroeconomic level. However, at the broadest level, economic growth is clearly associated with changes in disease profiles. This consideration is especially critical for countries undergoing major economic growth. Notably, transitioning from being a low- and middle-income country (LMIC) to being a high-income country is associated with a lag in health impacts, such that the country experiences a period of time with high levels of both communicable *and* noncommunicable diseases—a phenomenon known as the "double burden" (Boutayeb, 2006).

Macroeconomic policies concerning public expenditures targets, inflation control, tax policy, and exchange rates, among others, affect the provision of health care and a population's health status. For instance, national income and fiscal targets constrain how much a government can spend on health care; the exchange rate affects the costs of vaccines and drugs; and tax policies relating to tobacco, alcohol, and "fast food" influence people's demand for these products and ultimately their health. The health sector itself is also a major economic sector—in terms of employment, for instance—and is linked to other economic sectors via the consumption of other goods and services (e.g., electricity, construction, and pharmaceuticals). It is also integrated with the global market for goods, services, and people, which is subject to considerable international trade (see the *International Trade and Health* chapter).

Whether the final objective of development policy is economic growth, poverty alleviation, or improved quality of life, including health, these domains are inextricably linked. Given these interactions, it is critical that health professionals are equipped to understand the association between population health and the economy if they are to devise health and development policies that will improve people's quality of life worldwide. This chapter provides an overview of these interactions and relationships. It outlines the critical features, and terminology, of the macroeconomic perspective, and considers the relationships through the lenses of the household (looking especially at the interaction of economic growth and health), risk factors for disease (communicable, noncommunicable, and outbreaks), and the economy and its relationship with the healthcare sector.

A Macroeconomic Focus

Economics can be broadly split into microeconomics and macroeconomic. Microeconomics essentially concerns choices and activities at the individual or firm level. It considers which goods firms decide to produce and which goods households decide to consume. Households and firms interact within a market, where price movements seek to equate demand and supply. Typically, these markets combine to form "sectors," such as agriculture, manufacturing, or health care. In turn, the interactions of these sectors constitute "the economy." Macroeconomics then concerns choices and activities across several of these markets and sectors and, therefore, "the economy" as a whole.

Generally, health economic analysis addresses microeconomics, which focuses on the primary, secondary, and tertiary care services specifically designed to affect health status. The *Design of Health Systems* chapter, which focuses on the "economic costs" of specific diseases, takes this approach. Because the current chapter takes a much broader approach, it uses some specific terms that require definition (**EXHIBIT 19-1**).

The most central term is "gross national income" (GNI), which is used internationally to classify countries into stages of development. Each year, the World Bank revises the per capita GNI benchmarks that are used to classify countries. **TABLE 19-1** displays the World Bank's 2016 classification of countries, based on annual 2015 data (http://blogs.worldbank.org/opendata/new-country-classifications-2016).

Growth in GNI over time is termed "economic growth." This growth causes countries to transition between these classifications and is the core concept of economic development. GDP and GNI are also used to measure trends in economic activity. A *recession* is generally defined as a downturn in economic activity, with real GDP falling in two or more successive quarters (i.e., 3-month periods). Generally, economies face periods of economic growth and recession; these ups and downs are known as the *business cycle*. A *depression* is an economic downturn that is more severe than a recession, usually defined as a period when real GDP has decreased by more than 10%.

Economic performance and growth, expressed through GNI, is a major political goal and a key determinant, and result, of changes in population health.

EXHIBIT 19-1 Key Macroeconomic Terms

Appreciate: When a currency rises relative to other currencies, it is appreciating in value.
Balance of payments (BOP): A measure of the currency flows between countries.
Constant dollars: Constant dollars, or currency, correspond to values that have been adjusted for inflation and so reflect the "real" or actual purchasing power.
Current dollars: Current dollars, or currency, refer to the actual dollars spent.
Depreciate: When a currency falls relative to other currencies, it is depreciating in value.
Depression: A severe downturn in economic growth—often judged as a 10% decrease in real gross domestic product (GDP).
Devaluation: When a country's currency value declines in relation to other currencies, it is devaluating.
Fiscal policy: Policies introduced by the government to influence the economy through taxes and government spending.
Gross domestic income (GDI): The income from all economic activities that take place within a country, including wages, profits, rents, and interest.
Gross domestic product (GDP): The size or output of an economy. GDP comprises the total value of goods and services produced in one year in a country. It concerns the output produced in a specific geographic location, regardless of who produces it.
Gross national income (GNI): The income from the economic activities that citizens and firms of that country undertake, regardless of where they occur. GNI is GDP plus income that the country's citizens earn from abroad, minus income that foreign citizens earn in that country.
Hyperinflation: Inflation that exceeds 50% per month.
Inflation: The general rise in prices through time, which means that money loses its value over time.
Macroeconomics: The performance and functioning of the economy as a whole; the relationships among economic growth, output, employment, and inflation.
Monetary policy: Policies the government uses to reach its objectives by adjusting interest rates and the amount of money in circulation.
Purchasing power parity (PPP): An adjustment of prices that accounts for the currency's ability to purchase goods.
Recession: A downturn in economic activity wherein real GDP falls for two successive quarters (i.e., 3-month periods).

TABLE 19-1 World Bank Country Classification, 2015

World Bank Country Classification	2015 GNI per Capita	Number of Countries
Low-income countries	$1,025 or less	53
Lower-middle-income countries	$1,026–$4,035	55
Upper-middle-income countries	$4,036–$12,475	41
High-income countries	$12,476 or more	60

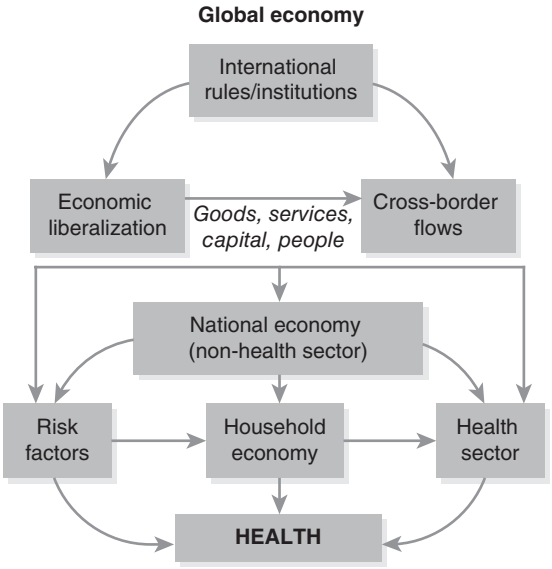

FIGURE 19-1 A simplified view of the relationship of the economy to health.

Modified from Smith, R.D., & Hanson K. (2012). *Health Systems in low-middle-income countries: An economic and policy perspective*. Oxford, UK:Oxford University Press.

FIGURE 19-1 illustrates the core mechanisms by which the economy relates to health. The lower half of the figure represents the national economy of interest, and the upper half represents the rest of the world and, critically, the trading relationships. In the lower half—the national economy—health looms large as the core concern for those reading this text. Surrounding it are four categories of factors that influence health status: (1) risk factors, representing genetic predisposition to disease, environmental influences on health, infectious disease, and other factors; (2) the household economy, representing factors associated with how individual and household behaviors and decisions impact health; (3) the health sector, representing the impact of goods and services consumed principally to improve health status; and (4) the non-healthcare sectors of the national economy, representing the meta-influences of non-health sectors and factors on these other three categories. How these factors relate is also illustrated in Figure 19-1. Those concerned with the health sector focus on one small part of this jigsaw puzzle—the links between the health sector and health.

The upper half of Figure 19-1 illustrates the influences of factors outside the national context—that is, the "rest of the world"—and highlights the main links to the domestic context. For example, various international influences directly affect *risk factors* for health, such as cross-border flows that increase exposure to infectious diseases through rapid cross-border transmission of communicable diseases. International factors also affect health by influencing the *national economy*. Economic liberalization—reducing barriers to make trade easier—influences economic growth and the distribution of positive and negative aspects of this growth, which in turn influence health (e.g., causing changes in consumption of various goods that are either beneficial or detrimental to health). Finally, trade directly affects the *health sector* by providing and distributing health-related goods, services, and people, such as pharmaceutical products, health-related knowledge and technology (e.g., new genomic

developments), and the movement of patients and professionals. The *International Trade and Health* chapter considers these aspects in more detail.

Also of note in the upper half of Figure 19-1 is the importance of international structures for governance, both of health and other aspects of life, which the *Global Health Governance and Diplomacy* chapter discusses. Here, we focus on the main impacts and relationships depicted in the lower half of Figure 19-1, using the structure of the three broad areas of the household economy, risk factors, and the health sector.

The Household as the Nexus of the Health–Wealth Relationship

Much macroeconomic policy concerns economic growth, as higher GNI leads to more opportunities to consume—which, in our specific context, will result, all else being equal, in better health. Central to this link between macroeconomic policy and health is the household. Health affects household income through its effects on labor productivity, savings rates, investments in physical and human capital (education, for example), and age structure. The other direction of causality derives from the impact that household income has on health through improved capacity to purchase food; adequate sanitation, housing, and education; and incentives to limit fertility.

In general, analyses suggest that "wealthier countries are healthier countries" (Pritchett & Summers, 1996). Although the direction of causation is debatable, a "virtuous circle" is engendered between increasing wealth and health such that both directions of causation are valid (Suhrcke, McKee, Arce, Tsolova, & Mortensen, 2006). This section looks at these links between health and wealth at the macroeconomic level, through the lens of the household, beginning with the role of health on wealth, and then turning to the role of wealth on health.

The Role of Health in Economic Growth

A considerable body of literature addresses the role of health in economic growth, both in general (Acemoglu & Johnson, 2007) and related to specific diseases, especially human immunodeficiency virus (HIV) (Lovász & Schipp, 2009; McDonald & Roberts, 2006) and malaria (Gallup & Sachs, 2001). One of the main empirical tools used is cross-country regression of economic growth (usually measured in terms of the growth rate of per capita GDP) on the variables believed to explain that growth, which include some proxy for "health," such as life expectancy, mortality rates, or disease prevalence (Bloom & Canning, 2000; Solow, 1956).

The evidence suggests that health is closely linked with economic growth and development. **FIGURE 19-2** illustrates the multiple pathways through which illness can influence economic development. The top half of the figure shows the age-structure effects of demographic transition as seen by a change in the dependency ratio, which has been a significant determinant of growth in East Asia, for example. High levels of fertility and child mortality (both, in part, a result of child illness), along with reductions in the labor force brought on by mortality and early retirement, can cause an increase in the dependency ratio that ultimately reduces income. Conversely, reversing these effects can decrease the dependency ratio, which increases per capita income. In addition, not only does the health of the mother before and during pregnancy affect the child's health (Kinra et al., 2008), but childhood health also affects adult health and productivity (Fogel, 2005; Park, Falconer, Viner, & Kinra, 2012). The lower half of Figure 19-2 illustrates the effects of illness and malnutrition in reducing labor productivity, operating through other factors such as reduced investments in human and physical capital. Finally, reduced labor productivity has a direct impact on reducing per capita income.

Life expectancy, in particular, has been shown to be a powerful predictor of household income levels and consequent economic growth: Lower levels of mortality and higher levels of life expectancy have a statistically and quantitatively significant effect on income levels and growth rates (Bloom, Canning, & Sevilla, 2004). When Jamison and colleagues (2005) combined their empirical estimates of the effects of adult survival rates on national income with country-specific estimates of improvements in survival rates across 53 countries, they found that, on average, 11% of total growth rate in per capita income is due to health improvements, although substantial variation across countries exists. Historical studies have reached similar conclusions using different types of data. For example, in a study of the determinants of economic progress in Great Britain between 1780 and 1979, Fogel (1997) estimated that 30% of per capita growth could be explained by health and nutritional improvements. Bloom, Canning, and Jamison (2004) reviewed the results of regression analyses that use life expectancy or other measures of mortality rates to explain economic growth. Their report indicates that findings in the literature of a large and significant impact of

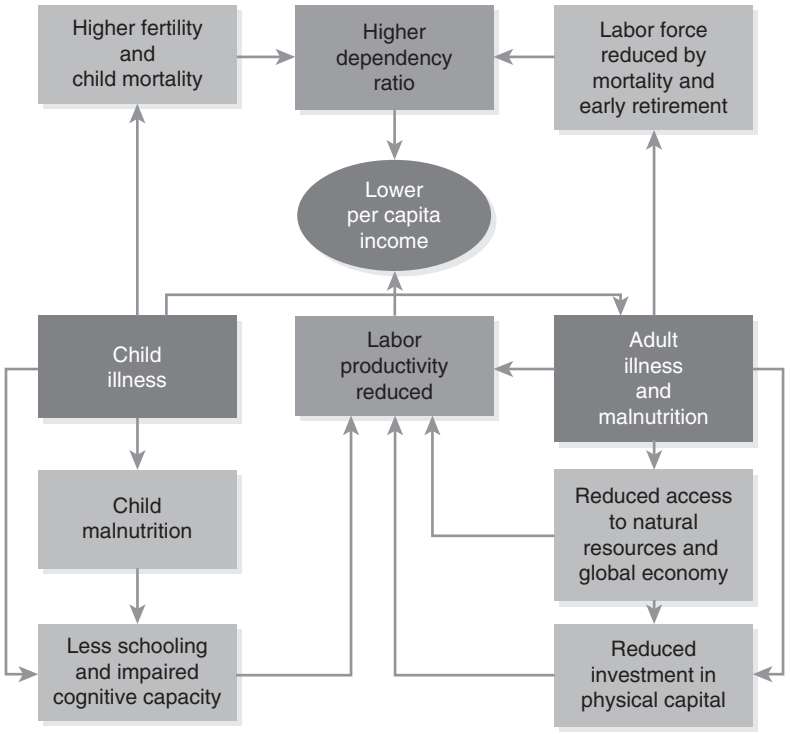

FIGURE 19-2 Channels through which illness reduces income.

initial health status on subsequent economic growth rates are robust.

Although solid evidence supports a large effect of health on economic growth, the issue of how to interpret this result remains a thorny one. Bhargava and colleagues (2001) concluded that the mechanisms underlying these effects are threefold: (1) the improvements in productivity that arise from a healthier workforce and less morbidity-related absenteeism, (2) the increased incentive that higher life expectancy gives individuals and firms to invest in physical and human capital, and (3) the increase in savings rates as working-age individuals save for their retirement years.

Productivity may be especially sensitive to health effects in low-income settings, as much of the work in these environments requires physical strength and endurance. For example, in one study, Indonesian men with anemia were found to have 20% lower productivity than men without it (Shastry & Weil, 2002). In an experiment, men were randomly assigned to receive either an iron supplement or placebo. Anemic men who received the iron treatment increased their productivity to nearly the levels of non-anemic workers; these productivity gains were relatively large compared to the costs of treatment. Further, the profile of disease in low-income settings, especially the predominance of infectious diseases, affects the full age range, whereas in high-income countries the predominance of non-infectious disease means that those most affected are at older ages. Thus, the effects of health on economic growth rates are likely to be strongest at the low levels of income. It has further been suggested that differences in health, physical capital, and education are roughly equal in their importance in producing cross-country differences in income levels, supporting the view that health has a large macroeconomic effect (Shastry & Weil, 2002).

The other potential explanations for life expectancy's importance relative to economic growth focus on the incentives to invest in education and to save for retirement. For instance, Bloom and colleagues (2003) have reported empirical evidence that life expectancy is linked to national savings rates. However, the incentive to invest more—both individually and nationally—in education as life expectancy increases is of particular significance because of the close links between health and education, and education and economic growth. Health and nutritional problems can have significant consequences for the educational success of many school-age children (also see the *Nutrition* chapter), which affects lifetime productivity and earnings, and therefore, national economic growth. A panel of experts taking part in the Copenhagen Consensus of 2008 (https://www.scribd.com/document/78190555/Copenhagen-Consensus-2008-Results) ranked a wide range of potential interventions in terms of their ability to advance global welfare, and particularly the welfare of LMICs Recognizing that limited funding

is available for such interventions, they examined the evidence base to determine the most cost-effective manner in which to spend development money. Six of the top 10 interventions involved disease control or nutrition, and their top-ranked intervention was micronutrient supplements for children.

The weight of the research evidence suggests, then, that improved health increases household income and, in turn, national GNI per capita, although the precise nature of this causation can be debated. The effect can also be modulated through effects on demography. Acemoglu and Johnson (2007) have argued that, even though health improvements may increase individual productivity, the reduced mortality rates will subsequently lead to a surge in population numbers that can depress income levels through a Malthusian effect of crowding out scarce resources such as land. This effect can be avoided, however, if fertility declines. Health advances in most high-income countries are associated with rapid declines in infant and child mortality rates. These declines, and increases in the proportion of surviving children, can substantially reduce desired fertility (Kalemli-Ozcan, 2002).

For example, in the 1940s, health improvements that led to changes in mortality and fertility rates in East Asia provided the impetus for a demographic transition. In the first phase of the demographic transition, an initial decline in infant and child mortality prompted a subsequent decline in fertility rates. These changes in mortality and fertility altered Asia's age distribution: The working-age population began growing much more rapidly than the youth dependent population. This resulted in a disproportionately high percentage of working-age adults, and thus a lower dependency-ratio, and led to increased rates of economic growth (Bloom, Canning, & Sevilla, 2002). Note, however, that while this "demographic dividend" provides an opportunity for increasing wealth, it does not guarantee such results. East Asia's growth rates were achieved because both the government and private sectors mobilized the growing workforce, successfully managed economic opportunities, adopted new industrial technologies, invested in education and human capital, and exploited global markets. These factors helped East Asia realize the economic growth potential created by the demographic transition.

The Role of Economic Growth in Health

We have seen how health can contribute to greater economic growth and reduced poverty. Here we consider the converse relationship—that is, how greater economic development can influence health. An important question in assessing the historical determinants of health is how increasing income, in relation to other factors, influenced health improvements, especially during the 20th century. Preston's (1980, 2007) seminal work provides a broad framework for assessing income's impact, and a classic study from the World Health Organization (WHO, 1999) provides a clear examination of these relationships.

FIGURE 19-3 shows that from 1952 to 1992, mean income on a global scale increased by approximately 66%, from roughly $1,500 to $2,500. The curves further indicate that the infant mortality rate (IMR) declined more than predicted (to 55 deaths per 1,000 births rather than to 116 deaths per 1,000 births) based on the 1952 relationship between income and IMR, suggesting that factors more important than income influence health.

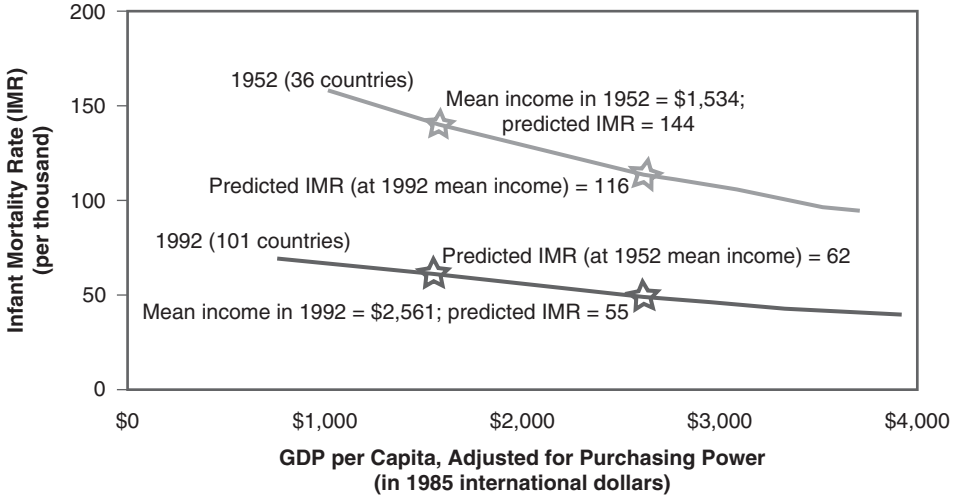

FIGURE 19-3 The role of improvements in income in reducing infant mortality rates.

At its heart, the positive impact of increased income on health is due to a variety of intervening determinants becoming more affordable (other than being directly made available through health care, which is considered later), such as housing, education, water, sanitation, and nutrition. There are also links from policies in other areas. Industrial safety programs and environmental regulations, for example, have specific health objectives and are targeted at specific groups—industrial workers and the general public, respectively. Housing policies aimed at subsidizing or providing housing for lower-income individuals have broader social and health objectives, but may also have concrete health impacts. Empowering women through better education, among other interventions, can enhance their capacity to improve their own health and that of their families (Thompson, 2007). The *Understanding and Acting on Social Determinants of Health and Health Equity* chapter provides an extensive overview of the determinants of health that are outside the health sector and their attractiveness from a health policy perspective.

It is important to remember that macroeconomic concerns *aggregate* populations, and not individuals. In many cases, changes in macroeconomic policy will have different impacts on different groups; some will benefit and some not. For example, employment creation in one area may be accompanied by job destruction in another area as labor moves from one sector or industry to another. This process, known as "churning," requires social safety nets and smooth employment transition mechanisms to avoid negative effects on the workforce. Not only might economic insecurity mean that nonpoor households become poor, affecting material conditions (nutrition, housing), but it can also itself be stressful, thereby directly impacting psychological health (Wilkinson & Marmot, 2003).

A growing body of research describes the impact of the distribution of economic growth on population health inequalities, and the experience of relative deprivation as a cause of ill health. In the United Kingdom, for example, the seminal Whitehall Study—a longitudinal study of behaviors and health status of more than 10,000 British civil servants—found that over a 10-year period males age 40 to 64 in the lower grades (clerical and manual) of the civil service had an age-adjusted mortality rate that was 3.5 times higher than that for males in senior administrative grades (Marmot et al., 1991; Marmot & Theorell, 1988; Wilkinson, 1986). A gradient in mortality stretched across all levels of the civil service: Each status group had a higher mortality rate than the group immediately above it, which the provision of medical care or other primary goods, such as absolute levels of income, shelter, food, or education, could not explain.

Other research, aimed at confirming the Whitehall Study findings cross-nationally, has revealed a similar correlation between hierarchy and health. In a study of 11 Organization for Economic Cooperation and Development (OECD) countries, conducted from 1975 to 1985, Wilkinson (1990) used two measures of income inequality—the Gini coefficient and the ratio between the percentage of income flowing to the top and bottom 30% of a country's population. The analysis identified an inverse relationship between income inequality in a country and the average national life expectancy. While nations with absolute levels of higher average income per capita had higher average life expectancy than those with a lower level of average national income (e.g., higher-income countries versus lower-income countries), the study suggested that greater income inequality *within* a country might also have a negative influence on life expectancy. Nations with a relatively flat income gradient, such as Japan and Sweden, had higher life expectancies than countries such as the United States and West Germany, which had steeper gradients (Preston & Elo, 1995).

More recent work supports the findings of an income–health gradient. A Canadian study found that people in lower-income deciles had a lower health-adjusted life expectancy compared with people in higher-income deciles (McIntosh, Finès, Wilkins, & Wolfson, 2009). Likewise, a study in South Korea found that both men and women in lower socioeconomic positions had lower levels of self-reported health status and higher levels of morbidity, even after controlling for behavioral risk factors (Kim & Ruger, 2010).

Other work has interpreted the apparent effects of income inequality on health as resulting from effects of ranking within a reference group that is much smaller than a country (Deaton, 2003; Karlsson, Nilsson, Lyttkens, & Lesson, 2010). If, for example, an academic had a low salary relative to other members within her discipline, this disparity might have a deleterious effect on health even if her absolute income was relatively high and she lived in a country where income was relatively evenly distributed. Even if individuals' reference groups are unobserved, individual income levels will provide partial information about the individuals' standing in their reference group (with the amount of information depending on the relative levels of within-group and across-group inequality). The widely documented adverse effects of inequality on average health status can occur even if either within-group or between-group inequality has no real

effect on health. Deaton and Paxson's (2001) analyses using U.S. data support the conclusion of no effect. Zhang and Wang (2010), in contrast, found differences in development among children in eastern and western China that were related to regional economic status and living standards. The jury remains out on how reference-group rankings and socioeconomic inequalities influence health.

Just as health conditions at any time seem to improve with income level, so, too, might adverse income shocks have detrimental effects on health. Economic recessions—with their concomitant declines in employment and income, as well as rising uncertainty regarding employment and financial well-being—have been linked to increased morbidity and mortality, and to poor nutrition and mental health (Catalano, 2009; Uutela, 2010).

An economic crisis may affect human health through myriad channels. First, loss of employment and reduction in wages can increase stress and lead to physical and mental health problems, including substance abuse, depression, and suicide (Uutela, 2010). An important finding in this line of research is that the health effects of economic fluctuations and resulting unemployment can be ameliorated by social protection mechanisms that offset the loss of income (Stuckler, Basu, Suhrcke, Coutts, & McKee, 2009).

Second, with less real income, individuals and households tend to spend less money on the promotion and preservation of health. This trend could mean reduced attention to primary care, inadequate adherence to medication regimens, and impaired access to high-quality food or adequate quantities of food. The Food and Agriculture Organization (FAO) of the United Nations reports that household attempts to cope with economic crises can put both child and adult nutrition and health status at risk. Such strategies include replacing more nutritious food with less nutritious and less expensive food options, reducing overall food consumption, and reducing the frequency of healthcare visits (Brinkman, de Pee, Sanogo, Subran, & Bloem, 2009; FAO, 2009).

Third, fewer financial resources may be available for public health programs during and after economic crises. During the 2008 economic crisis, for example, high-income countries spent large sums of public money on "bailout" initiatives to generate higher levels of market liquidity. These policies may put global population health at risk, to the extent that governments finance these macroeconomic policies through cuts in foreign assistance for health and cuts in their own future social spending.

Finally, individuals and households may spend down their savings and assets during economic crises. This practice then renders them more vulnerable to future economic shocks.

Past experience shows that the health of the poor is especially vulnerable to the negative effects of economic downturns. FAO (2009) has reviewed the impact of past crises on nutrition and health among the poor. For example, Cameroon's crisis of the 1990s was associated with an increase in the prevalence of underweight children, especially among the poorest half of the population. Zimbabwe's drought of the mid-1990s caused losses in real income, leading to stunting among young children in the poorest households—a phenomenon that has been linked to cognitive impairments and reduced earnings during adulthood (FAO, 2009). If past crises are any indication of what can be expected from the 2008 global economic crisis, the full effects are likely to be serious, widespread, and long-lasting, with significant implications for other realms of well-being (Chang, Stuckler, Yip, & Gunnel, 2013; Kaplan, 2012) (**EXHIBIT 19-2**).

EXHIBIT 19-2 Global Economic Crisis of 2008

The global economic crisis that began in 2008 has raised important and ongoing issues for population health. In discussing these issues, it is important to remember that the crisis came on the heels of the food and fuel crises of 2006–2008, which had already begun to erode people's health and the purchasing power of their income in a number of countries. In addition, the crisis began in high-income countries— unlike the financial crises of the 1980s and 1990s, which began in the low- and middle-income world. In LMICs, the 2008 global recession has meant declines in exports, foreign direct investment, remittances, and donor aid, and rising rates of unemployment. Government budgets were also negatively affected, which in turn has had detrimental effects on health-sector funding.

The true magnitude of the health effects of the 2008 economic crisis remains largely unknown, and the lack of systematized monitoring of the situation has been noted (Richards, 2009). In addition, little is known about the distribution of impacts across the income spectrum. For some groups within the larger population, reductions in income might potentially lead to improved health behavior and reductions in risky behavior, such as increased walking or cycling in place of driving (Catalano, 2009). For the most part, however, available data indicate an overall negative impact on population health from such economic downturns (Parmar, Stavropoulou, & Ioannidis, 2016). FAO (2009), for example,

reported on problematic consequences in Armenia, Bangladesh, Ghana, Nicaragua, and Zambia. In Nicaragua, the crisis led to a decline in the consumption of meat and dairy products, which provide macronutrients and micronutrients that are particularly vital for young children and women who are pregnant or lactating. FAO's Zambia case documents severe impacts of the crisis on healthcare access and utilization: Workforce reductions in the mining sector resulted in the loss of both income and benefits provided by mining companies. This, in turn, translated into a loss of access to the hospitals and clinics established by the companies, which provided not only antiretroviral treatment for HIV-positive individuals, but also nutritious diets.

Implications of the economic downturn for health systems have also been explicated. For example, U.S. hospitals reported increases in uncompensated care and reductions in revenues as a result of the crisis. In response, many hospitals postponed capital investments, such as infrastructure renovations, purchasing of equipment, or upgrades to information technology systems (Dranove, Garthwaite, & Ody, 2015).

Although a full picture of the 2008 crisis's impact on health is lacking, we can look to past crises to shed some light on this issue. For example, Frankenberg et al. (1999) examined data contained in the Indonesia Family Life Surveys to study the impact of the 1998 economic crisis on household expenditures, employment, education, utilization of healthcare and family planning services, and health outcomes. Although their study found little evidence of a negative impact of the crisis on health outcomes, perhaps because of the narrow time frame, it revealed that the economic stress had negative impacts on health-seeking behavior and health system operations. In particular, the study noted decreased use of public health services by both adults and children, declines in vitamin A supplementation for children, medication and supply stock-outs at public facilities, and price increases in both public and private health facilities.

Similarly, an Australian Agency for International Development (1999) report explored the magnitude of the health impacts of the 1997–1998 Asian economic crisis. The report cited a sharp increase in the price of pharmaceuticals, declines in vitamin A intake, and declines in the frequency of child healthcare visits during this period. In another study of the link between macroeconomic crises and health, Brainerd (1998) examined the effects of market reform on mortality in Russia and other transition economies in the late 1980s and early 1990s. Standardized death rates in these countries increased from 1989 to 1994, with Russia and Latvia experiencing the greatest increases—more than 50%. Brainerd provided strong evidence of a significant positive association between unemployment and the standardized death rate for adult males across 15 countries in the former Soviet Union.

Finally, it is important to recognize that most, if not all, economies are not self-contained, but rather are integrated into the global system, as indicated in Figure 19-1. Integration is generally associated with more rapid growth rates, which then accelerate the health effects from development, although the full picture for any one country will inevitably be more nuanced. We do not consider international trade further here, as the *International Trade and Health* chapter specifically focuses on aspects of trade and health.

Macroeconomics and Risk Factors for Disease

The relationship between the economy and health is mediated through risk of disease and injury, which is related in part to household behavior and in part to far wider considerations. Economic behavior partly determines this risk, and the cost incurred from this risk partly determines economic performance. Often a distinction is made between the direct costs—meaning the impact of prevention and treatment of disease and injury on health systems—and the indirect costs—meaning the non-health-system effects on labor productivity or other sectors. A distinction is also made between the risks associated with communicable disease (an important subset of which are major outbreaks or pandemics), which are often the most visible in a global context, and the risks associated with noncommunicable disease (NCD). For instance, most of the health areas subject to intensive global concern and funding relate to infectious diseases—especially malaria, HIV/AIDS, and pandemic preparedness—but increasing attention is now being paid to the (economic and health) impacts associated with diet, obesity, tobacco consumption, unhealthy consumption of alcohol, and aging. In this section, we look at the relationship between the macroeconomy and the risk factors associated with the three areas of communicable disease, pandemics, and noncommunicable disease.

Communicable Disease

Communicable diseases are transmitted by some type of vector—human, animal, or other. The relationship between macroeconomics and communicable diseases is twofold. First, the overall environment in which people live (e.g., air quality, sanitation, housing) is determined, in large part, by their income and wealth. Second, the increased movement of people, animals, and goods associated with an increasingly

active economy—especially internationally—affects the movement of disease. Although several other communicable diseases have emerged or re-emerged in recent years, the major international focus remains on tuberculosis (TB), malaria, and HIV/AIDS; the latter two considered in more detail here.

Malaria remains one of the most significant public health problems in lower-income countries and generates significant economic costs (as discussed in the *Infectious Diseases* chapter). Chima and colleagues (2003) and Malaney and colleagues (2004) categorize the direct costs of malaria as comprising the direct costs of prevention (e.g., mosquito coils, aerosol sprays, bed nets, residual spraying, and mosquito repellents) and treatment (e.g., drugs, treatment fees, transport, and costs of subsistence at a health center), and the indirect costs of labor time lost because of illness. Given these two components, household and public-sector expenditures are increased and labor inputs are decreased due to malaria. Reduced school attendance and performance, and increased cognitive impairment, can likewise reduce human capital. For example, using the malaria eradication programs in the United States in the 1920s and in Brazil, Colombia, and Mexico in the 1950s as natural experiments, Bleakley (2010) found that children in malarial areas in these countries born just after the eradication programs were undertaken had significantly higher earnings than those born just before the programs were initiated.

Although studies of malaria tend to evaluate the costs of disease within a specific economic environment, potentially more significant is the effect of disease on broader economic opportunities. If a factory goes unbuilt in a region because of malaria, for example, the consequences for income may be far more substantial than malaria's consequence for productivity in traditional agriculture. Gallup and Sachs (2001) advance this perspective, arguing for a macroeconomic approach that uses cross-country time-series data to capture effects that would go unobserved with collection of only household data. In particular, their seminal work uncovered a significant negative relationship between malaria and GDP growth, with the effects having a far greater estimated magnitude than those reported in household-level studies, and suggesting that the most important ways in which malaria affects long-run economic growth are through its effects on a country's ability to attract foreign direct investment and to create an environment suitable for modern economic growth. Thus, allowing countries to undertake new enterprises, rather than just improving productivity in traditional enterprise, may be the most economically significant consequence of malaria control programs.

The reverse is also true: Economic development can have a significant impact on risks of malaria. Tusting et al. (2013) undertook a systematic review and meta-analysis of studies that measured socioeconomic status and parasitologically confirmed malaria or clinical malaria in children age 0 to 15 years. The odds of malaria infection were significantly higher in the poorest children than in the least poor children, and were robust to subgroup analyses. Lower socioeconomic status was also associated with environments more conducive to malaria transmission, such as poor housing quality, inadequate diets, and lack of bed nets. The authors concluded that increased investment in interventions to support socioeconomic development is clearly warranted, as such initiatives could prove highly effective and, more importantly, be sustainable against malaria in the long term.

In contrast, and perhaps counter-intuitively, studies have found the economic effects of HIV/AIDS on the economy can be relatively small. For example, a seminal study of the impact of HIV/AIDS on India's national economy (Anand, Pandav, & Nath, 1999) found that the estimated total annual costs of HIV/AIDS in India under low (1.5 million infected), medium (2.5 million), and high (4.5 million) prevalence scenarios were 7 billion, 20 billion, and 59 billion rupees ($200 million, $571 million, and $1.7 billion), respectively. AIDS treatment and productivity loss were the two major components of these costs. From this, the estimated annual cost of HIV/AIDS (assuming a prevalence of 4.5 million persons) was roughly 1% of India's GDP. Likewise, other studies have found that, especially early in its course, the AIDS epidemic had an insignificant effect on the growth of per capita income (Haacker, 2004).

But this is not the entire picture. One reason for the small financial effects associated with HIV/AIDS is that economic consequences are usually measured in terms of income per capita. A high death rate reduces both income and the number of people in the economy, causing a sharp reduction in total output, but producing a more modest effect on income per capita. Thus, using as a metric the income level of the survivors, as is done with income per capita, is inappropriate. When Jamison and colleagues (2001) placed a value on decreases in a country's mortality rates and added this factor to the change in per capita income, they identified dramatic negative economic consequences of HIV/AIDS in five countries of eastern Africa in the period after 1990. The importance of the direct welfare effects of good health have also been emphasized by Nordhaus (2003), who argues that the welfare gains from improved health and longevity in the United States in the 20th century were greater than

the welfare gains due to rising income levels over the period.

According to Bell and colleagues (2003), the large number of orphans in countries with high AIDS mortality rates will lead to a higher short-term dependency ratio, lack of resources for education, and the production of successive cohorts with lower levels of schooling and income. In particular, this trend may plunge sub-Saharan Africa into even greater poverty. Moreover, the economic impact of HIV/AIDS could take years to realize and may be much greater and more widespread than forecasts estimate (Veenstra & Whiteside, 2005).

Outbreaks and Pandemics

There is a growing concern about the potential economic impact of infectious disease outbreaks and pandemics, following the outbreaks of severe acute respiratory syndrome (SARS) in 2003, H5N1 avian influenza in 2006, H1N1 swine influenza in 2009, and most recently Ebola in 2013 to 2016. Brahmbhatt (2005) highlights two major types of economic costs that arise from such outbreaks: (1) the costs of increased illness and death of affected people and animals, and (2) the costs of control and coping strategies to mitigate effects of the pandemic. For instance, the economic impact of the H1N1 outbreak in Mexico was estimated to be caused more by collapsing trade flows for pork products, and tourism, than by the health effects of the disease (Rassy & Smith, 2013).

The outbreak of SARS, in particular, caused a large decline in international travel due to quarantines, fear of infection, and worries about severe economic disruption (Wilder-Smith, 2006). According to Brahmbhatt (2005), the most immediate economic losses during the SARS outbreak were due to absenteeism, disruption of production, and severe decreases in tourism, mass transportation, retail sales, and hotel and restaurant use. Keogh-Brown and Smith (2008), however, found that, in retrospect, the effect of SARS on income levels was relatively short-lived and modest (**EXHIBIT 19-3**).

Pandemic influenza raises more concern, as it potentially combines the lethality of SARS with far greater pathogenicity. Studies have attempted to analyze the direct illness effects of influenza pandemics, typically through modeling the production effects of changes in labor supply. For example, Keogh-Brown and colleagues (2010) estimated the impact on the U.K. economy using epidemiologic data from pandemics that occurred in 1957 and 1968. Their analysis suggested that the economic impact of a repeat of the 1957 or 1968 pandemics would be short-lived, constituting a loss of between 3.35% and 21% of GDP in the first pandemic quarter and between 0.58% and 4.5% of GDP in the first year for various scenarios. Critically, the economic shockwave would be gravest when absenteeism (through school closures) increased beyond a few weeks, creating policy repercussions for influenza pandemic planning—the most severe economic impact is due to policies to contain the pandemic rather than the pandemic itself.

In another article by Smith and Keogh-Brown (2013), estimates are presented of the macroeconomic impact of the H1N1 (swine flu) pandemic of 2009 on the economies of South Africa, Thailand, and Uganda. Estimates suggest that the direct illness effects of such a pandemic are less than 0.5% loss of GDP, although the relative impacts on different economies will vary. In the 2009 pandemic, the impacts in Uganda were relatively larger than those in South Africa, and both

EXHIBIT 19-3 The Economics of SARS

Severe acute respiratory syndrome (SARS) is an infectious disease that spreads between humans in a similar way to the cold virus. Emerging in the Guandong province of China in late 2002, the disease was transmitted with great rapidity to Australia, Brazil, Canada, China, Hong Kong, South Africa, Spain, and the United States, creating serious public health concerns. The outbreak peaked during the second quarter of 2003 and was declared over by July 2003.

Although approximately 10,000 individuals were infected, of whom 10% died, the overall impact on health was far less devastating than initially feared. However, the possible economic impact of SARS was also a focus of concern. During the outbreak, travel and tourism income took a noticeable downturn in many infected countries. It was anticipated that fear of disease would negatively affect those industries that gather people in public places, such as restaurants, cinemas, and retail establishments.

The Canadian Public Health Agency (2003) suggested that SARS cost the country $350 million in lost tourism revenues, $220 million from reduced airport activity, and $380 million in lost nontourism retail sales. Estimates of the costs to Canada from SARS ranged as high as $2 billion. Keogh-Brown and Smith (2008) suggest that SARS caused losses to Hong Kong's GDP of approximately $3.7 billion and losses of 3% in China's GDP, even though less than 0.03% of Hong Kong's population and less than 0.0004% of China's population were actually infected with SARS. The overall estimate of the global macroeconomic burden was between $30 billion and $100 billion (approximately $3 million to $10 million per case).

of those countries' estimated GDP losses were 50% to 100% larger than the loss for Thailand. Interestingly, these studies found that the potential indirect effects on the economies concerned were more significant than the direct effects; a similar pattern found with studies of the Ebola outbreak (World Bank, 2015).

Based on the experience of the SARS outbreak, Smith (2006) argues that in the early stages of a new infectious disease, the key issue is risk, including the unknown dimensions of the threat, and the sense of panic that this uncertainty instills in the population. Thus, in the early stage of a pandemic, obtaining accurate assessments of the disease and appropriate responses is vital. Kleinman and associates (2008) also argue for a biosocial approach to new infectious diseases, combining the speedy acquisition of a biological understanding of the disease with policies that get the relevant information, and policy prescriptions, into the public domain.

A study by Smith and colleagues (2009) supports this general conclusion that the behavioral effects of a pandemic or significant outbreak are at least as important, if not more important, for an economy than the direct health impacts. These researchers examined the potential economic costs of a modern pandemic based on scenarios for pandemic influenza in the United Kingdom. While they found that moderate GDP losses would ensue (ranging from 0.5% in mild pandemics to 2% in severe pandemics), behavioral changes to avoid infection could potentially double these costs. For example, the cost difference between closing schools for 4 weeks at a pandemic's peak and closing schools for all 13 weeks of a pandemic was estimated to be £27 billion ($44 billion). Similarly, analysis of prophylactic absence from work showed that if a behavioral response that prompts individuals to refrain from work can be avoided, then the potential value of interventions to prevent a harmful economic response might be greater than the value of preventing negative health effects alone. In addition, if fear is the driver of behavioral change, the mortality rate of an outbreak might have a more significant effect than the number of people infected. The validity of these conclusions clearly depend on the assumptions made in scenario design, but the model results capture interaction effects that cannot be captured from a microeconomic approach focused on health alone. A further study by Smith and colleagues (2011) found similar behavioral change effects, such that prophylactic absence and school closure effects outweigh the economic impacts of the disease itself. An emphasis on preparedness, emergency procedures, risk assessment, and preventive actions at an outbreak's onset is potentially important to reduce the macroeconomic effects from such epidemics.

Nevertheless, in addition to the costs associated with an epidemic, or any other health concern, some financial benefits may accrue from such an event. Macroeconomics especially is concerned with flows of money around the economy. Thus, a financial cost to one sector, organization, or individual typically represents a financial benefit (income) to another sector, organization, or individual. For instance, a SARS outbreak or pandemic influenza can be good news if a company is involved in the manufacture of face masks or alcohol gel, or even drugs such as Tamiflu. It is even possible that a health emergency could engender positive economic outcomes overall on GNI, if the increases in incomes outweigh the losses. At the extreme, this is the effect associated with "post-war boom" involved in reconstruction. Of course, this does not mean that war is desirable, anymore than a pandemic would be. Rather, it illustrates the importance of recognizing the limitations associated with assessing macroeconomic impacts based on financial measures, and of critically understanding the basis for them to aid appropriate interpretation.

Noncommunicable Disease

Perhaps less obvious is the relationship between macroeconomic activity and risks concerning noncommunicable disease. Although macroeconomic growth can be beneficial when it leads to an expansion in the consumption of the goods that *improve* the probability of better health, such as clean water, safe food, and education, it also facilitates the increased consumption of goods that may be harmful or hazardous to health, such as tobacco, alcohol, and "fast food." As highlighted in the *Chronic Diseases and Risks* chapter, NCDs can have a significant impact on national economies, albeit often through a different profile of effects than communicable disease, and with greater impact on long-term reductions in productivity of the workforce (through morbidity) as well as impacts on the size of that workforce (through mortality) (Leeder, Raymond, Greenberg, Liu, & Esson, 2004).

In recent years, a greater effort has been made to document the economic impact of NCDs. For example, Tsai and colleagues (2011) estimated that 5% to 10% of overall U.S. healthcare expenditures is attributable to the NCD-related health effects of being obese or overweight. Other studies (Butcher & Park, 2008; Lakdawalla, Bhattacharya, & Goldman, 2004) suggest that some increases in unemployment rates in the United States, in the face of overall improvements in population health, may be attributed to obesity. Similarly, while their results may reflect associations rather than causal effects, Lindeboom and colleagues

(2009) present evidence of the existence of differences in employment probabilities between obese and nonobese men and women that do not disappear when controlling for many potentially important factors. Further, Carter et al. (2013) show that health shocks, such as cancer diagnosis, result in a significantly increased risk of subsequent nonparticipation in the labor force.

In general, perhaps the most significant relationship between the economy and NCDs is the risk posed through poor nutrition, and vice versa, especially in children. Research suggests that links exist between childhood health and adult productivity. For example, adult height as a marker for general health has been found to be inversely related to mortality, implying that a shorter height can ultimately result in fewer productive working years (Schultz, 2002). Other studies have assessed the effects of nutritional status on productivity in lower-income countries (Martorell, Melgar, Maluccio, Stein, & Rivera, 2010) and the cumulative impact of parental nutrition, childhood nourishment, and health over the course of the life cycle on adult height, which ultimately affects individuals' wage and earning potential.

In addition to the long-term effects of early childhood health and nutrition, adult health and nutrition have direct effects on productivity. For example, a number of studies over many years (Alderman & Linnemayr, 2009; Basta, Soekirman, Karyadi, & Scrimshaw, 1979; Gardner, Edgerton, Senewiratne, Barnard, & Ohira, 1975; Spurr, 1983) have demonstrated the influence of iron deficiency on oxygen consumption and the positive impact of iron supplementation on labor productivity. In Mexico, Knaul (1999) studied the productivity gains from investments in health and nutrition for women. The author analyzed the impact of age at menarche, or first menstruation (an indicator of cumulative health and nutritional status), on female labor market productivity, finding that investments in health and nutrition had significant effects on productivity. A 1-year decline in age of menarche was associated with a 25% increase in wages. More recently, Martorell and colleagues (2010) found substantial improvements in future human capital and economic productivity in a review of the long-term impacts of a nutritional intervention. Overall, the effects of nutritional status on work performance are of interest to policy makers in designing food and economic programs to improve energy and nutrient intake.

In a different approach, Lock and colleagues (2010) assessed the macroeconomic impacts of healthier eating as a result of reductions in consumption of meat and dairy products in the United Kingdom and Brazil using a linked trade model. These authors suggest that, while reducing consumption of unhealthy goods can generate positive health-related macroeconomic effects, the substitution effects from reduced consumption are key drivers of both the health and economic impacts. For example, if reducing consumption of meat and dairy products leads to increased consumption of other unhealthy food goods, it will reduce the health benefits. In addition, the ease with which other sectors can expand in response to reduced consumption of unhealthy products drives the economic impacts. The authors highlight that countries that are dependent on international trade in meat products—as is true for Brazil—may suffer economically if their trade partners reduce consumption of meat. Such countries will also suffer in terms of adverse health effects if reductions in trade lead to increased availability of unhealthy goods on the domestic market.

Perhaps the most studied NCD is cardiovascular disease, with a major report from the U.S. Institute of Medicine (2010) indicating that this disease has significant economic consequences for health care and beyond. Leeder and colleagues' (2004) overview indicated major impacts across a range of countries from cardiovascular—for instance, payroll losses to India of more than $198 million per year and social security costs due to disability payments of $64 million in 2000. The same authors also demonstrated how NCDs further affect economies by dampening productivity and economic growth.

Similarly, there are significant economic costs from mental health disorders, as indicated in the *Global Mental Health* chapter, again due to reduced productivity and premature mortality. Although the evidence supporting this relationship is growing, it comes mainly from high-income countries, with relatively few studies focusing on LMICs (Lund et al., 2011). It is also the case that economic conditions, especially unemployment, can significantly determine mental health, with the most extreme association being between economic distress and suicide (Chang, Gunnell, Sterne, Lu, & Cheng, 2009).

The Macroeconomy and the Healthcare Sector

Considerable research has addressed the internal aspects of finance and delivery of health systems, as covered in the *Design of Health Systems* chapter. Nevertheless, health systems ("sectors" in macroeconomic language) warrant attention here as well, because they are greatly influenced by the economy, are significant and growing economic sectors, and in many cases are one of the largest government (public) sectors.

Perhaps the most visible link between macroeconomics and the health sector is at the overall level of healthcare spending. Most nations, rich or poor, face the problem of per capita healthcare costs rising faster than per capita GDP. For instance, total global expenditures on health care grew from 3% of GDP in 1948 to 9.9% by 2014. Moreover, this sector takes an increasing proportion of GDP for countries as they develop, rising from 4.5% in lower-middle-income countries to 12.3% in high-income countries (World Bank, 2017).

An important piece of work conducted by Schieber and Maeda (1997) found that the income elasticity of demand for health services—defined as the percentage change in health expenditures as a result of a 1% change in income—in 1994 was roughly 1.13 worldwide, with the range being 1.47 for high-income countries, 1.19 for middle-income countries, and 1.00 for low-income countries. Thus, for every 1% increase in per capita income, health expenditures increase by 1.47% in middle- and high-income countries, by 1.19% in middle-income countries, and by 1.00% in lower-income countries.[1] As these data indicate, the increase in health expenditures in low-income countries is less responsive to increases in income than it is in middle- and high-income countries. Schieber and Maeda also found that private health spending (income elasticity of 1.02) is less responsive to increases in per capita income compared to public health spending (income elasticity of 1.21).

On a global scale, healthcare outlays are absorbing an increasing share of government, employer, and household incomes. This constant fiscal pressure forces nations to confront two basic questions: How to finance this rising burden and how to contain the pressures for health expenditures growth. Thus, an essentially macro issue drives the most fundamental of all health system issues. Most countries spend less than 10% of GDP on health care, which is seen as perhaps the stable upper limit. Of course, for low-income countries, and for some middle-income countries, their GDP levels are so low that even a 10% allocation produces very little actual health care. Aid assistance is therefore required if they are to provide essential health care. Importantly, for low-income countries, increasing the share of GDP devoted to health care means that less is available for spending on other vital areas that would encourage broader economic growth, which itself will enable increased nominal (actual monetary amount) spending on health care (**EXHIBIT 19-4**).

EXHIBIT 19-4 Development Assistance for Health

For many of the lowest-income countries, the absolute level of spending they are able to devote to health care is deemed to be well below the minimum required; instead, these countries rely on international finance to fund their healthcare services. International finance can take many forms. Official development assistance (ODA) is defined as funding flows to the Organization of Economic Cooperation and Development, Development Assistance Committee's (OECD-DAC) list of recipients, which are administered for the purposes of promoting the economic development and welfare of developing countries, and which are concessional in character. ODA includes loans with an equivalent grant element of 25% or more. Development assistance for health (DAH) is slightly broader than ODA and includes non-concessional loans and funds from private foundations and nongovernmental organizations (NGOs) that contribute directly to the promotion of development and welfare in the health sector in developing countries.

The provision of DAH is complex, with no dominant group of actors, standardized set of aims, or consistent approach. A wide variety of public and private institutions provide assistance, from both OECD and non-OECD countries. Moreover, development funds often do not flow directly from sources of finance (government treasuries, private contributions to NGOs) to the recipient, but rather may flow through a variety of channeling institutions such as bilateral aid agencies, multilateral institutions, and development banks, or through intermediary funds such as the Global Fund for Aids, Tuberculosis and Malaria.

Funds can be provided with the aim of improving health services directly or indirectly (e.g., improving governance) or to support economic well-being that may impact the determinants of health. Conversely, funding to health sectors may be used to support and complement broader development objectives such as good governance or ensuring security. Finally, implementation can be done directly by governments, by donors, or through third parties, such as private companies (Vassall & Martínez Álvarez, 2012).

[1] Many economists view the evidence regarding the income elasticity of expenditures on health as indicative of the nature of health as a normal consumption good, or even a "luxury good" (with rising proportions of income spent on it as income increases). However, in recent years there has been an upsurge of interest in the nature of health care as an investment good. Expenditures on health care can lead to improvements in health status that, in turn, promote income growth, and the efficiency and equity of health systems are important in both improving health and affecting income, productivity, and the overall economy.

TABLE 19-2 Health Expenditures by Income Group and Region, 2014

Region or Income Group	Total Health Expenditures per Capita	Total Health Expenditures (% of GDP)	Public Health Expenditures (% of GDP)	Public Health Expenditures (% of Total Health Expenditures)
World	1,059	9.9	6.0	60.1
Low-income countries	37	5.7	2.4	42.4
Middle-income countries	290	5.8	3.0	52.0
High-income countries	5,266	12.3	7.7	62.3
Low- and middle-income countries	265	5.8	3.0	51.7
East Asia and Pacific	329	5.3	4.6	55.1
Europe and Central Asia	575	9.5	7.2	75.5
Latin America and Caribbean	694	7.3	3.8	51.0
Middle East and North Africa	253	5.3	3.1	49.5
South Asia	67	4.4	1.4	31.2
Sub-Saharan Africa	98	5.5	2.3	42.6

World Bank, 2017.

As **TABLE 19-2** illustrates, in 2014 LMICs, on average, spent 5.7% of GDP on health, whereas high-income countries spent 12.3% of GDP on health. Regionally, South Asia spent the least, 4.4% of GDP, whereas Latin America and the Caribbean spent the most, approximately 7.3% of GDP. In cash terms, average spending on health care by low-income countries was $37 per capita in 2014, compared with $290 for middle-income countries and $5,266 for high-income countries. In the lowest-income countries, annual health spending can be as low as $2 or $3 per capita. As well as health spending generally, the public share of health spending increases with increases in national and per capita income. As shown in Table 19-2, the public share of health expenditures (as a percentage of total health spending) was 42% in low-income countries, 52% in middle-income countries, and 62% in high-income countries in 2007 (World Bank, 2017).

Two elements of the economy also determine overall healthcare finance, which are linked to wider trade and, therefore, covered in more detail in the *International Trade and Health* chapter. Briefly, government income available to spend on health care (and other public services) is generated primarily through taxes. Tax income is broadly dichotomized into taxes that are "easy to collect" (such as import tariffs) to those that are "hard to collect" (such as consumption taxes, income tax, and value-added tax [VAT]) (Aizenman & Jinjarak, 2009). Tariff revenues are a important source of public revenues in many developing countries; their share ranges from less than 1% of public revenues within the OECD to approximately 80% in Guinea, with typical examples of Cameroon at 28% and India at 18%. As economies develop and join more fully with the global trading environment, these tariffs tend to fall, reducing the proportion of government income from "easy to collect" sources. Although theoretically governments should be able to shift tax bases from tariffs to domestic taxes, such as sales or income taxes, in practice LMICs find this

difficult, especially because of the informal nature of their economies and the large subsistence sectors (Aizenman & Jinjarak, 2009). Whereas high-income countries are usually able to replace 100% of the lost tariff revenues, middle-income countries replace only 40% to 60% and low-income countries at best manage just 30% replacement of these tariffs (Baunsgaard & Keen, 2005).

The most common source of tax revenues as countries increase their economic development is income tax, or more precisely payroll tax. This is basically any tax that is taken off the wage, through the payroll, before the employee receives it—the difference between the gross wage and the net wage is reflected in the payroll tax. It includes elements such as wage tax, national insurance contributions, the employed person's insurance contributions, and so forth. As countries grow and expand their spending on health care (as indicated earlier), they increasingly rely on payroll taxes to fund their expenditures. This shifts an increasing amount of the burden of healthcare costs to the formal paid workforce, which may affect the relative efficiency of the workforce in the global economy (i.e., wages may be higher to reflect these costs, which are then passed through to increased costs for exports and a reduction in the country's competitive position).

A second macroeconomic determinant of health sector finance, also linked to trade, is the exchange rate. This factor is a key determinant of the relative prices of imported and domestically produced goods and services. Importantly for the health sector, many of the goods (principally pharmaceuticals, but also various elements of other technologies, such as computer equipment, surgical tools, and even lightbulbs) used to provide health care are imported. Changes in the exchange rate brought about by macroeconomic developments may, therefore, prompt the price, and hence the cost, of health care to increase or decrease. Conversely, changes in demand for domestically produced goods from overseas importers may trigger changes in the price of those goods domestically in response (e.g., increased foreign demand may push up local prices). Thus, increased linkage between economies at the macro-level generates greater levels of exogenous (i.e., beyond the domestic health sector control) influences over prices, and hence the costs of health care.

The Macro-Efficiency of Healthcare Sectors

Irrespective of funding, countries differ in how efficiently their health systems convert resources into population health status, a relationship that is often referred to as the "macro-efficiency" of health systems. The macro-efficiency reflects how aggregate healthcare expenditures are linked to health outcomes. Considerable variation exists by country in health status as well as healthcare expenditures. For example, in 2015, life expectancy at birth ranged from 51 years in the Central African Republic to more than 80 years in France, Hong Kong, Iceland, Italy, Switzerland, and Japan (World Bank, 2017). While the global average life expectancy was 72 years, for low-income countries it was 62 years, middle-income countries 71 years, and high-income countries 81 years (World Bank, 2017). Of course, as indicated earlier, many factors influence health outcomes, and expenditures on health care often correlate poorly with outcomes, as illustrated in **TABLE 19-3**.

There is little, if any, evidence of the opposite relationship—that is, the impact on the economy of greater spending on health care. It is clear that a sector accounting for more than 10% of GDP is a significant component of that economy, but little research has addressed how changes to the overall size of the health sector affect, for instance, overall GDP or employment. For instance, higher healthcare expenditures might reduce a country's relative productivity in the global economy due to the large costs of health benefits for the labor force, and due to the resultant reduced investments in other sectors of the economy. Even so, it is not clear that overall productivity and growth are severely hindered by high healthcare expenditures.

Overall, it is not possible to determine the most efficient level or percentage of healthcare spending for any given economy. Given the wide range of spending on health care, the challenge is to increase spending among lower-income countries and for all countries to enhance the efficient production of health within health systems. This topic is explored in more detail in the *Design of Health Systems* chapter.

Conclusion

Evidence shows a solid positive bidirectional relationship between a country's wealth and its population's health. Whatever the precise mechanisms, broadly wealthier populations are healthier, and healthier populations are wealthier. Yet, despite the long-established relationship between health and the macroeconomy, application of a macroeconomic lens in health policy debate is comparatively rare. Moreover, health effects are disregarded in many macroeconomic policy applications. Much remains to be done to enable holistic policy analysis that correctly values the health effects and health implications of

TABLE 19-3 Healthcare Expenditure (HCE), Proportion of Expenditure That Is Government-Funded, Infant Mortality Rate, and Life Expectancy at Birth for Selected Countries in 2014, Ranked by Overall HCE

Country	HCE (% of GDP)	% of HCE That Is Publicly Funded	Infant Mortality Rate (per 1,000)	Life Expectancy (years)
India	4.7	—	38	68
Mauritius	4.8	49.2	12	74
China	5.5	55.8	9	76
United Kingdom	9.1	83.1	4	82
Japan	10.2	83.6	2	84
Germany	11.3	77.0	3	81
France	11.5	78.2	4	83
United States	17.1	48.3	6	79

World Bank, 2017.

economic policies and—perhaps more important in leveraging health policies—the macroeconomic effects of health policies. Although detailed, sector-specific health economic analysis has an important role to play in capturing individual-level costs and health-sector implications of health policies and disease burdens, the macroeconomic implications and methods for macroeconomic analyses of health are currently under-researched and underutilized. This chapter has provided an overview of this relationship, examined through the lenses of the household (looking especially at the interaction of economic growth and health), risk factors for disease (communicable, noncommunicable, and outbreaks), and the economy and its relationship with the healthcare sector.

Much macroeconomic policy concerns economic growth, as higher GNI leads to more opportunities to consume, which is in turn expected to result in better health. The chapter presented evidence that suggests health is closely linked with economic growth and development, through multiple pathways, including the demographic transition, improved educational attainment, and labor productivity. Indeed, as much as 10% to 30% of economic growth may be due to improved health of a country's population. Similarly, greater economic development can influence health, especially though increased access to more-affordable health determinants, such as housing, education, water, sanitation, and nutrition, as well as through improved health care (although it is important to remember the "income–health gradient").

A clear relationship also exists between the economy and health directed through the risk of disease and injury. Economic behavior partly determines this risk, and the cost incurred from this risk partly determines economic performance. This is true for communicable diseases, including malaria, HIV/AIDS, and pandemics. The overall environment in which people live (e.g., air quality, sanitation, housing) is determined, in large part, by their income and wealth, and the increased movement of people, animals, and goods associated with an increasingly active and international economy will affect the movement of disease. Communicable diseases, then, affect aspects of the economy related to, for instance, educational attainment or labor productivity. Outbreaks provide specific challenges for economies—not just through the immediate costs of increased illness and death of affected people and animals, but also due to the costs of control and coping strategies to mitigate effects of the pandemic such as quarantines, and the reductions in economic activity through fear of infection. In terms of noncommunicable disease, economic growth increases the ability of populations to consume both goods that *improve* the probability of better health, such as clean water, safe food, education, and goods

that may be harmful or hazardous to health, such as tobacco, alcohol, and fast food. Diet, and the impact of under- and over-nutrition, were highlighted in this chapter as significant impacts on economies across countries at all levels of development.

Finally, health systems are greatly influenced by the economy, and are themselves significant and growing economic sectors. The most visible link is the level of healthcare spending that an economy can "afford," with clear relationships being established between the level of economic development and the level of spending, both in absolute terms and in terms of per capita GDP.

Policies that have positive health effects can have significant wider economic impacts, which are often positive. As observed in *The Lancet* (2013), "It is sadly true that most health ministers lack domestic political muscle. They might talk tough amongst themselves, but back home they have to get in line behind colleagues in finance, defence, trade, and even education." Finance often speaks more to those in power than does health. While health may have a powerful economic case to make, it must embrace greater engagement with macroeconomics. As outlined in this chapter, simultaneous capture of the macroeconomic implications of health policies on other sectors and the wider economy is essential for health policies to be considered and weighed fairly against environmental, trade, and agricultural policies. Similarly, the potentially significant health effects and externalities of non-health-focused policies should be captured and considered, as their contributions may be relevant to policy optimization decisions. Macroeconomic assessments and modeling provide an even playing field for policy assessments from both health and non-health perspectives and a medium through which health and non-health policy implications can be jointly assessed using the same framework. This also facilitates dialogue across sectors to enable optimal policy decisions that weigh both the health benefits and the overall economic implications of policies, while accounting for important demographic, welfare, environmental, trade, and agricultural implications (Smith, 2012).

The consequences of health and health policy for economic development are crucial to policy makers in the health and development fields. Development institutions, nongovernmental organizations, and academic communities should seek to investigate strengthen the links between health and economic development. Primarily, they can encourage continued efforts to understand health and development links by helping LMICs develop their own capacity to study these connections; by encouraging further generation of relevant primary data; and by ensuring that the appropriate household-level and cross-national databases are maintained, updated, and accessible to all.

Acknowledgments

Much of the original work used in the 2001 version of this chapter was prepared for the 1998 transition team of the then-incoming World Health Organization Director-General Dr. G. H. Brundtland. Preparation of that version was supported by grants from the Royal Norwegian Ministry of Foreign Affairs to WHO and the World Bank. The WHO Commission on Macroeconomics and Health supported extension and revision, and discussions with the commission's chair, Jeffrey Sachs, provided valuable ideas and feedback during preparation of the 2006 version of this chapter. Conclusions and opinions are those of the authors and not necessarily those of any of the sponsoring agencies. Felicia Knaul, Lawrence Lau, Michael Merson, Pia Malaney, and Anne Mills also made valuable suggestions and comments on earlier versions. Previous versions also benefited from assistance by Leslie Evans to prepare the tables and graphics, Christina Lazar for research assistance, and Elizabeth Cafiero and Marija Ozolins for research and editorial assistance. This version was supported by detailed comments from Anne Mills.

Discussion Questions

1. In what ways and to what extent do major infectious diseases, such as malaria and HIV/AIDS, affect the income and well-being of people living in LMICs?
2. What can policy makers and practitioners do in non-health-service–related settings, such as schools, to improve the health and well-being of girls and boys in LMICs?
3. How do changes in fertility and mortality patterns influence the level and capacity of those persons contributing to economic production in a given society?
4. How have recent pandemics directly and indirectly affected national and global economies?

CHAPTER 20

International Trade and Health

Johanna Hanefeld, Richard Smith, and Rupa Chanda

Introduction

Trade—the movement of goods, services, people, and capital between countries—has become established as a critical determinant of public health, both positively and negatively, that "directly and indirectly affects the health of the global population with an unrivalled reach and depth" (MacDonald & Horton, 2009). The last decade has seen the development of an overwhelming evidence base highlighting the connections between trade, trade agreements, and population health. Trade itself is seen as a defining feature of the current era of globalization, making trade and health a core aspect of the field of global health. For instance, increased trade in food, facilitated especially by refrigerated transport, has diversified many diets and improved access to fruit and vegetables. At the same time, dependency on global food markets, intensive farming methods, and cash crops have created concerns about food security and environmental degradation. Closely associated aspects of trade liberalization—policies to reduce the barriers to trade—and trade agreements—the legal basis for the rules that govern trade—have also come under increasing scrutiny. Those concerns have ranged from access to medicines to treat human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) in the 1990s, to the focus on the World Trade Organization (WTO) and increasing trade in services in the 2000s, to the emphasis on food security and alcohol availability in recent years.

As the raison d'être of trade is to increase both wealth and the availability of goods and services, changing trade patterns—whether through an increase or a reduction in trade—will inevitably impact many of the known determinants of health, including employment, nutrition, environmental factors, social capital, and education. For instance, increased trade in alcohol and tobacco products is likely to be harmful to health, and intensified competition for foreign investment may create pressures to reduce health and safety measures in the workplace. Trade will also affect the health sector itself, most clearly through direct trade in health-related goods and services (such as pharmaceuticals, health workers, foreign direct investment in health services, and patient mobility), but more broadly as well. For instance, trade liberalization can affect overall public expenditures by allowing governments to purchase less expensive foreign goods and services, which will in turn affect the amount of money available to fund public health care. Alternatively, it may reduce tariffs, and hence government income, and lead to a reduction in public spending on health care. Moreover, trade—especially rapid and widespread movement of people, animals, and goods—may facilitate the rapid and extensive spread of disease, a factor associated with outbreaks such as severe acute respiratory syndrome (SARS) and Ebola. In addition, trade has triggered changes in the structure of companies, with the 20th century especially seeing a huge increase in the number of transnational corporations with a global footprint rather than a

national one, a key aspect of "globalization" covered in the *Health and "The Economy"* chapter. For all these reasons, trade, and associated policies governing and responding to that trade, have become increasingly recognized as a critical driver of health issues.

It is important to note that the current era of globalization has been associated largely with a rapid increase and liberalization of trade and the regimes governing it (Dollar, 2001a, 2001b; Dollar & Kraay, 2004; Hanefeld, 2015). Trade may not be growing in some countries, however, and the populist politics evident in the 2016 election of Donald Trump to the U.S. presidency have been associated with a backlash against globalization and specifically trade (McKee, Greer, & Stuckler, 2017). Nevertheless, the vast majority of evidence focused on the link between trade and health that has emerged over the past two decades and is discussed in this chapter has concentrated on the increase and liberalization of trade.

This chapter provides an overview of these issues. We first look at the relationships between international trade, determinants of health, and health care itself, along with evidence of the impact on health and health equity. This discussion provides an indication of the changes and current levels of trade in key areas. The legal foundations, in the form of trade agreements, are outlined, focusing especially on the wider political and policy landscape and the ways in which this shapes global health governance. We next examine the different pathways through which trade affects health generally (not focusing on the health system beyond the effects of government revenue generated from trade). Attention is paid to how trade in goods, for example, affects communicable and noncommunicable diseases. We then focus on the impact of trade on health systems, including trade in health services and its likely current and future effects. The concluding section explores the response from the global health community to date, and raises likely future issues relating to trade and health. There is synergy between this chapter and the *Health and "The Economy"* chapter in terms of their focus on governance, negotiation, and diplomacy, especially in the concluding sections, and because of this they are best read in conjunction.

Relationship Between Trade and Health

Increased trade in goods, services, people, and capital—whether directly health related or not—affects health through a number of channels, including the cross-border flow of infectious disease, advertising of unhealthy lifestyles, health professional migration, and so forth. Health and health care are affected by changes in general trade liberalization, international legislation, and international institutions, as well as those changes specific to health; in turn, they affect national economies.

Building on the analysis presented in the *Health and "The Economy"* chapter, we can summarize these main proximal and distal determinants and linkages between trade and health as shown in **FIGURE 20-1**. The lower half of the figure represents the country under consideration, and the upper half indicates the aspects of international trade expansion and liberalization that affect the country, with the three arrows between them indicating the major linkages. (A more comprehensive exposition is provided by Woodward, Drager, Beaglehole, and Lipson [2001].)

Taking the lower half of the figure first, the standard influences on health are as follows:

- Risk factors, representing genetic predisposition to disease, environmental influences on health, infectious disease, and other factors.
- The household economy, representing factors associated with human capital and the investment in health by individuals and households.
- The health system, representing the impact of goods and services consumed principally to improve health status.
- The national economy, representing the meta-influences of government structures and general economic well-being.

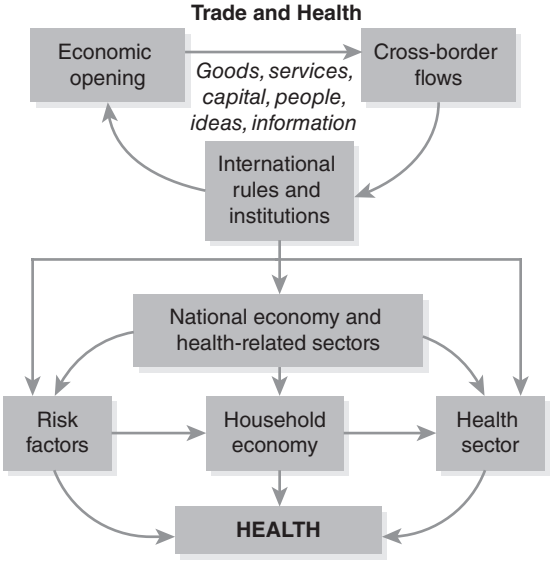

FIGURE 20-1 A simplified view of how trade affects health.

Modified from Smith, R. D., & Hanson, K. (Eds.). (2012). *Health systems in low-and middle-income countries: An economic and policy perspective*. Oxford, UK: Oxford University Press.

The range of interlinkages between these factors is also illustrated in Figure 20-1, many of which are covered in the chapters *Health and "The Economy"* and *The Design of Health Systems*.

The upper half of Figure 20-1 depicts the influences of factors outside the national economy, or national "control." For example, a wide variety of international influences directly affect risk factors for health, including increased exposure to infectious disease through the rapid cross-border transmission of communicable diseases via the movement of people, animals, and products (especially food products); increased marketing of unhealthy products and behaviors; and increased environmental degradation as a result of increased industrialization. Trade also affects health through its influences on the national economy. An extensive literature addresses the relationship between health and wealth: To the extent that trade influences economic growth, and the distribution of positive and negative aspects of this growth, it also influences health (e.g., changes in consumption of various goods that are either beneficial or detrimental to health) (Blouin, Chopra, & van der Hoeven, 2009; Sachs, 2002). Finally, trade affects health through the direct provision and distribution of health-related goods, services, and people, such as through access to pharmaceutical products, health-related knowledge and technology (e.g., new genomic developments), and the movement of patients and professionals.

Also in the upper half of Figure 20-1, we see the importance of international trade agreements in the governance of this system. This aspect of trade has gained particular prominence over the past decade with a newer generation of trade and investment agreements (TIAs) whose provisions have often limited the ability of national governments to introduce public health regulations (Walls, Smith, & Drahos, 2015).

Each of the elements is covered in the remaining sections of this chapter, but we begin by looking at the legal foundation for trade: trade agreements.

Trade Agreements Creating a Governance for Health and Trade

Trade is far from a modern phenomenon. The exchange of goods and services, along with the movement of people, predates the establishment of nation states, and indeed contributed to the development of what are now considered to be major cities such as Venice, New York, and Tokyo. Developments in transport and communications assisted trade in expanding in scope (e.g., the advent of refrigeration opened up the trade of perishable goods), scale (e.g., super-tankers and cargo ships increased the volumes that can be traded), and speed (e.g., air travel for goods, the Internet for financial transactions) over the centuries. Indeed, trade contributed as large a share of global gross domestic product (GDP) at the end of the 19th century as it did at the end of the 20th century. So, what happened?

The events of the early 20th century have important parallels today. That era saw a closing in of borders, especially by the United States, under a protectionist nationalist agenda. This, at least in part, generated the Great Depression of the 1930s, which has been identified as a major contributor to World War II. Following the war, a key component of the new United Nations system was the General Agreement on Tariffs and Trade (GATT), which was to lead to successive reductions in global tariffs and other barriers to trade. It established a global trade regime whose current incarnation is the WTO, which superseded GATT in 1995 and has a much expanded remit compared to its predecessor (Lee, Sridhar, & Patel, 2009). Although in recent years the focus has moved away from such global initiatives and toward more regional, multilateral, and bilateral trade and investment agreements, trade agreements remain the glue that holds trade together.

Despite the prevailing rhetoric, no trade is truly "free." Instead, it is organized through trade agreements of myriad kinds that provide the regulatory framework—or rules—under which trade is conducted. Trade agreements are important because they are at the core of the trade–health nexus. Critically, trade is structured and has a highly formalized governance system, whereas global health governance is almost completely unstructured, features a greater diversity of actors and approaches, and imposes weaker legal obligations on states. These differences help explain why the trade–health nexus is dominated by trade agreements rather than "health regulation" (Fidler, Drager, & Lee, 2009). This topic is covered in more detail in the *Health and "The Economy"* chapter.

The WTO is the center of authority for the governance of trade, as indicated by its large number of member states and the substantive reach of its agreements. The WTO provides the overarching legal and normative framework for trade between its 164 member states, and sets the tone for other agreements beyond its membership (**EXHIBIT 20-1**).

Multilateral and Bilateral Trade Agreements

Although much of the interest regarding trade and health stems from, and has related to, the WTO,

EXHIBIT 20-1 The World Trade Organization and Health

In an effort to regularize an increasingly complicated system of international trade, the WTO was created in 1995 as the successor to GATT, which had been drafted in 1947. The WTO is a global agency that sets the rules for international trade (including trade in services, goods, and intellectual property). In June 2017, 164 countries were members of the WTO. The aim of the WTO is to stimulate economic activity and promote economic development, through progressive trade liberalization. Its philosophical basis is that liberalization will encourage a global increase in efficiency, through the traditional economic arguments relating to comparative advantage, thereby ensuring continued product availability for consumers and reducing the economic power of individual economic operators (Chanda, 2002). The WTO seeks to achieve this goal by creating a credible, reliable, and binding system of international trade rules to ensure transparency, consistency, and predictability in international economic policies (Adlung & Carzaniga, 2001).

The WTO negotiates and implements new trade agreements, serves as a platform for trade negotiations, settles trade disputes, reviews national trade policies, assists low- and middle-income countries (LMICs), and cooperates with other international organizations. Its role has five aspects (Lee et al., 2009):

1. Provision of a forum for negotiations between WTO members about their multilateral trade relations in matters dealt with under WTO agreements
2. Administration of multilateral trade agreements
3. Promotion of the transparency of WTO members' trade policies and actions regarding the implementation of WTO obligations, through regular monitoring and surveillance
4. Provision of a process for WTO members to mediate and settle trade disputes
5. Working in cooperation with relevant international organizations to achieve greater coherence in global economic policy making

To become a WTO member, a country has to agree to accept 17 main multilateral agreements and 60 agreements, annexes, decisions, and understandings that contain binding obligations on, among other things, tariffs and nontariff barriers on industrial and agricultural goods; trade in all kinds of services; application of measures to protect human, animal, and plant health (sanitary and phytosanitary measures); implementation of technical barriers to trade; use of trade-related investment measures; imposition of additional tariffs on dumped or subsidized imports; and protection of intellectual property rights. The large number of WTO member states means that most of the international community has committed itself to implementing this vast array of obligations. Why? Members benefit because the WTO stimulates increased world trade by securing stability and predictability through its legally enforceable and indefinitely binding nature, although this binding nature has raised concerns (Pollock & Price, 2000).

A key element of WTO membership is that all countries commit to the "most favored nation" principle. This means that privileges, such as reductions in tariffs or market access, granted to one country must also apply to all other WTO members.

The Dispute Settlement Body is an important element of the WTO that highlights the recognition of the importance of health as a political and social objective. In various cases, the WTO Dispute Settlement Body has ruled that (1) the protection of health is a national objective of vital importance; (2) WTO members are free to select the level of health protection they believe appropriate for their populations; (3) health effects should be included in the case-by-case analysis of whether products or services are alike; and (4) in cases analyzing measures to protect human health under the necessity test, the potential effectiveness of less trade-restrictive alternatives should receive strict scrutiny. In this respect, public health has a much stronger profile in international trade law than the protection of human rights, which is not an objective that trade treaties recognize as a legitimate reason for restricting trade. In short, in implementing trade treaties, national policy makers and legislators have a foundation in the treaties on which to build coherency between trade and health.

The WTO has drafted several agreements that directly involve and include health and health systems. These include:

- The General Agreement on Trade in Services (GATS)
- The agreement on Technical Barriers to Trade (TBT), which requires that technical product regulations and standards be applied in a nondiscriminatory manner, be harmonized where possible on the basis of recognized international standards, and be the least trade-restrictive measures possible to achieve the level of health protection sought
- The agreement on Sanitary and Phytosanitary measures (SPS), which comprise national measures that aim to reduce hazards to animal, plant, and human health, including food safety regulations
- The agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) (Blouin, Drager, & Smith, 2006)

We will return to these agreements in the relevant sections later in the chapter.

Over the past decade, the WTO has seen a decline in its influence owing to an increase in regional and bilateral trade agreements and the lack of conclusion to the Doha trade round (Bown, 2017).

significant developments have also occurred in the form of regional and bilateral agreements. For instance, there has been a recent flurry of activity around the proposed Trans-Pacific Partnership (TPP) and the Transatlantic Trade and Investment Partnership (TTIP) between the United States and the European Union (Thow et al., 2014). These agreements have a much broader scope and wider provisions that might potentially limit national sovereignty, including constraints on the ability of national governments to regulate areas including public health (Labonté, Schram, & Ruckert, 2016; Ruckert et al., 2017). These agreements have engendered much opposition, including protests from the public health community and public advocates. Indeed, the controversy led to the TTIP talks being suspended in the second half of 2016. Further uncertainty over both the TPP and the TTIP emerged with the election of Donald Trump to the U.S. presidency. Trump campaigned on an openly anti–free trade platform, and one of his first actions in office was to cancel the TPP (Labonté, Schram, & Ruckert, 2017). Despite the apparent slowdown in implementation of some of the newer trade and investment agreements in the last few years, regional and bilateral trade agreements have generally regained importance over the past decade.

Often liberalization is more easily negotiated at the regional level, which tends to involve countries with geographic proximity, cultural ties, and similar levels of economic development. Regional and bilateral trade agreements also often involve a more limited number of participants and, therefore, allow for greater reciprocity, as well as often being undertaken for reasons other than purely economic motivations, such as strategic, cultural, and political reasons. At least in part, regional and bilateral agreements of recent years have also been pursued in response to the slow pace of WTO negotiations (Crawford & Fiorentino, 2004).

Indeed, since the creation of the WTO in 1995, member states have notified the organization of more than 400 additional regional trade agreements (RTAs). This is in addition to 124 RTAs that were in place when the organization was founded (WTO, 2017a). An estimated 55% of all international trade occurs through RTAs (Jones, 2007; Organisation for Economic Co-operation and Development [OECD], 2003). Within these kinds of regional or bilateral agreements, countries are typically obliged to ease or eliminate restrictions on entry of people and foreign investment, and to protect investors against adverse government regulation or confiscation. Multinational organizations dealing in tobacco, alcohol, and arms can challenge governmental regulations that hinder trade and potentially recover monetary compensation under RTAs. Indeed, these agreements often provide more predictable protection for multinational companies than either WTO law or regional legislation (Walls, Smith, & Drahos, 2015). In addition to the elimination of tariff and nontariff barriers, bilateral agreements facilitate the establishment of industry presence, which can further aid the marketing of foreign products such as alcohol and tobacco, and significantly reduce barriers to trade by breaking up protected markets, thereby contributing to increased consumption (Onzivu, 2002).

Regional, and increasingly bilateral, trade agreements do pose a danger of benefiting developed countries and being detrimental to LMICs. This discrepancy in impact arises because they create the potential for trade diversion, as the "most favored nation" principle (see Exhibit 20-1) does not apply in this sort of agreement. Often LMICs engage in regional and bilateral agreements in hopes of securing access to the market for their goods, without taking into account the impact that engaging in such agreements could have on their health systems (Mattoo & Fink, 2004). In addition, a significant body of evidence has emerged over the past decade suggesting that trade and investment agreements, including investor protection mechanisms, may allow corporations to seek to avoid public health regulations. Cases here include the court case brought by Philip Morris (which the company lost) against the Australian government's introduction of plain packaging for cigarettes (Hawkins & Holden, 2016).

The Impact of Trade on Health: Different Pathways

Impact of Trade on "The Economy"

Trade affects health through its general macroeconomic impact on countries, including government revenue, living standards, and types of employment and other determinants of health.

But why is trade encouraged in the first place? Simply speaking, because it promotes economic growth. Macroeconomic policy is concerned with GDP, which measures the value of all goods and services produced in a country during a given time period (see the *Health and "The Economy"* chapter). An increase in GDP represents economic growth. International trade is a key factor leading to economic growth through specialization, given that specialization allows each country to

exploit its absolute or comparative advantage in particular areas. Differences between countries in terms of their technology, labor skills, climate, institutions, and other factors mean that their production functions across different goods and services also differ (Maneschi, 1998). If each country specializes in the production of those goods and services that best suit its relative endowment of skills and resources, and if it trades these for other goods and services from countries that are relatively more efficient at producing those goods and services, all parties stand to benefit. In this way, specialization and international trade change relative prices and allow countries to produce and consume more than they would otherwise. Trade liberalization increases competition, which leads not only to lower prices but also increased specialization. Overall, those countries that engage in trade will see increasing GDP, lower prices, a wider selection of available goods and services, higher employment, and higher government revenues (due to higher income and the ability to tax that income) (Dollar, 2001b; Mattoo, Rathindran, & Subramanian, 2001; United Nations Conference on Trade and Development [UNCTAD], 1995).

Trade liberalization is about reducing barriers—financial or otherwise—to the movement of goods, services, capital, and people, with countries being aligned along a spectrum of what may be termed "openness" to trade (Smith, Lee, & Drager, 2009). As the raison d'être of trade is to increase both wealth and the availability of goods, changing trade patterns can influence both income (buying power) and its distribution. In turn, it may influence health through determinants including employment, nutrition, environmental factors, social capital, and education (Blouin et al., 2009).

General analyses suggest that "wealthier countries are healthier countries" (Bloom & Canning, 2000; Pritchett & Summers, 1996). The relevant factors in this relationship are generally improved nutrition, sanitation, water, and education (Becker & Tomes, 1986; Deaton, 2003; Fogel, 1994; Frankel & Rose, 2005; Hunt, 2007; Subbarao & Raney, 1995). The direction of causation is subject to some debate, although it is widely accepted that a "virtuous circle" exists between increasing wealth and health such that both directions of causation are valid (Suhrcke, McKee, Arce, Tsolova, & Mortensen, 2006). For instance, evidence shows a solid positive relation between a country's wealth and its population's health, defined in terms of increased life expectancy (Preston, 1975) or reduced child mortality (Pritchett & Summers, 1996). Importantly, open economies appear to grow more rapidly than restricted ones, such that the health gains from higher growth will accrue more quickly in those countries that engage in more international trade (Dollar & Kraay, 2004; Edwards, 1993; Frankel & Romer, 1999; Levine & Rothman, 2006; Winters, 2004; Winters, McCulloch, & McKay, 2004).

Although there is generally a positive relationship between trade liberalization and national income (Ben-David, 1993; Dollar, 1992; Feachem, 2001; Sachs, Warner, Åslund, & Fischer, 1995), there is increasing recognition, including among international financial institutions such as the World Bank, that trade liberalization in the absence of other policies will not necessarily lead to higher growth (Winters, 2004). In recent years especially, in the aftermath of the global financial crisis and subsequent recession from 2008, analysis has become more nuanced and less certain. Considerable evidence also indicates that poverty and income inequality are associated with poorer health (Deaton, 2003). Thus, although trade liberalization generally is advantageous, the crucial factor in how advantageous and to whom is "how countries manage the process of integrating into the global economies" (Lall, 2004). For example, trade liberalization often triggers both creation and destruction of jobs within and across sectors, as firms adjust to the new competitive environment (Ghose, 2003). To ensure that the movement of labor is as smooth as possible and to avoid excessive unemployment, effective labor market policies are required (Hoekman, 2005; Milanovic & Squire, 2005; Mundial, 2005; Winters, 2004; Wood & Ridao-Cano, 1999).

Distributional Impacts Are Critical for Health

It is important to remember that analyses of trade and the economy relate to *aggregate* populations and incomes, rather than to individuals (Ravallion, 2006). Although evidence supports the proposition that trade liberalization will be poverty alleviating in the long run and on average, it is important to remember that this outcome implies adjustment and distributional impacts and that trade reform is not always the most important determinant of poverty reduction (Winters et al., 2004). Most macroeconomic indicators do not account for these distributional impacts; that is, they focus on the aggregate of total income, trade volume, employment, and so on, rather than the composition of that total.

Expanding the availability of goods, reducing prices, and increasing access to high-speed communication and travel may benefit those who produce these goods and services and the wealthy. For others, these trends may mean lower wages, greater pollution, and insecurity. Much of the benefits of trade "trickle-down" may be dammed at specific points by those with power and influence. Consider the example of food security:

Between 2006 and 2008, the cost of food overall increased by 57%, generating major crises in many LMICs as people struggled to buy even the basic foodstuffs. Although several factors were associated with this increase, including devaluation of the U.S. dollar, rising oil prices, and increased demand from emerging economies, a significant factor was increased support for biofuels. Biofuel development was promoted primarily by the United States and European countries as a cost-effective means to meet greenhouse gas emissions targets as well as to support their own embryonic biofuel industries, which were subject to sizable government subsidies (Hallam, 2009). But it also meant that food crops were being diverted to produce ethanol. For example, Brazil took this course and became a major producer of ethanol-producing crops over this period (Tenenbaum, 2008).

Lowering tariffs (taxes on imports) may generally benefit consumers, who can purchase imported goods at lower prices, but it may also create losses in competing domestic firms and reduce import tax revenues. Trade reforms inevitably create both winners and losers: Some sectors of the economy might not be able to compete with new imported goods, whereas others get access to new markets and opportunities. Moreover, individual incomes can change because jobs can be created or lost and prices of and external demand for goods produced can rise or fall. Therefore, some losers from trade liberalization might be poor households, whose incomes will decline even further (Winters, 2006). Losses to domestic firms can, in turn, negatively impact the employees and other stakeholders of the firms, such as via lost jobs, reduced wages (Arbache, Dickerson, & Green, 2004), or reduced revenues from both corporate and personal income taxes. For these reasons, countries are often careful in opening sectors to international competition. Depending on the economic geography of a country, some regions might benefit more than others from liberalized trade. For instance, it might be the case that export goods are produced in urban areas. Increased income from trade accruing to these urban areas may benefit those areas and surrounding rural areas (through higher demand due to rising incomes), but may not reach areas farther away. However, if managed wisely by the government, the new income opportunities could, in principle, benefit the entire population.

Thus, although in aggregate trade liberalization may generate economic benefits for a country, it is also likely to require adjustment at various levels, including at the individual level. This adjustment process can cause a feeling of increased economic insecurity with implications for psychological well-being (Cornia, 2001; Marmot, 2000; Scheve & Slaughter, 2004).

Effect of Trade on Government Revenue for Health Care

Trade liberalization will also affect government income and hence the ability to finance or provide public services, including those related to health. Trade directly affects government revenues via taxes (tariffs) imposed on imports to the country. However, trade can also indirectly affect government revenues via income taxes paid by local businesses and their employees, although these streams are harder to trace. Thus, establishing the net contribution of trade to government income—where gains in tax revenues traceable to increased export income exceed losses in tax revenues due to increased imports—is difficult. Nonetheless, understanding the potential impacts of trade on the different types of taxes is important because certain types of tax income are relatively easy to collect (such as tariffs), whereas other types may be harder to collect (such as consumption taxes, income taxes, and value-added taxes) (Aizenman & Jinjarak, 2009).

In many LMICs, tariffs on imports are an important source of public revenues and contribute to the capacity of these countries to adopt policies that affect the various determinants of health. The contribution of tariff revenues to total government revenues may be less than 1% for members of the OECD, but is as much as 80% in Guinea, with more typical examples including Cameroon at 28% and India at 18% (Laird, Vanzetti, & Fernandez de Cordoba, 2005). The concern in such cases is that trade liberalization may change the tax revenue structure, reducing the proportion of government income from easy-to-collect sources such as tariffs. Although governments should theoretically be able to shift tax bases from tariffs to domestic taxes, such as sales or income taxes, in practice many (especially low-income) countries find this difficult due to the informal nature of their economies, which often have large subsistence sectors (Aizenman & Jinjarak, 2009). For instance, high-income countries (HICs) are usually able to recover 100% of the tariff revenues lost through trade liberalization, while middle-income countries accrue approximately 40% to 60%, and low-income countries can gather only 30% or so (Baunsgaard & Keen, 2010; Blouin et al., 2009; Glenday, 2006; Khattry & Rao, 2002). Ultimately, the reduced import tariffs in the latter cases result in a decline of government income available to pursue public policies, whether related to health care, education, water, sanitation, or social safety nets.

Conversely, lower import prices might benefit the public provision of health care, as inputs into health services become less expensive and more widely

available. Furthermore, consumers are likely to benefit from lower prices, which enable them to spend more on health care, education, and other beneficial services.

Finally, it is important to note that lower tariffs on imports are not necessarily correlated with lower total revenues (Glenday, 2002). In fact, trade liberalization can increase the volume of international trade such that the base expansion may exceed the rate reduction and hence yield higher revenues, at least where tariffs are reduced rather than eliminated. For instance, halving import tariffs may be entirely offset if trade doubles. This appears to have been the case in a few countries at the early stage of implementation of World Bank trade reform programs (Bamou, 1999). Import tariffs can also have complex structures. Lower average duty rates are not necessarily the result of across-the-board rate reductions. For example, high duty rates may be lowered, while low duty rates may be raised. Interestingly, the impact of liberalization on tariffs may be an argument for increased multilateral, rather than bilateral, trade negotiations, as the latter often involve more severe tariff concessions than the former.

Trade and the Risk Factors for Disease

Trade also affects health through its direct impacts on risk factors for disease. These effects occur as a result of the pathogens that travel with goods, including livestock and plants traded, and through the commodities traded and their health effects—for example, medicines, alcohol, food, or tobacco. Trade significantly affects the spread of disease either by acting as a "vector" for pathogens, or by increasing or limiting the availability of goods that affect health. Some of the concerns relating specifically to the spread of infectious disease are further elaborated on in the *Public Health Infrastructure* chapter.

Trade and Communicable Disease

As indicated elsewhere (see the *Environmental and Occupational Health* chapter), concerns have arisen that changes in climate will facilitate the spread of vectors for infectious disease, especially mosquitoes. Trade may play a role in this relationship through increased production, consumption, and transportation of goods globally contributing to climate change. This is a much wider issue than trade itself, and the interested reader is referred to the *Environmental and Occupational Health* chapter for more details. Here, the focus is on the more direct relationship between trade and infectious disease.

The most worrisome scenario remains the impact of trade—in terms of the rapid and widespread movement of people, animals, and goods—on possible pandemic disease. The prospect of an infection emerging with the transmissibility of the common cold but with a much higher pathogenicity is the public health community's worst nightmare. This fear was stoked especially by the SARS outbreak in 2002, with emergence since then of possible pandemic influenza strains raising visions of the Spanish flu, which killed an estimated 40 million people in 1918–1919, and the recent outbreaks of SARS and Ebola (**EXHIBIT 20-2**). Minor changes to the influenza virus (antigenic drift) happen continually over time, which is why it can reinfect populations over and over again, but this change is usually minimal such that vaccine created from the previous year can offer protection. Perhaps every decade or two, a major change in the virus (antigenic shift) occurs, against which most people have little or no immunity. The Spanish flu was one such event, as was H1N1 ("swine flu") in 2009. The danger arising from antigenic shift may be exacerbated by increased trade: Once strains emerge, they can travel worldwide at great speed using animals, people, and even goods as vectors. Whereas a century ago spread of the new strains may have taken months, and by 1918 took weeks, it now takes only a matter of hours.

It is, of course, of major importance to public health to have a system that can respond to infectious disease outbreaks. Notably, the rapid spread of cholera associated with increased global trade in the 19th century led to a considerable death toll; while governments imposed containment measures to control the disease, the economic interests of the mercantile elite suffered as these measures slowed the circulation of people and goods that was so crucial to commercial profit. These economic interests prompted the assembly of 12 governments in Paris in 1851 to establish a basis for common agreements on quarantine and the containment of cholera, leading eventually to the first International Sanitary Convention (ISC) in 1892. Other international treaties in the following decades ultimately resulted in the International Health Regulations (IHR), which were adopted at the fourth World Health Assembly (WHA) in 1951.

The IHR have historically coordinated the public health response to infectious disease threats, although countries were originally obliged to report only outbreaks of cholera, plague, and yellow fever (Liverani & Coker, 2012). However, compliance has been notoriously weak because of the economic consequences of notification, in the form of trade barriers. In short, the IHR have lacked the means and incentives to work effectively. Recognition of this problem prompted

EXHIBIT 20-2 SARS and Ebola

Severe Acute Respiratory Syndrome

The outbreak of SARS in 2002–2003 demonstrated how the modern world can be more vulnerable to disease spread. SARS is a respiratory illness caused by previously unknown type of coronavirus. Coronaviruses usually cause mild to moderate upper respiratory tract symptoms, but SARS led to high fever, cough, shortness of breath, and eventually severe pneumonia or respiratory failure that could be fatal. Between November 2002 and July 2003, there were 8,096 cases of SARS, causing 774 deaths in 27 countries. Although the disease burden ultimately proved to be low (in comparison, seasonal influenza causes 250,000 to 500,000 deaths each year worldwide), the outbreak caused alarm due to its unprecedented speed and extent of global spread. Its airborne transmission, the lack of diagnostic technology, and the lack of a vaccine, combined with this rapid dissemination, led to mass concern and widespread measures to restrict movement, including WHO's unprecedented step in issuing an advisory against travel to Toronto. It is believed that air travelers led to the spread of SARS from China, where it originated, to 16 countries (Bonn, 2003). Whereas the plague may have taken 3 years to cross from Asia to Europe in the Middle Ages, SARS took just 15 hours to get from Hong Kong to Toronto.

As outlined in the *Health and "The Economy"* chapter, the overall global macroeconomic burden of the outbreak was between $30 billion and $100 billion—a sum vastly out of proportion to the health impact (Keogh-Brown & Smith, 2008). The Canadian Public Health Agency suggested SARS costs included losses of $350 million from tourism, $220 million from reduced airport activity, and $380 million from non-tourism retail sales (Naylor, 2003). Overall estimates of the direct and indirect costs to Canada of SARS were placed at as much as $2 billion (Keogh-Brown & Smith, 2008).

Costs were distributed across a wide range of countries, some of which had no confirmed cases of SARS, illustrating the vulnerability of the global economy to a public health threat. Had the outbreak been more serious, more widespread, or of a longer duration, it is possible that quarantines and greater restrictions on movement of people and goods could have led to the closure of factories or worse in many areas. Moreover, this outbreak served as an illustration of the shared interests globally in ensuing effective surveillance and management of outbreaks.

Ebola

The recent outbreak of Ebola virus disease in West Africa during 2013–2016 confirmed the devastating link between trade and the spread of disease, as well as the effects of infectious disease outbreaks on trade. The lack of adequate surveillance and countries' slow initial responses, paired with the movement of people, including traders, allowed the initial outbreak to spread from Guinea to Liberia and Sierra Leone (Moon et al., 2015). In reaction to the outbreak, some neighboring countries closed their borders and sought to suspend trade against the explicit advice of WHO. The human costs aside, the World Bank estimated that the outbreak cost the three countries most affected—Liberia, Guinea, and Sierra Leone—approximately $2 billion.

substantial review and revision starting in 1995 to widen the IHR's remit beyond the three diseases and to address issues of means and incentives for compliance (WHO, 2002). The SARS outbreak provided the impetus for the final push, and the final revision was endorsed at the 2005 WHA and came into effect in June 2007. Under these revised IHR, countries are obligated to report any "public health emergency of international concern"—basically any adverse health event that has the potential to spread beyond borders—and allows notification from nongovernmental as well as governmental sources.

Yet, while the scope of IHR was expanded, incentive and repercussion issues remain: The suggestion to integrate some form of reparation, financial support, or other measures in relation to the timing and extent of possible barriers to cross-border movement from affected countries was not implemented. The economic imperative to protect trade stemming from the ISC in 1892 also remains, as the IHR are to "prevent, protect against, control and provide a public health response to the international spread of disease in ways that are commensurate with and restricted to public health risks, and which *avoid unnecessary interference with international traffic and trade*" (emphasis added). Some of these issues have since been highlighted by the H1N1 and Ebola outbreaks. Most critical of these is the ability of member states to impose trade and travel restrictions against countries experiencing outbreaks, to an extent that might be excessive and harmful to the latter's economies. In 2009, for example, the H1N1 outbreak led several countries to ban live pig imports or even pork products that originated in Mexico, despite the absence of scientific evidence that humans might contract the virus from animals or animal products. Under competing international law from WTO, the burden of proof is on health science to show that there is no chance that humans could catch the disease—that is, the burden to provide evidence is always with the health authorities and countries may adopt a

"precautionary principle" of "if in doubt, ban." Thus, there is no system of governance to regulate the economic impact of reporting or experiencing outbreaks, and hence no incentive to report them, fundamentally undermining surveillance and control strategies. The recent outbreak of Ebola has led to much greater emphasis on the importance of an effective global governance to respond to disease outbreaks. Further discussion of these approaches and implications is found in the *Public Health Infrastructure* and *Global Health Governance and Diplomacy* chapters.

Movement of goods, including livestock and food, has also important implications for health in two other ways. First, the noncommunicable disease (NCD) epidemic has highlighted the link between obesity and trade. In this case, recent research has focused on the role of trade in shifting patterns of consumptions as less healthy, high-fat and -calorie, processed foods, for example, undercut the price of local fresh produce (Friel et al., 2013; Hawkes & Thow, 2008; Thow, 2009; Thow & Hawkes, 2009). Second, the transmission of disease through livestock and food has drawn attention. This area is regulated by the WTO Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement), which states that countries have the right to protect human, animal, and plant health on the basis of scientific evidence; in other words, countries are allowed to ban products that are thought to endanger health. Similarly, the Codex Alimentarius of the Food and Agriculture Organization (FAO) is a set of international standards to ensure that food products are safe and can be traded. Recent attention has also focused on the role of trade in livestock and food products in creating AMR (Hanefeld, Khan, Tomson, & Smith, 2017).

Trade Liberalization and Noncommunicable Diseases

The *Chronic Diseases and Risks* chapter highlights the economic impact of NCDs. Trade—including not just movement of goods, animals, and people, but also foreign investment and marketing—has important implications for the spread and control of NCDs. Trade liberalization, through reduced tariff and nontariff barriers, can be beneficial when it leads to an expansion in the consumption of the goods that improve health, such as clean water, safe food, and education. However, it also facilitates the increased consumption of goods that may be harmful or hazardous to health, such as tobacco, alcohol, and unhealthy food items. Furthermore, increased trade in high-technology products such as mobile phones and computers increases the volume of toxic products that cross borders, and ultimately leads to an increase in toxic wastes as obsolete products are discarded. This trend may directly impact the health of those who handle such products and waste, and indirectly affect health via environmental degradation. In this section, we consider each of the four core areas where trade and risk of NCDs intersect.

Trade and Tobacco. Strengthening of tobacco controls in Western Europe and North America, coupled with LMICs' reductions of their trade barriers and expanded advertising by transnational tobacco companies, has shifted the market share for tobacco products toward the emerging economies across Asia, Latin America, the Middle East, and Eastern Europe (Chaloupka & Corbett, 1998; Grise, 1990; Hagihara & Takeshita, 1995; Hsieh, Hu, & Lin, 1999). Given the inverse relationship between price and consumption, as well as the positive relationship between advertising and demand, rates of cigarette smoking and tobacco use can be expected to increase as tobacco markets become more open, all else equal. In turn, the mortality and morbidity attributable to tobacco use can also be expected to increase.

As early as the 1980s, the United States used bilateral trade agreements to exert pressure on countries such as Thailand, Taiwan, and South Korea to open their domestic economies to U.S. cigarette imports. In fact, U.S. market share in these countries was approximately 600% higher, on average, in 1991 than it would have been had these markets remained closed (Chaloupka & Laixuthai, 1996). Furthermore, opening of the cigarette markets in these countries led to a significant increase in rates of cigarette smoking, with per capita cigarette consumption being 10% higher by 1991, on average, than it would have been in the absence of the bilateral agreements (Chaloupka & Laixuthai, 1996). The Uruguay Round of GATT, which concluded in 1994, focused on liberalizing trade in "raw" tobacco; subsequently, 1994–1997 saw a 12.5% increase in nonmanufactured tobacco exports globally, after a decade of virtually no growth (Chaloupka & Warner, 2000).

Since the WTO replaced GATT in 1995, it has significantly reduced tariff and nontariff barriers to tobacco trade. In response to "plain packaging" requirements and minimum sizes for health warnings, which some condemn as unjustifiably encumbering trademark rights (Bettcher et al., 2003; Callard, Chitanondh, & Weissman, 2001), pressure has been brought to bear in manufacturers' home countries to include

EXHIBIT 20-3 Regulating Trade in Tobacco: The Framework Convention on Tobacco Control

The FCTC, which came into force in 2005, requires contracting parties to do the following:

- Implement public health protection measures by addressing issues such as tobacco advertising, promotion, sponsorship, packaging, and labeling.
- Improve regulation of the domestic tobacco industry, specifically by requiring disclosure of the contents of tobacco products and tobacco smoke.
- Address such issues as illicit trade in tobacco products, price and tax measures, sales of tobacco to and by young persons, government support for tobacco manufacturing, treatment of tobacco dependence, passive smoking and smoke-free environments, surveillance, research and exchange of information, and scientific, technical, and legal cooperation.

Its final text contains provisions that have implications for trade rules, with potential opportunities as well as challenges for domestic tobacco control. The first clause of the preamble to the FCTC provides that parties to the convention are determined to give priority to the right to protect public health. Consistent with the free trade principle allowing the imposition of nondiscriminatory taxes, the FCTC requires parties to prohibit or restrict, as appropriate, the tax-free and duty-free sale of tobacco. The FCTC's regulation of advertising, packaging, and labeling of cigarettes is relevant to trade law. For instance, cancellation (or prohibition of registration) of the terms "light" and "mild" should not contravene the relevant provisions of international intellectual property law, especially the TRIPS Agreement (McGrady, 2004). FCTC Article 9 provides for the development of international standards for the testing and measuring of the contents and emissions of tobacco products, which can be recognized under the WTO TBT agreement, thereby helping to advance tobacco control within the trade agenda (Shaffer, Brenner, & Houston, 2005). However, public health advocates must continue to monitor and advocate transparency in the implementation of the FCTC, as measures to implement the FCTC could be affected by other trade obligations, especially through regional, multilateral, and bilateral trade agreements.

tobacco in negotiations to liberalize the agricultural sector and to reduce tobacco control measures under the terms of trade agreements.

Tobacco companies have also sought to use provisions within trade agreements to fight national tobacco control policies. An example is the use of intellectual property rights relating to trademarks to contest plain packaging for cigarettes—for example, in Australia (Gleeson & Friel, 2013; Thomas & Gostin, 2013). In such cases, trade agreements provided the opportunity for companies to contest the issues in a national court. Another avenue is to contest public health regulation through trade agreements, and to report countries to the WTO dispute settlement mechanism or to bilaterally threaten or impose sanctions on them. Again, these mechanisms have been employed by transnational tobacco companies (Alemanno & Bonadio, 2011).

Such moves have meant that the regulation of trade in tobacco has been a high priority for the public health community for many years. Two competing views have emerged regarding the best way to regulate tobacco under international trade rules. First, tobacco may be excluded from schedules of liberalization and treated as a special product for stricter regulation or even prohibition (Weissman, 2003). Second, tobacco may be regulated like any other good, in accordance with international treaties such as those of the WTO (Bettcher et al., 2003; McGrady, 2007). In the end, the latter approach was adopted, through the WHO Framework Convention on Tobacco Control (FCTC),[1] described in **EXHIBIT 20-3**.

Trade and Alcohol. Excess consumption of alcoholic beverages has many detrimental effects on health, and various proposals have been made to prevent excess consumption, including imposition of a minimum legal purchasing age, restrictions on hours or days of alcohol sale, outlet density restrictions, public service educational campaigns, and alcohol taxes. Of these measures, a common call is to tax alcoholic beverages so that they become more expensive and hence less accessible. However, the "national treatment" provisions embodied in many trade treaties make it clear that governments must be careful not to tax products, including alcohol, in ways that (even unintentionally or incidentally) protect domestic production from foreign competition. Thus, although governments may appear to have the option to discourage alcohol consumption by imposing taxes, they face challenges in doing so in practice.

[1] http://www.who.int/fctc/en/index.html

An alternative is to regulate the time, place, and manner in which alcohol is sold. For example, as a general matter it is permissible for a government to restrict the hours or days during which alcohol can be sold, require retail businesses to obtain licenses (authorization) before selling alcohol, or require retail businesses to demand proof of age from those seeking to purchase alcohol. Again, policy makers must be careful to design such measures so as to avoid discrimination, indirectly or inadvertently, based on the national origin of the product.

The regulation of advertising is another way for governments to prevent harm caused by alcohol. In 2001, the European Court of Justice (preliminary ruling C-405/98) ruled that Sweden's law limiting alcohol advertising affected foreign alcohol products more adversely than more familiar domestic products. However, the Court also held that the ban could be justified if it were proportionate to the public health objective and not a disguised restriction on trade; thus, it allowed the case to be further processed within the Swedish court system. Sweden's domestic court ultimately upheld the ban, finding that it was indeed "proportionate" to its purpose (Center for International Environmental Law, 2003). This example illustrates that trade treaties can accommodate appropriately designed policies intended to further public health objectives.

The issues with strongest relevance for alcohol policies within the WTO system are now covered by the discussions under GATS. These negotiations do not cover the products themselves, but rather the services related to the products (such as sales and marketing). For example, GATS provisions provide a framework for how, when, and why governments can impose regulations on alcohol licensing procedures, state monopolies, the number of suppliers or outlets, and advertising and promotion activities. Alcohol is treated like any other good under WTO law, and any regulatory action must meet the nondiscriminatory principles. However, recognition of the harmful effects of trade in alcohol has led to the inclusion in some RTAs of provisions that allow some restrictions on alcohol trade. For example, Association of Southeast Asian Nations (ASEAN) trade agreements have enabled the group's members to exclude alcohol and guns from the list of goods subject to trade liberalization (Onzivu, 2006).

Trade, Food, and Agriculture. Trade liberalization has the potential to influence food-related nutrition and health issues through a series of pathways, and measures designed to liberalize trade influence the entire food supply chain. These measures include those to reduce financial and regulatory barriers to food imports and exports across national borders; harmonize or remove national food-related regulations; remove limits on the percentage of domestic companies that can be owned by foreign businesses; decrease government support to domestic food production; and support the development of infrastructure and capacity for trade and investment, such as transportation routes and storage facilities. Such efforts create changes along the food supply chain that influence the environment in which consumers make food choices, such as the availability of foodstuffs (amount, type, and nutritional quality), the safety of that food, what it costs, and how it is marketed. These factors, which represent important components of national and household food security, influence the choices people make about the food they eat. Thus, they affect the diets of consumers and, therefore, the prevalence of malnutrition, diet-related NCDs, and foodborne illness (De Vogli, Kouvonen, & Gimeno, 2014; Popkin, 2001; Stuckler, McKee, Ebrahim, & Basu, 2012). In addition, trade liberalization may affect human nutrition and health through a range of indirect effects—for example, the inadvertent entry of emerging human, animal, and plant diseases via the food supply, as well as effects on income, employment, and industry restructuring in response to trade liberalization.

Similar to tobacco and alcohol, food has seen major shifts in patterns of trade across the world. According to the OECD, the share of global agri-food trade between countries with RTAs rose from 20% to 40% between 1998 and 2009 (Bureau & Jean, 2013). Between 1980–1981 and 2006, world agricultural trade rose from $243 billion to $945 billion in real terms (Peterson, 2009). Between 1970 and 2001, gross world food imports, measured in terms of calorie equivalents, grew by almost 60%. The share of agricultural production that is exported increased from 19% in 1971 to 40% in 2003 (Bloom, Canning, & Sevilla, 2001). Exports from high-income OECD countries—which are responsible for the vast majority of trade in processed products—more than doubled, increasing from $169 billion in 1995 to $363 billion in real terms in 2008. Exports from LMICs increased even more, tripling and even quadrupling during this time.

While increased trade can make energy- and nutrient-rich food more widely available, with consequent benefits for the undernourished, this outcome also carries risks associated with over-consumption. Reductions in the prices of unhealthy foods (i.e.,

foods that are calorie rich, nutrient poor, and/or high in saturated fats and salt) compared with healthy foods, increased desirability and availability of unhealthy foods, worsening asymmetry between consumers and suppliers of foodstuffs, and growing urbanization and changes in lifestyle are all possible means by which trade liberalization could affect popular diets, especially those of poor populations. For instance, changes in trade policy in Central America have been directly linked to changes in the availability of meat, dairy products, processed foods, and temperate (imported) fruits (Thow & Hawkes, 2009). Similar trends have been observed with the lowering of trade barriers between Mexico and the United States following the signing of the North American Free Trade Agreement (NAFTA), after which imports of corn, soybeans, sugar, snack foods, and meat products into Mexico increased significantly (Clark, Hawkes, Murphy, Hansen-Kuhn, & Wallinga, 2012). Such an impact has been especially documented in the Pacific Islands, where several studies have noted displacement of traditional diets with high-fat imported foodstuffs and a concomitant increase in obesity rates and chronic diseases (Cassels, 2006; Evans, Sinclair, Fusimalohi, & Liava'a, 2001; Hughes & Lawrence, 2005; Thow & Snowdon, 2010).

Although the effects of the liberalization of food trade on food safety, availability (volume and variety), prices, quality, and marketing are not straightforward, and depend on the nature of the implementing legislation and other contextual factors (Thow, 2009), trade clearly plays a major role in influencing food prices. Prices are important because they affect incentives for food production and consumption. In practice, the effects of trade liberalization have varied, but trade has generally led to a lowering of the relative cost of energy-dense foods and diets (Drewnowski, Hanks, & Smith, 2010).

Finally, increased trade in advertising and other telecommunications services facilitates the commercial promotion of highly processed foods (Nestle, 2006). The ability to advertise and promote is a major "pull" factor for inward investment by large transnational food corporations into LMICs. Processed foods are commonly advertised and marketed all over the world, using a wide range of communication channels and marketing techniques. Estimates from Asia suggest that food accounts for a significant proportion of child-targeted advertising, ranging from 25% in the Republic of Korea to 70% in Malaysia (Escalante de Cruz, Phillips, Visch, & Bulan Saunders, 2004). Studies in Latin America suggest a high proportion of advertisements during children's programming are for processed foods, such as sweetened beverages, candy, sugar-sweetened cereals, and chips (Chopra, Galbraith, & Darnton-Hill, 2002).

Trade and Toxic Substances. Trade in toxic substances (e.g., heavy metals, persistent organic pollutants, and other substances that may have adverse health effects) has a long and well-documented history (Agege, 1985; Broad, 1981; Smith, 1980). In an unintended side effect, it is the stricter environmental protection in the industrialized countries that is contributing to the buildup of these hazardous wastes in the developing world. In the 1990s, governments in the European Union, Japan, and some states of the United States set up recycling systems for hazardous substances, but many did not have the capacity to deal with the sheer quantity of material collected or with its hazardous nature—in particular, the increased waste consisting of electronic devices (e-waste). Those devices often comprise a complex mixture of several hundred materials, many of which contain heavy metals such as lead, mercury, cadmium, and beryllium, as well as hazardous chemicals (Singhal, 2005).

The prospect of earning foreign currency in return for importing international waste is attractive to LMICs. Unfortunately, these countries often have neither the technical expertise nor adequate facilities for safely recycling or disposing of such waste. Substandard facilities contribute to the improper handling of hazardous waste in these countries. In addition, many employees at recycling facilities lack adequate protective equipment. As a result, workers in the recycling industry may develop a variety of health problems. For example, laborers who melt down car batteries may develop lead poisoning. When e-waste or polyvinyl chloride (PVC) is burned, employees are exposed to cancer-causing dioxins and other toxic chemicals. Adverse health effects attributable to unsafe handling of hazardous wastes include mercury poisoning, birth defects and miscarriages, kidney disease, cancer, and even death. Exports of e-waste to LMICs are likely to increase unless greater support is given to initiatives that ensure that companies take greater responsibility for the recycling, reuse, or disposal of potentially hazardous electronic products.

Trade and its effects on health—especially NCDs—specifically through trade in products has been facilitated to an extent by financial liberalization and foreign investment. While liberalization of financial markets lies beyond the scope of this chapter, some of

EXHIBIT 20-4 Facilitating Trade Liberalization: Foreign Investment

The expansion of trade has been facilitated by concomitant liberalization of financial markets and regulations related to advertising and promotion. Foreign direct investment (FDI) is an investment by an enterprise from one country into an entity in another, in which the parent firm owns a substantial, but not necessarily majority or controlling, interest. The foreign enterprise becomes an affiliate of the parent company, thereby creating or joining a transnational corporation (TNC). FDI is one of the mechanisms through which TNCs enter new markets, and it reflects a company's intention to remain invested in the market over the longer term. It has played an unprecedented role in recent decades as a source of capital for economic growth and development in many LMICs, facilitated by increased opening of global capital markets since the 1990s.

The global financial crisis of 2008 saw a sharp decline in FDI, from approximately $2 trillion in 2007 to $1 trillion in 2009 overall, although the drop-off was less marked in emerging economies. These trends are important for incidence and prevalence of NCDs, as FDI often takes the form of strong investments in tobacco, unhealthy food, and alcohol in emerging markets. For example, 10 of the top 100 TNCs (ranked by value of foreign assets) manufacture tobacco, food, or alcohol, as do a large proportion of the largest affiliates of foreign TNCs in emerging economies. There are also wider associated investments in other areas that may be hazardous for health, such as the disposal and recycling of hazardous waste.

Clearly, substantial FDI can bring much-needed capital, skills, technology, and other benefits to local economies, encouraging further investment and providing support for infrastructure developments, increased foreign exchange earnings, and a general lift to the host economy. However, they may also lead to reduced health and safety standards, or compromise policies to protect public health. For example, FDI by TNCs involved in food processing may exert pressure against enhanced food labeling, development of nutritional standards, or costly improvements in production methods. With respect to tobacco, a study showed that British American Tobacco and Philip Morris—the world's largest transnational tobacco corporations—are among the largest foreign investors in Russia and Moldova, where the companies have been able to negotiate tax breaks, exemptions from monopoly legislation, and other conditions beneficial to their business but not beneficial to public health (Gilmore & McKee, 2004).

the main links between trade and foreign investment are summarized in **EXHIBIT 20-4**.

Trade and Its Effects on Health Systems

In addition to having varied impacts on health status and risk factors for disease, trade has led to significant changes in the way in which health systems function, interact, and are financed. These effects have been created through trade in both goods—principally pharmaceuticals—and services; both of which are explored in this section.

Trade in Pharmaceuticals

As outlined in the *Pharmaceuticals* chapter, pharmaceuticals are a significant element of healthcare expenditures, accounting for some 7% to 21% of such spending in HICs and 24% to 66% in LMICs. They are the single most important health-related product traded, representing some 55% of all health-related trade by value; by comparison, the share of the next most significant health-related goods traded, small devices and equipment, is 19% (Smith & Hanson, 2012).

Over the last few decades the pharmaceutical industry, as a mainstay of modern medical care, has grown in both size and concentration. At the turn of this century, the industry earned some $500 billion in global sales, but by 2013 this amount had increased to $950 billion in current prices (Hanefeld, 2015). It is an industry dominated by TNCs, with the top 10 earning more than half of these total revenues (increasing from earning just one-third in 1995). This concentration of the industry in fewer, larger firms (**TABLE 20-1**) has been accelerated by a need to exploit economies of scale, given the increasing costs of research and development (R&D); market positioning (especially with tighter regulation of pricing in HICs and emergence of markets in LMICs); the firms' desire to broaden their portfolios (with less reliance on a single blockbuster drug); and acquisition of generic manufacturers to both reduce the cost of production and remove competition, especially in India and in Asia more widely (Busfield, 2003; Lee, Yach, & Kamradt-Scott, 2011).

In general, however, despite increases in production and consumption of pharmaceuticals in LMICs, the pharmaceutical industry retains a strong HIC focus. Both production and consumption remain concentrated in HICs. Moreover, many companies retain a national base and even identity in HICs (e.g.,

TABLE 20-1 Top Ten Pharmaceutical Companies in Rank Order by Sales Value, 2012

Corporation	Headquarters	Sales Value (U.S. $ million)
Novartis	Switzerland	50,761
Pfizer	United States	46,930
Merck & Company	United States	40,115
Sanofi	France	37,780
Roche	Switzerland	35,069
GlaxoSmithKline	United Kingdom	32,714
AstraZeneca	United Kingdom	31,893
Johnson & Johnson	United States	27,933
Abbott	United States	26,715
Teva	Israel	24,846

Data from IMS Health (2013)/IQVIA.

Pfizer as a U.S. company), with 75% of the industry concentrated in Europe, North America, and Japan. Importantly, the size and concentration of the industry creates specific issues for trade policy and governance, compared to other areas covered in this chapter that tend to be more diffuse and national in character.

A critical issue is the business model of pharmaceutical R&D: It front-loads the costs of drug discovery, development, and licensing, with returns coming only after this substantive investment has been made, through the temporary monopoly provided by intellectual property (IP) rights. IP rights—and patents more specifically—grant legal exclusivity as a compromise to remove the disincentive to R&D, but also provide only a limited amount of time in which to recoup costs before the product faces competition (Smith, 2003). Patents have been the mainstay of policy to ensure investment in pharmaceutical R&D, acting as guarantor of monopoly rents. However, the high price charged at a product's launch and for several years thereafter creates problems for poorer countries and populations as they seek to access these medicines. Additionally, patents generate investments only when profitable markets exist; they do not work for drugs needed to address many of the diseases that prevail in LMICs (such as malaria).

This clear tension between the need for incentivizing private-sector funding of R&D and the need to use the drugs developed as widely as possible to meet public health goals was expressed as early as the 1970s. On one side, multinational pharmaceutical producers based in HICs expressed growing concern over alleged "misappropriation" of their patented technology by enterprises based in LMICs. On the other side, LMICs expressed deep concerns about the imbalance between technological capacity and ownership of technology as occurred between HICs and LMICs. This dialogue played out in a series of negotiations at UNCTAD, the World Intellectual Property Organization (WIPO), and ultimately the GATT during the Uruguay Round of trade negotiations. The last culminated in 1993, with the WTO's Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) entering into force in 1995 (Smith, Correa, & Oh, 2009).

The TRIPS agreement served as the catalyst for the change from the GATT to the WTO, as it moved beyond goods and into services trade. TRIPS established minimum standards for protecting and enforcing nearly all forms of IP (patents, trademarks, and copyrights) for WTO member states across all products, with standards derived from legislation in HICs. All member states are required to comply with these

standards, and where necessary to alter their national legislation to do so. In an important departure from previous conventions, pharmaceutical products were accorded full IP rights under TRIPS, and companies were granted the legal means to prevent others from making, using, or selling the new invention for a period of time—specified as 20 years.

There is a clear conflict between TRIPS and public health. By their very nature, the monopoly rents afforded by patents are reflected in the final product's pricing, so they act as a barrier to affordability. A flashpoint on this issue occurred toward the end of the 1990s, concerning HIV/AIDS medications. The annual cost for treatment of persons with HIV/AIDS with life-saving medications at the beginning of the 2000s was approximately $12,000 per year, putting the treatment beyond the reach of most public health systems and patients in the LMICs where the greatest burden of HIV is found (Roemer-Mahler, 2010). At the same time, the patent provisions within TRIPS initially prevented the export and use of generic, less expensive versions of such intellectual property being made in India, where the largest capacity for generic pharmaceutical manufacturing exists. Even in countries where domestic manufacturing capacity existed, notably in South Africa, drug companies initially sought the protection of their intellectual property.

For example, in South Africa, manufacturers of HIV/AIDS medications took the government to court over this issue in 1998. Subsequently, in 2001 the South African government sought to amend the South African Medicines and Related Substances Control Amendment Act, which would allow the import and use of less expensive generic versions of prescription drugs required to treat HIV/AIDS. The key clause stated that the government could find and "parallel import" the cheapest drug available globally and also grant "compulsory licensing" to other companies to allow them to make copies of the patented drugs. The government argued that this policy was justified and acceptable under Article 8 of TRIPS, which states that in framing national laws, members "may adopt measures necessary to protect public health and nutrition, and to promote the public interest." The prevalence of HIV/AIDS was such that the South African government felt that this article applied in this circumstance. Thirty-nine pharmaceutical companies, including GlaxoSmithKline, Merck, and Roche, launched legal action against this amendment, arguing that it was a direct violation of their patent rights. Supported by nongovernmental organizations (NGOs) such as Health Action International and Médecins sans Frontières, the case generated huge public pressure on the pharmaceutical companies, and the industry eventually withdrew the case. However, it left a lasting legacy in terms of its effects on TRIPS (Berger & Kapczynski, 2009).

Doha and Beyond

Attempts to address continued concerns related to public health protection under TRIPS led to the Declaration on the TRIPS Agreement and Public Health—known as the "Doha Declaration"—in November 2001. This affirmed the right of WTO member states to interpret and implement TRIPS in a manner supporting the protection of public health and, in particular, access to medicines (**EXHIBIT 20-5**). Critically, the Doha Declaration gave rights to countries to grant compulsory licenses and engage in parallel importation where a "public health crisis" made this necessary. Interestingly, countries have remained reluctant to use these available "TRIPS flexibilities" due to political pressures (Songkhla, 2009).

The comparatively limited application by countries of the TRIPS flexibilities has been repeatedly noted, including by the UN Secretary General's High Level Panel on Access to Medicines, and countries' right to use these flexibilities was explicitly affirmed as a target (3B) in the Sustainable Development Goals:

> Support the research and development of vaccines and medicines for the communicable and noncommunicable diseases that primarily affect developing countries, provide access to affordable essential medicines and vaccines, in accordance with the Doha Declaration on the TRIPS Agreement and Public Health, which affirms the right of developing countries to use to the full the provisions in the Agreement on Trade Related Aspects of Intellectual Property Rights regarding flexibilities to protect public health, and, in particular, provide access to medicines for all.

Specific concerns have arisen regarding those countries unable to access medicines due to their lack of manufacturing capacity. Paragraph 6 of the Doha Declaration recognized that "WTO members with insufficient or no manufacturing capacities in the pharmaceutical sector could face difficulties in making effective use of compulsory licensing under the TRIPs Agreement," and instructed the Council for TRIPS to find an expeditious solution to this problem. In 2003, a waiver was temporarily introduced that allowed countries with limited or no manufacturing capacity to import medicines produced under a compulsory license. For example, countries neighboring

EXHIBIT 20-5 TRIPS Flexibilities

The patent represents a balance that governments establish between inventors and the wider public. Sometimes the government will determine that the balance between the patent holder and the public needs to be adjusted. That is, the exclusive rights being exercised by the patent holder are perceived as causing a difficulty that the public should not be expected to bear. The TRIPS agreement and the Doha Declaration set out a series of flexibilities designed for countries to redress these imbalances.

Compulsory licensing is a core component of a country's patent law that is necessary to ameliorate potentially harsh consequences of patents on public health. The TRIPS agreement ultimately incorporated rules on compulsory licensing in Article 31. Article 31 addresses compulsory licensing by establishing procedural requirements for the granting of such licenses, without imposing restrictions upon the circumstances or grounds that justify the granting of such licenses. In terms of procedural requirements, Article 31 provides an accelerated or "fast track" mechanism when compulsory licenses are granted to address national emergency, in other circumstances of extreme urgency, or for public noncommercial use. The Doha Declaration on the TRIPS Agreement and Public Health, adopted on November 14, 2001, re-emphasized that governments may grant compulsory licenses on grounds of their own choosing, and that HIV/AIDS, malaria, TB, and other epidemics may constitute national emergencies.

Governments may also opt for *parallel importation,* which refers to authorization of importation of drugs under patent within the importing country that have been lawfully placed on the market outside the country. The TRIPS agreement authorizes WTO members to allow parallel importation of patented medicines, and this was confirmed by Paragraph 5(d) of the Doha Declaration. Parallel importation may help a country lower the cost of patented medicines because it allows for the purchase and importation of the lowest-priced version of the same medicine from anywhere in the world.

Although the basic concept of parallel importation is widely accepted, there are different schools of thought regarding the precise practices that are permitted. It is generally accepted that parallel importation covers patented products put on the market in any country by or with the consent of the patent holder. Some respected commentators take the view that pharmaceutical products lawfully placed on the market under compulsory license may also be parallel imported. Others have rejected this view on grounds that such products have not been placed on the market with the patent holder's consent.

In some countries, such as South Africa, authorization of parallel importation of patented medicines is expressly incorporated in national legislation. In most countries, rules on parallel importation are made by judicial decision. If a country authorizes parallel importation of patented medicines, it typically must also authorize parallel importation using the patent holder's trademark, since most pharmaceutical product packaging will also include a trademark or "brand name" of the patent holder. This is also permitted by the TRIPS agreement. Because originators may claim copyright protection for brochures or leaflets accompanying pharmaceutical products, it may also be useful to recognize parallel importation for copyrighted medical information as part of an authorization.

It is sometimes argued that parallel importation of pharmaceutical products does not actually reduce the price of medicines to consumers, because parallel traders and middlemen retain the price differential between imported and locally supplied products that should otherwise benefit consumers. However, the mere possibility of parallel imports of lower-priced medicines from foreign sources should exert downward pressure on local prices even if middlemen may absorb part of the price differential.

South Africa were permitted to import medicines that had been produced in South Africa under a compulsory license. This "temporary waiver" became a formal amendment to the TRIPS agreement in 2017, when two-thirds of WTO member states ratified the amended protocol (WTO, 2017b). It is hoped that this significant step will lead to much greater uptake of TRIPS flexibilities by the poorest countries facing the greatest barriers to access of medicines.

Three key issues continue to hinder improved access to medicines. The first issue is the inability of many countries, especially the very poor, to implement the "flexibilities" given their stark resource constraints. Even when medications are available at reduced cost, increased funding is still required for their purchase.

The second issue is the undermining of the flexibilities by provisions adopted under bilateral and regional trade agreements, known as "TRIPS-plus" measures, which are more restrictive than TRIPS and not bound by the flexibilities attached to TRIPS (Correa, 2006). TRIPS-plus refers to unilateral or bilateral trade negotiations in which standards beyond TRIPS (e.g., increasing patent life from 10 to 20 or 30 years, restricting compulsory licensing, removing the option to parallel import, and/or increasing exclusivity rights

over test data) are incorporated in exchange for trade concessions, particularly the promise of free access to markets for agricultural goods. Free trade agreements (FTAs), signed by the United States and European Union especially with a growing number of LMICs, have constituted one of the main routes for TRIPS-plus standards to be implemented. For instance, both China and Argentina are on the "Priority Watch List" of Special Section 301 of the U.S. Trade Act, which applies pressure to those countries to introduce their own TRIPS-plus standards (Office of the United States Trade Representative, 2007).

The third issue preventing greater access to pharmaceuticals is the need to achieve an appropriate balance between ensuring access to medicines and creating incentives for drug development and innovation. To date, this balance has remained elusive. Most recently, the concerns over new antibiotic production—how to incentivize R&D for new antibiotics when policy is also geared toward restricting their use—has promoted new energy and processes to develop systems that move away from current IP restrictions, although none has yet been implemented (Hanefeld, Khan, Tomson, & Smith, 2017; O'Neill, 2016).

Trade in Health Services

Trade does not only affect health care through goods. Advances in information, communication, and travel technologies have meant that increasingly services, such as telecommunications and electricity, as well as health and finance, are traded across borders (Smith, Chanda, & Tangcharoensathien, 2009). Trade in health services covers a wide range of areas, typically categorized according to the classification used in the WTO GATS (**EXHIBIT 20-6**). This model identifies four

EXHIBIT 20-6 General Agreement on Trade in Services

GATS, like all other WTO agreements, is binding on all member countries that sign it. There are some obligations and exemptions associated with GATS. Member countries have the right to restrict trade in services if they find that it poses a threat to human health. Although GATS is legally binding, countries have the opportunity to pull out after three years of officially adopting the agreement. However, they may have to compensate trading partners.

GATS permits WTO members to design the scope of their market access and national treatment commitments ("commitments" here refers to the obligations that countries enter into under the trade agreements), should they decide to make such commitments. From the national implementation perspective, the specific commitments are more important than the general obligations because GATS makes modification of specific commitments difficult to achieve. In general, the number of sectors for which commitments are made is positively related to the level of economic development, although some anomalies exist with respect to the health sector. In that area, overall commitments are lower than in any other sector except education, yet far more LMICs than HICs have made commitments in health. This suggests that trade in health services is more common between LMICs. The low overall level of commitments may exist for a number of reasons: Many countries simply ratified existing trade arrangements, which in health have historically been rare; health is seen by pace setters for trade—the United States and the European Union—as having less comparative economic value (compared with telecommunications or financial services, for example); and for most countries both health and education are recognized as public goods and have historically been subject to significant government involvement.

It is difficult to measure the effects of GATS on health systems. Not only are data lacking, but it is also difficult to isolate the influence of GATS from the many other factors that affect health systems simultaneously. Trade through all of the GATS modes has the potential to benefit health systems, but there are concerns that these benefits may be concentrated among the wealthy, increasing inequities within the health sector. In this respect, three specific aspects of GATS have particular importance:

1. GATS applies to services provided in competition, so it excludes services provided in the "exercise of government authority." While health services not supplied competitively fall outside GATS, if there is a combination of public and private providers, then the public providers are covered by GATS. This point is significant, as many health-sector reform programs have introduced some element of health care that is provided through private entities but publicly funded.
2. Sectors that are opened may contain qualifications, such as limitations on foreign equity investment, size limitations on facilities, or exclusion from subsidy. However, GATS requires as an absolute general obligation that members extend to all other members the best treatment that they give to their most favored trading partner (the "most favored nation" principle).
3. GATS does not affect member rights concerning market regulation for social policy purposes, such as universal access to care, but it could affect which types of regulations are allowed. For example, the "necessity test"

allows governments to deal with economic and social problems as they wish, provided that the measures and regulations are not more trade restrictive or burdensome than necessary. Obviously, much depends here on how "necessary" is defined.

Levels of activity and policy engagement in health-related services trade are growing under the combined influence of rising incomes in LMICs; demographic change, particularly population aging in LMICs and the ensuing pressures to contain health budgets; technological applications that facilitate the remote supply of an increasing range of health-related services, including to isolated populations in LMICs; continued liberalization of investment in services; and growing demand for skilled medical personnel and their cross-border mobility. A growing number of LMICs, particularly middle-income countries, regard health services, especially those that can be combined with tourism-related activities, as a potentially significant source of foreign exchange earnings, foreign investment, and skills upgrading. In turn, they are devoting significant policy attention to building health-related export clusters, with some having developed targeted investment promotion strategies. Current, and especially future, rounds of negotiations may yield much greater engagement and commitments by countries under GATS.

Information on GATS negotiations and up-to-date information on levels of commitments can be found at https://www.wto.org/english/tratop_e/serv_e/gatsqa_e.htm.

modes of supply of services, each of which is overviewed in this section (Blouin et al., 2006):

- Mode 1: Cross-border supply of services. This mode regulates the remote provision of health services, such as diagnostics and radiology, from one country to another.
- Mode 2: Consumption of services abroad. This mode covers "health tourism," the movement of people across borders to receive medical services.
- Mode 3: Commercial presence. Mode 3 involves FDI from one country to another. In the health sector, it usually involves setting up private hospitals and the presence of foreign insurance companies.
- Mode 4: Presence of natural persons. This mode covers the temporary movement of people from one country to another. In the case of health services, it would involve healthcare workers.

TABLE 20-2 summarizes these modes and the associated types of trade.

Mode 1: E-Health

Mode 1 refers to the cross-border provision of medical services. This is primarily telemedicine, in which diagnosis or expertise is provided by, for example, a physician in a different country, or in which medical records are transcribed by a service provider in another country (Smith, Chanda, & Tangcharoensathien, 2009). For instance, the shift from hard copy to digital imaging has enabled the remote storage, interpretation, and access of radiology images. Companies in China, for example, now provide hospital diagnostic services via this kind of electronic means for patients in Macao, Taiwan, and other countries (Blouin et al., 2006). A recent review of telemedicine found that examples documented in the literature mainly relate to telepathology, telesurgery, emergency and trauma telemedicine, and teleradiology, and that exchanges across borders were mainly between physicians consulting on patient cases, rather than between patients and physicians (Saliba et al., 2012). It identified cross-border supply of health services as driven by the need to address shortages in expertise predominately in LMICs, highlighting the positive potential of this form of trade.

Trade within this mode presents several opportunities: increased healthcare delivery to remote and under-serviced areas; alleviating (some) human resources constraints in service delivery; enabling more extensive and cost-effective disease surveillance; improving quality of diagnosis and treatment; and upgrading skills, by disseminating knowledge through interactive electronic means. It also raises some risks—namely, that such capital-intensive activity may divert resources from basic preventive and curative services, and that by largely catering to urban affluent populations, it may adversely impact on equity of access to services. Moreover, the implementation and use of e-health, even within national health systems, raises issues about the recognition of credentials and licensure; legal liability and malpractice considerations, including provider insurance coverage; provider remuneration; patient privacy and confidentiality; the existence of enabling infrastructure and compatibility of standards in areas such as data, images, and medical records; infrastructure and future operating costs; and the quality and appropriateness of care (Van Doosselaere, Wilson, Herveg, & Silber, 2007). The primary concern, though, is that electronic trade requires appropriate telecommunications and power

TABLE 20-2 Characterization of Trade in Health Services by GATS Modes of Supply

	Trade in Health Services	Trade in Ancillary Services	Trade in Goods Associated with Health Services
Mode 1: Cross-border supply	Telemedicine, including diagnostics, radiology	Distance medical education and training	Healthcare equipment
		Medical transcription, back office	Pharmaceuticals
		Medical research tools and databases	Medical waste
		Medical insurance	Prosthesis
Mode 2: Consumption abroad	"Medical tourism" (i.e., voluntary trip to receive medical treatment abroad)	All activities associated with health tourism (e.g., transport, hotel, restaurant, paramedical, local purchases)	
	Medically assisted residence for retirees	Local medical education and training of foreign nationals	
	Expatriates seeking care in country of residence		
	Emergency cases (e.g., accident when abroad)		
Mode 3: Commercial presence	Foreign participation or ownership of hospital/clinic or medical facilities (e.g., capital investments, technology tie-ups, collaborative ventures)	Foreign-sponsored education or training centers	
		Foreign-sponsored medical research facilities	
Mode 4: Presence of natural persons	Temporary movement of doctors and health personnel for the purpose of commercial medical practice	Temporary movement of doctors and health personnel for other purposes (e.g., education or training)	

infrastructure, which has led to developments in this mode becoming concentrated in countries that have this type of infrastructure, especially middle- and high-income countries.

Such remote supply of health services has the potential for impact on the health systems of both the countries contracting the services and the countries supplying them. The countries contracting the services can potentially improve the efficiency and the flexibility of their health systems if services can be carried out overnight—that is, if they are contracted to countries at a considerable time difference. More importantly, this has the potential to alleviate some of the staff shortages that some diagnostic services face. As some of these services are contracted to countries where salaries are lower, such as India, there is also potential for cost savings. In addition, this type of trade can increase the capacity of the country delivering the

services. The health systems of these countries, therefore, may benefit from increased profits and higher employment. At the same time, concerns have arisen that these services, and the higher salaries associated with them, may drive medical staff away from domestic services. Questions also exist about the quality of the services provided; the recognition of foreign degrees; and legal, malpractice, and liability issues related to telemedicine. **EXHIBIT 20-7** provides an illustrative case study of e-health trade.

EXHIBIT 20-7 Offshore Medical Transcription and Other E-Services in the Philippines and India

Medical transcription (MT) is the process of interpreting/encoding electronically the oral dictation of health professionals regarding patient assessment, therapeutic procedures, diagnosis, and so forth. U.S. outsourcing is the main driver of the global MT business. Since the entry into force of the Health Insurance Portability and Accountability Act (HIPAA) of 1996, which provides guidelines for safeguarding patient medical data, the need for medical transcription in the United States has expanded rapidly, growing at 20% per year. At the same time, the number of transcriptionists in the United States has declined at a rate of 10% per year.

The Philippines

The first large MT company, Outsource Transcription Philippines, started in the late 1990s. As the third-largest English-speaking nation in the world, with a large workforce, 94% literacy rate, and a strategic location with an ideal 12-hour time difference from the United States, the Philippines possessed key inherent advantages as a "first choice MT outsourcing destination" for the United States (Smith & Hanson, 2012, p. 183). Medical transcription is one of the five subsectors identified by the Philippines Department of Trade and Industry in its campaign to promote the country as a global hub for outsourced information technology (IT)–enabled services, carried out through the Center for International Trade Expositions and Missions (CITEM). The Philippines government has lent strong support to the MT industry by implementing an important e-commerce law, the Data Protection Bill (2006), and setting up the Information Technology and Electronic Commerce Council. The government has also sought to develop and expand the IT infrastructure of the country. Furthermore, the vast majority of companies exporting these services from the Philippines are ultimately owned by U.S. investors.

In the case of Philippines–United States outsourcing, privacy concerns have recently begun to increase. While patient information is protected though service contracts between importing hospitals in the United States and exporting transcription companies in the Philippines, it is expected that an increasing number of U.S. insurers will move to a model that legally requires information to be stored in the United States.

India

India has considerable opportunities in many aspects of e-health, including teleradiology, telediagnostics, telepathology, intensive care, ophthalmology, dermatology, psychiatry, and, to some extent, continuous online remote monitoring. Telemedicine is provided to other countries by independent telemedicine providers as well as reputed Indian IT companies such as Wipro. The Apollo Group in India exports e-health services. It provides telemedicine services (e.g., consultation, diagnostic, telepathology, teleradiology) from its Apollo Gleneagles Hospital in Kolkata to patients in Bangladesh, Nepal, Bhutan, and Myanmar. It also provides telediagnostic and teleconsultation services from its center in Karaganda Oblastu in Kazakhstan to the Central Asian region.

The United States and Singapore are also important markets for Indian telemedicine. The client base in the United States for leading Indian telemedicine providers has expanded from one hospital to 60 hospitals in just a few years. The National Healthcare Group of Singapore has contracted with telemedicine institutions in India to provide teleradiology services to designated hospitals in Singapore. Contracts have also been signed with Malaysia and with Dubai. India's potential in cross border e-health provision is driven by its cost advantages and the fact that specialized medical staff and doctors are involved in reporting and interpretation work (Chanda, 2008).

In addition to telemedicine, India exports health services in other forms through mode 1. It is an attractive market for outsourcing of healthcare business processes such as medical transcriptions, billing, coding, and data conversion, with potential to provide cost savings of 20% to 30% for client companies. For instance, Apollo has partnered with Health Services America and Med Staff International in the United States for billing, documentation of clinical and administrative records, coding of medical processes, and insurance claims processing for Medicare/Medicaid-claim policy holders and third-party administrators.

Outsourcing of pathology services is also emerging as a huge opportunity due to the high cost differential in India. Some Indian research labs and contract research organizations provide sophisticated tests such as molecular diagnostics for autoimmune disorders, cytogenetics, and diseases related to abnormalities in chromosomes and hormones. Some laboratories are able to offer a wide test menu of more than 1,500 tests under one roof.

Mode 2: Medical Tourism

Mode 2 is defined as the consumption of health services abroad. It is the most prevalent and long-standing form of trade in health services. Commonly referred to as medical travel or medical tourism, mode 2 involves the movement of consumers from one country to another for purposes of diagnosis, treatment, and rehabilitation and follow-up services.

Estimates of the number of medical tourists globally per year vary tremendously depending on the source, from a lower bound of 5 million to an upper bound of more than 40 million, with intermediate estimates putting the number at approximately 14 million per year. The financial value of mode 2 in health services trade is difficult to pin down, but conservative estimates place it in the range of $60 billion to $100 billion annually. According to McKinsey, 25% to 30% of these patients are expatriates, another 30% to 35% are seeking emergency care, and the remainder are patients who go abroad to seek treatment (Lunt, Horsfall, & Hanefeld, 2015). These numbers and values are much debated, as highlighted by Helble (2011), and currently no reliable data are available for global volume and flow of medical tourism (Lunt et al., 2015). This is particularly the case because medical treatment of travelers often takes place in the private sector, where companies may be reluctant to share commercial information.

Trade in mode 2 in health services is driven by differences in cost, quality, and availability of treatment across countries. Other factors include natural endowments; existence of alternative medicines and treatment procedures; long waiting lists for treatment in the source country; and cultural, linguistic, and geographic proximity between the sending and receiving countries. An in-depth study of outbound U.K. patients revealed that while factors such as cost, perceived quality and availability (including regulation and laws around treatment), and cultural affinity are important, so are interpersonal networks in determining where patients travel for treatment (Hanefeld, Lunt, Smith, & Horsfall, 2015).

In principle, medical travel occurs in all directions among high-, middle-, and low-income countries. In the absence of "hard" data, an initial common assumption has been that patients from HICs travel to LMICs to access cheaper health services there (Lunt, Horsfall, Exworthy, Smith, & Hanefield, 2013). Nevertheless, a small but increasing number of regional and national studies have revealed a much more diverse pattern (Bustamante, 2014; Crush & Chikanda, 2015; Hanefeld, Horsfall, Lunt, & Smith, 2013; Lautier, 2008; Noree, Hanefeld, & Smith, 2016). It is common for affluent patients in LMICs to seek specialized high-quality treatment overseas in HIC hospitals or in neighboring LMICs with superior healthcare standards (Hanefeld et al., 2013). For example, over the past decade there has been an increase in Nigerian patients seeking treatment in the United Kingdom, and in patients from the Middle East seeking treatment in Thailand (Noree et al., 2016). It is also common for persons in HICs to seek quality treatment at a fraction of the cost in LMICs, or to seek alternative medicines and treatments and take advantage of natural endowments in LMICs. For instance, patients from developed countries such as the United States and the United Kingdom can get bypass surgeries or transplants done at one-fourth or one-fifth of the cost in high-quality corporate and super-specialty hospitals in middle-income countries such as India, indicating the tremendous scope for gains from trade due to cost differences (**EXHIBIT 20-8** describes medical tourism in Thailand as an example). In addition, legislative differences and the availability of types of treatment have led to certain countries becoming known for areas of treatment—for example, fertility treatment and surrogacy in India (Whittaker, 2010).

Along with the travel of more affluent patients, increasing evidence suggests that a significant amount of cross-border trade in services involves the general population moving between LMICs, such that people cross land borders in search of treatment either at small-scale private providers or in the public sector (Crush & Chikanda, 2015). Research suggests that these patients are far from the empowered affluent consumers commonly associated with medical tourism, but rather are poorer members of the population seeking to access services and medicines unavailable in their countries of origin. Studies have, for example, focused on patients from Indonesia accessing services in Malaysia (Ormond, 2013), or patients from neighboring countries seeking treatment in South Africa (Vearey et al., 2016; Walls et al., 2015).

In addition to this trade in health services driven by individual motivation, governments have developed their own mode 2 schemes, whereby a country seeks to import health services for its population to address unmet needs. This has been the case in small island states such as the Maldives, for example, as they seek to achieve universal health coverage (Suzana & Chongsuvivatwong, 2015).

In sum, the different types of trade in health services under mode 2 and the pathways by which people travel or services are imported vary greatly, as do the health and health systems impacts associated with these flows. Common concerns have related to the equity impact on health systems of countries receiving medical

EXHIBIT 20-8 Medical Tourism in Thailand

Thailand has long been recognized as prime medical tourism destination. Since 2003, the Thai government has explicitly sought to make Thailand a destination for foreign patients, in an effort to increase government revenues.

An initial evaluation of the Thai policy reported that income from medical tourists contributed as much as 0.4% of Thai's GDP, with 1.2 million international patients visiting the country annually by 2006 (NaRanong & NaRanong, 2011). However, a large cross-sectional study of foreign patients in Thailand's five largest private hospitals published in 2016 provided greater detail and nuance on the shape and size of medical tourism in Thailand (Noree et al., 2016). Importantly, it suggested that the actual number of patients visiting Thailand was smaller than previously thought.

The 2016 data revealed that, on a regional basis, the largest number of medical tourists came from the Middle East, followed by Southeast Asia and Europe. The United States ranked third in terms of country of origin, however, with 7.5% of all medical tourists coming from that country. These findings highlighted the regional aspect of medical tourism.

Analysis of the conditions for which patients traveled also revealed a clear pattern. Middle-aged male patients from the Middle East predominantly traveled for heart procedures, while women from Southeast Asia traveled for cosmetic and fertility treatments, and Europeans tended to purchase digestive and orthopedic procedures. Other patterns included the finding that almost all medical tourists from Australia were female, visiting Thailand for cosmetic surgery only.

In terms of medical tourism's contribution to the Thai economy, the research found that many patients engaged in significant tourism activities, with short medical treatments as "add-ons." Indeed, a survey among medical tourists identified that their tourist expenditures (on accommodation, food, and activities) were higher than the tourism expenditures of nonmedical tourists, indicating the former are particularly lucrative. Using the estimated numbers and expenditures, Noree et al. (2016) concluded that the gross tourism revenues from medical tourists and their companions in 2012 was approximately $900 million.

Taken together, these study findings confirm that Thailand is a key destination for medical travel, albeit on a modest scale. They also suggest net benefits to the economy may be substantially smaller than previously thought, highlighting the need for good-quality data. As for health systems impact, there has been little evidence of a substantial internal brain drain from this practice: Doctors working within the private sector continue to also work in the public sector, and private clinics cater to both domestic and foreign patients. At the same time, private hospitals do draw on publicly trained human resources.

tourists (i.e., exporting health services). Other criticisms have focused on potential cost increases in the private sector for domestic patients (Noree, Smith, & Hanefeld, 2014), internal brain drain within countries from the public to the private sector owing to the focus on serving wealthier medical tourists (Lautier, 2008), and the ethical issues when gametes or organ donations are sought from poorer people in LMICs (Whittaker, 2011). A persistent challenge to addressing some of these issues has been the lack of an international governance structure tackling the issues arising in mode 2 (Hanefeld, Mandeville, & Smith, 2017).

Mode 3: Commercial Presence/FDI

Health services can be traded through commercial presence (mode 3), wherein hospitals, clinics, diagnostic and treatment centers, and nursing homes may be established across countries. In some cases, joint ventures, alliances, and management tie-ups may be forged between healthcare organizations across countries and regional networks of healthcare providers that are engaged in delivering health care through modes 1 and 2. Such arrangements may involve acquisition of facilities, management contracts, and licensing arrangements with some degree of local participation. Although conventional data from balance of payments statistics do not provide information on this mode of trade in health services, available information such the Foreign Affiliates Trade in Services Statistics (FATS), which cover a variety of indicators (exports, imports, sales, turnover, and employment) regarding the activities of foreign companies in overseas markets, indicate that health services FDI has been growing in significance over time.

Traditionally, HICs have been the leading sources and destinations for FDI in health service. However, over the past decade, a growing number of LMICs have also emerged as host nations. The value of mergers and acquisitions in health and related social services reached $14 billion in 2006 in terms of sales transactions, with diversification of source and recipient markets occurring over the years. Transnational hospitals and healthcare providers with both regional and global presence have emerged in recent years, with several middle-income country health services firms based in Asia and Africa entering foreign markets through investment, mergers, and acquisitions of service providers and hospitals. It is also interesting to note the emergence of South–North and South–South

TABLE 20-3 Recent Acquisitions of Healthcare Providers Involving Non-OECD Countries

Year	Investor	Subsidiary	Exporting Country	Importing Country	Value of Investment	Nature of Investment
2006	Netcare	General Healthcare	South Africa	United Kingdom	£2.2 billion (~ $2.5 billion)	52.6% stake
2007	Mediclinic	Emirate Healthcare Holdings	South Africa	United Arab Emirates	$46.4 million	49% stake
2007	Mediclinic	Hirslanden	South Africa	Switzerland	$2.4 billion	100% stake
2005	Bumrungrad International	Asian Hospitals	Thailand	Philippines		45.5% stake
2006	Bumrungrad International	Bumrungrad Hospital Dubai	Thailand	United Arab Emirates		49% stake (joint venture with Istithmar)
2007	Bumrungrad International	Asia Renal Care	Thailand	Singapore (operates clinics in 6 Asian countries)	$75 million	100% stake
2005	Apollo Hospitals	Apollo Hospitals Dhaka	India	Bangladesh	$35 million	100% stake
2005	Parkway Healthcare	Pantai Hospitals	Singapore	Malaysia	$139 million	31% stake

Reproduced from Mortensen, J. (2008). International trade in health services-assessing the trade and the trade-offs: DIIS Working Paper no 2008/11. https://www.diis.dk/node/1587

flows of capital in health services, as highlighted in **TABLE 20-3**. The bilateral pattern of investment indicates the significance of factors such as geographic and cultural proximity, regional markets, growth dynamics, and market size.

EXHIBIT 20-9 highlights the growing regional and global presence of healthcare providers from selected high-, low-, and middle-income countries, and provides more detail on some of the firms shown in Table 20-3. Entry into overseas markets has taken place through joint ventures, franchises, greenfield investments, acquisitions, tie-ups, contractual arrangements, and public–private partnerships. Linkages are also evident with other forms of health services trade.

The growth of the foreign commercial presence in health services has been mainly driven by the relatively recent opening of the health sector to participation by foreign hospitals, diagnostic centers, and clinics, as well as privatization and deregulation of the healthcare sector in many countries. For instance, Indonesia allows Singaporean, Australian, and Canadian firms to operate in its market. India has permitted automatic approval for 100% FDI in hospitals since 2000. Between 2000 and 2006, nearly 100 FDI projects in hospitals and diagnostic centers were approved in India, representing a total of $53 million in investment from high-, middle-, and low-income country sources. Thailand's open FDI regime for hospital services has resulted in several part-foreign-owned hospitals, mainly in the Bangkok area, with investments from Japan, Singapore, China, Europe, and the United States being funneled to the country's healthcare sector. Cambodia permits cross-border investment in hospital services and foreign ownership; it also permits management of private hospitals and clinics as long as at least one director is a national. Foreign firms are allowed to provide dental services through joint ventures with Cambodian legal entities.

EXHIBIT 20-9 International Health Services Provider Firms

Singapore

The Parkway Healthcare Group is the biggest investment group for health care in Singapore and one of the largest healthcare organizations in Asia. It created Gleneagles International as an international brand. The company has been interested in acquisition of hospitals in Singapore, building up a base there, and entering countries such as India, Indonesia, Malaysia, Sri Lanka, and the United Kingdom, mostly through joint ventures with local partners. It entered the Indian healthcare market in 2003 through a joint venture with the Apollo Group and built the Apollo Gleneagles Hospital, a multispecialty hospital at a cost of $29 million. It has formed a joint venture with the Mumbai-based Asian Heart Institute and established a research center to provide medical excellence. It is in the process of setting up a specialized heart hospital in London.

The Singapore-based Raffles Medical Group is building strategic alliances through triangular business associations with healthcare organizations from high- and middle-income countries. It is venturing into low-income countries in partnership with host country investors.

Thailand

Bumrungrad Hospital in Thailand has entered into management contracts with hospitals in Bangladesh and Myanmar. It has formed a joint venture with a hospital in the Philippines. Bangkok Hospital has 12 branches in Southeast and South Asia, located mostly in tourist towns.

India

The Apollo Group of Hospitals has centers of excellence in several countries, including Nepal, Sri Lanka, Ghana, and Bangladesh. It has also entered into contract-based management of hospitals or clinics in the United Arab Emirates, Oman, Kuwait, Mauritius, Malaysia, Sri Lanka, and Nigeria. It has established a telemedicine center in Kazakhstan. Apollo Hospitals has a joint venture with Amcare Labs, an affiliate of Johns Hopkins International, to set up a diagnostic laboratory in Hyderabad.

South Africa

South African health services firms are present in the United Kingdom, Switzerland, and the United Arab Emirates, and are also the main source of regional FDI in southern Africa. Some major firms include Netcare, MediClinic, Life Healthcare, and the Afrox Health Care Group. MediClinic owns private hospitals in Namibia; Life Healthcare operates private hospitals and clinics in Botswana; and the Afrox health care group has operations in Botswana, Namibia, Zambia, and Mozambique. Netcare has a public–private partnership with the Lesotho government to build a hospital, refurbish two feeder clinics, and run clinical services for the government.

China

The public and private sectors in China have jointly developed a strategy to attract foreign health providers to set up a commercial presence. Chinese institutions have entered into joint ventures with partners in the medical profession and with local authorities overseas. Traditional Chinese medicine (TCM) facilities have been established in more than 20 countries. Such joint ventures help spread TCM overseas, enable the deployment of Chinese health workers and their exposure to other systems under contractual arrangements, and help attract patients to China.

Other Countries

The large U.S. corporate healthcare sector, which owns for-profit hospitals, has entered foreign markets mainly through small specialized clinics, such as eye clinics, rehabilitation centers, and outpatient clinics. U.S. firms typically enter these markets through joint ventures with local specialist doctors or surgeons.

Columbia Asia Group, a Seattle-based hospital services company, is a worldwide developer and operator of community hospitals. It has started the first American-style medical center in Bangalore.

The Fresenius Medical Care group (FMS) is headquartered in Germany and is one of the leading foreign healthcare providers in the United States. FMS has operations in Belgium, France, Italy, the Netherlands, Portugal, Switzerland, and the United Kingdom. It has affiliates in Australia, Singapore, Malaysia, Thailand, Korea, Taiwan, Philippines, Hong Kong, and Japan, and representative or branch offices in New Zealand, India, Indonesia, and China.

Nevertheless, numerous regulatory barriers restrict mode 3 trade in health services. These constraints include limits on foreign equity participation; limits on type of foreign commercial presence; economic needs tests; authorization, certification, and licensing requirements; discriminatory taxes; and technology collaboration and transfer conditions.

The impact of foreign commercial presence in health services can be seen in its effects on capacity, quality, and equity. The literature indicates that these effects are shaped by the existing structure of the health system, its public–private mix, and the national regulatory environment. In terms of its implications for efficiency, mode 3 trade in health services can augment a country's health resources by bringing in additional financial resources, enabling capacity expansion, and alleviating the pressure on government budgets. On the downside, it could create inefficiencies by encouraging overinvestment of resources in high-end and highly capital-intensive and specialized treatments and procedures with lower cost-effectiveness, while diverting funding from basic healthcare services. Likewise, it could lead to long-term outflows of payments to foreign investors, along with direct and indirect subsidization costs for incentives given to foreign investors.

On the quality front, foreign commercial presence in hospitals and health management may improve the quality of national health systems through the introduction of better management techniques and information systems; better technology, equipment, and infrastructure; and improved standards and accreditation. There could also be positive spillover effects on the standards and practices of domestic establishments. Such improvements in the quality of the domestic healthcare system and presence of foreign healthcare providers of global standards could, in turn, benefit the country by reducing its residents' spending on expensive treatments overseas. These gains are contingent on the regulatory environment's ability to ensure quality and standards, the ease with which technology and equipment can be accessed, and the spillovers to the rest of the healthcare system.

Likewise, mode 3 trade in health services has mixed implications for equity. If such establishments cater to the urban and affluent segments of the population who can afford to pay, then they may aggravate existing inequities in access to health care. Such establishments are more likely to focus on tertiary care, specialized treatments, and curative and intervention-oriented procedures rather than primary and preventive healthcare needs. There may be cost implications as well, if foreign-owned and managed health providers charge higher fees. Foreign investment in health services, particularly in hospitals, could also distort the healthcare market by encouraging a brain drain—that is, the movement of the most qualified and specialized health personnel toward such establishments and away from domestic establishments owing to offers of better pay and facilities. This could adversely affect the quality of medical human resources in competing institutions, particularly public-sector hospitals.

On the bright side, there could be positive effects on equity through the creation of employment opportunities in the healthcare sector at all levels, with better remuneration, especially for specialized and senior medical professionals. Such establishments may attract overseas medical professionals and returnees who are internationally accredited, thereby augmenting the human resources capacity and quality in the host country. Once again, factors such as the extent of health insurance penetration, the public–private mix in the healthcare system, and regulatory requirements on pricing and access for the poor will shape the equity consequences of mode 3 trade in health services.

Mode 4: Migration of Healthcare Workers

Health services can also be traded through the temporary movement of health personnel (mode 4), including doctors, specialists, nurses, paramedics, midwives, technicians, consultants, trainers, health management personnel, and other skilled and trained professionals. Today, much of cross-border mobility of health providers does not constitute mode 4, but rather involves permanent migration. Mode 4 trade in health services is a subset of such movement, which is temporary in nature, usually occurring under bilateral contracts between institutions and/or governments and aimed at addressing shortages such as of nurses or specialists in the receiving market (Kingma, 2007). As with other modes of health services trade, it is difficult to estimate the value of mode 4 trade in health services, as statistics on these flows are rare. This is especially the case in terms of delineating temporary from permanent cross-border movement in the health sector aligned with the guidelines laid down in the Manual on Services of International Trade in Services (MSITS).

Notwithstanding the limited data, existing mobility patterns clearly indicate that both HICs and LMICs are engaged in health services trade via mode 4. There are mode 4 exports on short-term contracts from LMICs to HICs, such as from India and the Philippines to countries in the Persian Gulf region, or from Cuba to countries in Africa and the Caribbean (Eastwood et al., 2005). The Middle East is an important host market for a wide range of health professionals from high-, middle-,

and low-income countries, including doctors, nurses, x-ray technicians, lab technicians, dental hygienists, physiotherapists, and medical rehabilitation workers. **TABLE 20-4** highlights some of the individual "push" and "pull" factors that help explain the pattern of movement of health workers under mode 4 (Eastwood et al., 2005).

An important aspect of mode 4 trade in health services is managed mobility through bilateral and regional trade and economic cooperation arrangements (Buchan, 2006; Plotnikova, 2014). Some of these arrangements are narrow in their focus, with their objective being to facilitate movement of health providers. Others go beyond the issue of mobility to address a wide range of associated issues including recruitment, return and reintegration, recognition of qualifications, harmonization of standards and training, and capacity building. Some arrangements also address aspects such as cooperation in health systems development and best practices for induction, training, and treatment of foreign health professionals. These types of agreements reduce the need to use commercial recruitment agencies by relying on cooperation between recognized agencies/institutions in the sending and receiving countries, thereby narrowing the risk of exploitation of migrating professionals, enabling greater transparency in the mobility process, and shifting much of the mobility costs from the migrating individual to the client. A broader objective of some of these arrangements is to create win–win possibilities for both the receiving and sending countries through health worker mobility and to avoid the negative consequences that arise from long-term migration of health services providers.

Examples of arrangements that address health worker mobility in a broad-ranging manner are CARICOM and the Caribbean Free Trade Agreement (CARIFTA) (Stilwell et al., 2004). The focus of these agreements in the context of mode 4 trade in health services is regional collaboration and regionally managed migration. This includes a nursing campaign within the Caribbean to increase the supply of nurses within the region and measures to improve human resources management so as to retain and attract back nurses (Salmon, Yan, Hewitt, & Guisinger, 2007). To augment the regional supply of nurses, the member countries are collaborating on training capacity, including establishing distance education programs at the BSc and MS levels in nursing, a mentorship program directed at recruitment and retention of nurses, and a regional training program for nurses. To improve human resources management of nurses, a regional convention on nursing has sought to address issues related to the work environment. In addition, regionally coordinated incentives have been created to value nursing and to improve the utilization and deployment of nurses through a workload measurement system.

There is a regionally managed migration program between countries such as St. Vincent, which trains healthcare providers for export, and countries such as Jamaica and Trinidad and Tobago, which have shortages of such workers (Salmon et al., 2007). Skilled professionals across many sectors, including health care, are encouraged to work in other countries of the region on a rotational basis for three years, and then return to the home country. To facilitate the movement of health professionals within the region without

TABLE 20-4 Push and Pull Factors in International Markets for Skilled Health Workers

Push Factors	Pull Factors
Low pay; late payment and non-payment	Higher pay
	Opportunities for remittances
Low job availability	Vacancies
Poor working conditions (inadequate resources; high workload; poor human resources planning)	Better working conditions
Lack of resources to work effectively	Better resourced health systems
Limited career opportunities	Career opportunities
Limited educational opportunities for workers and children	Provision of post-basic education; good general education system
High prevalence of HIV/AIDS	Low prevalence of HIV/AIDS
Unstable/dangerous work environment	
Unstable general political environment: risks of political and criminal violence	Political stability
	Low crime rates
Economic instability	Economic stability

compromising the quality of health services, initiatives have been launched, with the involvement of nursing associations and regulatory bodies in member countries, to harmonize educational standards and entry requirements in the profession. For instance, nurses in all of the English-speaking Caribbean countries sit for the same registration examination.

Overall, the Caribbean strategy is multifaceted. It covers aspects such as recruitment, retention, training, utilization, deployment, work terms and conditions, management practices, and long-term human resources development in the health sector. It also attempts to pool regional resources in the health sector and to address human resources imbalances within the region through managed migration policies, supplemented by efforts to develop regional capacity through training programs (with the aid of technology) and improved human resources management.

Other preferential agreements that address the issue of temporary mobility of healthcare providers, but are not as broad ranging as the aforementioned Caribbean arrangements (Kanchanachitra et al., 2011), include the Japan–Philippines Economic Partnership Agreement (JPEPA) and the India–Singapore Comprehensive Economic Cooperation Agreement (CECA). Under the JPEPA, one of the major issues negotiated was the easing of restrictions in Japan's labor market to accommodate more Filipino healthcare professionals. Following difficult negotiations on this issue, Japan agreed to allow a limited number of nurses—100 in the first year—to stay beyond the current four-year time limit if they acquired a Japanese license and underwent vocational training. Japan also insisted on Japanese language proficiency requirements as an eligibility condition for entry. However, the program was not deemed a success, in part due to low uptake (Yagi, Mackey, Liang, & Gerlt, 2014).

An important regulatory issue that has been addressed in some economic integration arrangements is mutual recognition and harmonization of qualifications. In the European Union, several directives relate to the facilitation of free movement of doctors, nurses, pharmacists, and other health professionals and mutual recognition of their diplomas, certificates, and evidence of other formal qualifications, among the member countries. These directives provide mechanisms for convergence and coordination. They entitle any EU physician who has completed basic training in a member state and who holds a recognized qualification to be automatically registered in any other member state. The sectoral directives are based on the principle of mutual confidence and comparability of training levels. This mindset is reflected in the "Recognition of Foreign Professional Qualifications Act," which requires EU member states to consider the practical experience of an individual in the process of recognition of qualifications. Where there are major structural differences in training requirements, the host country is entitled to require compensation through an adaptation period or an aptitude test.

In other regions, mutual recognition of qualifications has also been an important issue in the context of mode 4 trade in health services. Under the ASEAN Framework Agreement on Services, which aims at achieving an FTA in services by 2020, one of the seven priority sectors is health services (Kanchanachitra et al., 2011). Nevertheless, challenges have emerged in operationalizing this mutual recognition among the member countries due to differences in educational standards and programs, regulatory systems and licensing practices, and language and culture.

Likewise, under the India–Singapore CECA (Chandra, 2010), visa restrictions have been eased for Indian professionals in 127 categories, including for medicine and nursing. The two governments have decided to mutually recognize degrees for the purposes of issuing multiple entry visas. This decision reflects a synergy of interests regarding the mobility of health workers: India is interested in overseas deployment of its healthcare professionals, while Singapore needs foreign health personnel to meet its local requirements for care (Chandra, 2010).

In addition to trade and cooperation agreements, sector-specific bilateral labor agreements may be created to address health worker mobility. For instance, Cuba has signed bilateral agreements with various countries in the Caribbean and in Africa. It provides doctors to these countries to address domestic shortages in underserved areas (Feinsilver, 2009). It also sends health personnel to these countries to help enhance host country capacity through the provision of training to local personnel. Cuba has such agreements with Botswana, South Africa, Namibia, and Zimbabwe. The agreement between Cuba and Guyana involves broad cooperation in terms of human resources deployment and educational exchange in the health sector. For example, for more than 20 years, a Cuban medical brigade has provided its services in Georgetown, Guyana, and other locations of that country. Cuban specialists founded the medical school in Georgetown, Guyana (Blouin et al., 2006).

Interlinkages Between Modes

Although each delivery mode for health services trade has been discussed separately in the preceding

subsections, the considerable links between these modes should be recognized. For example, Cuba has used joint ventures with Canadian, German, and Spanish companies (mode 3) to attract patients from these countries for specialized treatments (mode 2). This trade has helped establish Cuba as a hub for teleconsultation and telediagnostic services (mode 1) to the Central American and Caribbean market and has led to the establishment of specialized Cuban clinics in Central and Latin America (mode 3), where Cuban physicians and nurses are employed (mode 4). Thus, health services trade should be considered as an integrated package to appreciate fully the potential risks and opportunities presented (Chanda, 2006).

Other examples highlight the scope for such linkages. A mix of modes is evident where South African hospital companies have succeeded in winning healthcare contracts abroad, including with the United Kingdom's National Health Service. Netcare established its presence in the United Kingdom in 2001. The company has sent teams of medical personnel from South Africa to its U.K.-based establishments for fixed periods, thereby enabling its employees to work 4 to 6 weeks at a time abroad, get exposure to opportunities overseas, and supplement their income with fixed-term contracts abroad.

India's Apollo Group of Hospitals engages in mode 2–based health services exports, which have been facilitated by its overseas marketing offices and management contracts with hospitals in the United Arab Emirates, Saudi Arabia, Oman, Kuwait, Mauritius, Tanzania, United Kingdom, Sri Lanka, Bhutan, Nigeria, Pakistan, and Bangladesh. Apollo Gleneagles, which is a joint venture with the Singapore-based Parkway Group, exports health services to patients from neighboring countries such as Bangladesh, Nepal, Bhutan, and Myanmar. It also provides telemedicine services such as medical consultation, diagnostic, telepathology, teleradiology, and scanning services. In addition, Apollo provides contract research and medical education and training services through its overseas subsidiaries, using a combination of cross-border supply (online training and research services) and temporary on-site deployment of professionals at its subsidiaries, thereby benefiting its own professionals as well as host country professionals.

Overall, this overview of trade in health services and the different modes highlights the message that such trade is an area of significant growth. At the same time, it is one where data are limited, and our understanding of how these practices will affect health and health systems is still underdeveloped and in much need of further research.

Conclusion: From Conflict Between Trade and Health to Coherence

In the final paper in the 2009 *The Lancet* series on trade and health, three cross-cutting priority areas were outlined to cut across the many issues related to health and trade: "(i) highlighting the need for stronger evidence concerning trade and health links; providing (ii) the foundation for building trade and health engagement and capacity; in order to (iii) facilitate the assertion of health goals in trade policy" (Smith, Lee, & Drager, 2009). These priority areas still stand.

There remains a lack of sound empirical evidence demonstrating how trade and growth in trade are linked directly and indirectly to health. Even though the positive links among increased trade, poverty reduction, and economic growth are widely accepted, evidence regarding the impact of increases in trade on the determinants of health varies from one national context to another. Hence, adapting trade to national conditions is important in ensuring desired outcomes. This requires consideration of "flanking" policies that may be undertaken to mitigate adverse consequences, and the design of trade policies that reduce the potential health risks associated with freer trade while maximizing the positive impact of more trade on the social determinants of health.

Trade policies adopted by national governments affect health and health systems through a diverse set of channels and intermediate variables. Unfortunately, these causal linkages can be difficult to track and monitor. Moreover, in many political systems, health authorities are not in a position to directly affect trade policy decisions at the national level. Even so, their existing knowledge of the determinants of population health and their jurisdiction over social and health policies place health policy makers in a privileged position to ensure that, in an increasingly global economic environment, domestic policies and regulations are designed to maximize the potential of, and to minimize the risks presented by, increasing levels of trade.

Although more evidence on this topic is necessary, it is not sufficient to ensure that health is more integrated in trade negotiations and decision making. A common theme in this chapter is the dynamics of the *linkages* between the various constituent elements. For example, the delivery of health care is subject to pharmaceutical availability, which depends

on local price negotiations, international legislation, and domestic exchange rates. At the regional and global levels, changes in food production processes through trade liberalization will affect health and consequently demands for health care. Thus, those with a health focus will need to engage with agricultural reforms and policies to target agricultural commodity and food retail prices and other influences over food security, such as food safety, security within the food supply chain, and the balance in the use of agricultural land for biofuels and other "cash crops" versus nutritional foodstuffs. Another example is the enormous potential for increases in zoonotic outbreaks: It will require health-sector involvement in the development of international rules and legislation concerning movement of people, animals, and food products. Linkages such as these imply a substantive requirement for those with a health remit to engage in negotiation with those from other sectors and from other geographic locations.

Ultimately, perhaps the biggest challenge is breaking the "silo mentality" that suggests trade and health operate as separate policy spheres. Developments such as those mentioned in this chapter mean that these areas will face an ever more expanded agenda of issues. Although some issues have produced closer cooperation between the two sectors, others have exposed tensions between the goals of protecting health and promoting trade. Indeed, a former Health Minister of Thailand has said that "The lessons from compulsory licensing in Thailand reflect poor governance and double standards in global trade and health" and that "inadequate support was provided by WHO and the World Trade Organization" in the country's dispute over TRIPS (Songkhla, 2009). In this respect, the potential risks associated with trade and health are further increased by the added complication of conflicts, or misunderstandings, between the trade and health sectors, and therefore by further confusion in estimating the potential benefits and risks of trade liberalization for health. When making trade commitments, national ministries of trade (and perhaps finance and foreign affairs) often do so in isolation from health ministries—yet those decisions have an impact on health, of which the trade officials have limited knowledge. Conversely, ministries of health typically have limited knowledge in trade issues. A critical issue in trade and health is the need to address this asymmetry of information, by enabling ministries of health to make informed and comprehensive presentations to ministries of trade concerning decisions to be taken with respect to trade and trade agreements.

The pace of change, especially at the global level, has affected the ability of national domestic health sectors to set policy and to engage fully in such activities without wider understanding and capacity in negotiations at the international level. Indeed, it has been suggested that WHO should develop a "Committee C"[2] to provide a forum for debate about major health initiatives by WHO member states and non-WHO organizations, including international agencies, philanthropic organizations, multinational health initiatives, and representatives from major civil-society groups (Kickbusch, Hein, & Silberschmidt, 2010). This idea, colloquially termed "global health diplomacy," is covered in more detail in the *Global Health Governance and Diplomacy* chapter.

Of course, the question is where to begin. Many national and international information sources discuss trade and the general macroeconomy, such as public expenditure reviews and trade policy reviews. The key challenge facing health policy makers is how to interpret this information with respect to the health sector. Which information needs to be extracted? How might this information be interpreted? Which health and trade policies should be adopted in light of the information? To help guide policy makers through this quagmire, Smith and Chanda (2005) developed a framework to investigate these issues, which is provided in **EXHIBIT 20-10**, and which could offer a first step in the desired direction.

In sum, health and health care are affected by trade and trade liberalization in a number of direct and indirect ways: Healthcare activities, products, and services can themselves be traded; health systems are impacted by changes in exchange rates; the health profile of a country is affected by global impacts on communicable and noncommunicable diseases; and numerous aspects of trade policy influence health system flexibility. Trade liberalization has both beneficial and detrimental effects for the health systems of the countries engaging in it. The challenge facing national governments is to capitalize on the positive effects and regulate their healthcare markets appropriately to avoid the negative ones. To achieve this goal requires that all those engaged in health understand the importance of trade and engage with their counterparts involved in trade and trade policy.

[2] Currently the World Health Assembly prepares resolutions and decisions to be taken in two main committees: Committee A deals with program matters, and Committee B focuses on budget and managerial concerns.

EXHIBIT 20-10 Framework for Collecting Data on the Impact of Trade in Health Services on Health Systems

The following steps represent a framework that national governments may adopt to evaluate the impact of trade on their health system.

1. Establish the country's general background on macroeconomic and trade environment. This requires determining the following:
   a. Country's macroeconomic status and stability
   b. Trade and balance of payments
   c. Degree of openness to trade and investment regime
   d. Overall policy objectives
2. State of domestic health system. This is done by collecting data on:
   a. Amount of investment in the healthcare sector
   b. Demand and supply conditions
   c. Balance between public and private provision of care
   d. Policy environment
   e. Infrastructure conditions
   f. Regulatory framework
   g. Human resources capabilities
   h. Labor market conditions in the health sector
3. Agreement (or particular mode within agreement) specific elements. This requires determining the following:
   a. Current state of trade and investment in the health sector
   b. Direction of policy
   c. Current status of international commitments and proposed liberalization by the agreement or mode in question
   d. Institutional capacity with regard to trade in health services
   e. Data sources and availability of information on the health sector

Discussion Questions

1. Identify at least two positive examples and two negative examples of traded goods or services that affect health.
2. How do you think your own field of work or interest within public health is being affected by trade? Which regulatory mechanisms or incentive systems do you think may be needed to tackle the issues this trade raises?
3. Looking across the different modes of trade in services, which ones do you think will be key for achieving universal health coverage, and why?

CHAPTER 21

Global Health Governance and Diplomacy

Kelley Lee

Introduction

There is wide-ranging evidence that human societies worldwide, along with the natural environment, are being fundamentally altered by processes collectively referred to as globalization. Although globalization has been unfolding for many centuries, if not longer, it is broadly recognized that the changes occurring since the late 20th century have been faster paced, farther reaching, and more profound in their impacts (Beck, 2015; Scholte, 2005; Stiglitz, 2007).

Within the public health community, understanding of globalization and its population health consequences has led to a shift in attention from *international* health to *global* health. Many of the chapters in this text concern the direct impacts of globalization on public health. For example, there is clear evidence of new patterns of communicable disease outbreaks since 1980, including a four-fold increase in their number and a 20% rise in the specific types of diseases causing them (Smith et al., 2014). Similarly, a shifting and growing burden from noncommunicable diseases (NCDs) is rapidly emerging in populations across the world (see the *Chronic Diseases and Risks* chapter). These new epidemiologic patterns have created a "double burden" in many countries, as they struggle to cope with both communicable and noncommunicable diseases, as well as new distributions of health and disease for populations that cut across national borders (Lewis & MacPherson, 2013; World Health Organization [WHO], 2009).

The need to better understand how globalization is affecting population health has, in turn, opened up new avenues of inquiry and action. Foremost are renewed efforts to identify and explain the social determinants of health related to globalization, such as changes in the world economy, patterns of migration, changes to natural and human-built environments, and trends in human conflict. There is now a thriving body of scholarship conceptualizing and empirically demonstrating these complex linkages between globalization and population health as a precursor to strengthening public health policies (Huynen, Martens, & Hilderink, 2005; Labonte & Schrecker, 2007; Martens, Akin, Maud, & Mohsin, 2010). Overall, global health research, policy, and practice have made significant advances since the late 1990s, with key areas of focus being diagnoses of the changing public health problems faced and the likely causes posed by globalization (Birn, Pillay, & Holtz, 2017).

Alongside this growing evidence of the direct impacts of globalization, and awareness of the linkages between the social determinants of health and

globalization, there have been efforts to understand the collective actions needed to better protect and promote population health in a globalizing world. What should be the agreed and shared responses by societies to the health impacts of globalization? How can these responses be best achieved within and across societies?

This chapter is about the forms of collective action needed to address public health issues arising from globalization, broadly known as global health governance (GHG), and the best ways to achieve them. GHG concerns the institutional arrangements—in the form of rules, responsibilities, and processes—for achieving agreed goals related to global health needs. This chapter begins by briefly setting out clear definitions for two concepts underlying GHG: globalization and global health. While widely used, these terms are often poorly defined, which in turn contributes to confusion regarding the needed scope and nature of collective action. Not all changes taking place since the late 20th century have been due to globalization. Not all public health issues are global in nature. Moreover, while globalization is having profound impacts on a vast array of health determinants and outcomes, not all public health issues require GHG. A clear understanding of these concepts, therefore, helps to define the parameters of this chapter.

Focusing on GHG, this chapter then describes the existing institutional arrangements that structure collective responses to global health needs. These arrangements are located within a historical background of international health cooperation, established after World War II, as well as contemporary efforts to transition to new arrangements that enable new forms of collective action. This discussion includes the limitations of existing institutions, in terms of governance gaps. In this context, global health diplomacy (GHD) is understood as a key feature of GHG. GHD concerns emerging processes of political negotiation and consensus building that enable the creation of the institutional arrangements needed for GHG.

Finally, this chapter reviews the enduring challenges faced by the global health community in strengthening GHG. These challenges stem from the diverse interests, ideas, and institutions shaping global health and the invariably political nature of governance. Importantly, these challenges are not intractable. The changing context within which GHD takes place, including the changing roles of particular state and non-state actors, brings new opportunities. The chapter concludes by discussing ways that institutional innovation is beginning to facilitate the transition from international to global health governance. This paradigm change requires the global health community to navigate between longstanding efforts to reform the World Health Organization, which have yielded limited success, and the creation of an entirely new institutional architecture, which has been hindered by a lack of political consensus on what this structure should look like.

Globalization and Global Health Needs

The widely used term "globalization" articulates a shared sense that the contemporary world, beginning in the last decades of the 20th century, has become more interconnected, with events in one part of the world having potentially far-reaching consequences elsewhere. This phenomenon has spawned a vast and multidisciplinary scholarly literature, spanning the natural and applied sciences, social sciences, arts, and humanities, characterized by diverse theoretical perspectives, normative frameworks, and empirical debates about whether globalization is really happening, what the key drivers are, and, perhaps most controversially, whether it is having positive or negative impacts on human societies and the natural world.

It is beyond the scope of this chapter to review this substantial and diverse literature with its many points of contestation. At the same time, if we are to understand the collective action needed to manage the health impacts of globalization, a clear and shared understanding of the nature of the changes occurring, as a distinct phenomenon, is an essential starting point. To achieve this goal, we can begin by locating globalization within a historical context.

Although the "globalization" term has been coined relatively recently, contemporary shifts can be linked to social changes over the course of centuries, if not millennia. The earliest beginnings of globalization can be traced to the migration of *Homo erectus* out of the African continent 1 million years ago, or perhaps more specific to modern humans, the migration of *Homo sapiens* around 80,000 years ago. The latter hominids eventually colonized much of the planet, forming societies that interacted with other societies across ever-increasing distances and with greater frequency. Globalization, in this historical sense, can be understood as a continuum from lesser to greater social formation and integration across societies over time. Earliest human societies were circumscribed in membership and territory, infrequently interacting with each other, and often competing for available resources. Over time, the invention and use of new modes of transportation (from horse-drawn carts to ships and railroads and then cars and airplanes) and

communication (from papyrus scrolls to telegraphy to the Internet) enabled people to connect across greater distances in ever-larger numbers. Social, political, and economic history is correspondingly marked by events denoting this gradual interconnectedness of human societies—the opening of the Silk Road between Asia and Europe, the arrival of Christopher Columbus in the Americas, the formation of the modern state system, the colonial empires of European powers, the establishment of the slave trade, and the Industrial Revolution. Characterizing all of these developments was the increased mobility of people (voluntary or otherwise) and other life forms (plants and animals); flows of capital, goods, and services; and dissemination and exchange of knowledge and ideas. Thus, what many refer to as contemporary globalization can be understood as the acceleration and intensification of a historical process resulting in even more frequent and deeper interactions across human societies.

Yet, while globalization can be understood as a historical process, it is also necessary to identify what is distinct about the term. The work of Jan Aarte Scholte (2008) is helpful in this respect. Scholte begins by arguing that the term "globalization" is often used when people really mean something else. He identifies this "something else" to be several existing terms—internationalization, liberalization, universalization, and Westernization—that are not synonymous with globalization, but rather "redundant concepts of globalization." Each of these terms already has an existing and particular meaning:

- *Internationalization.* This is the most commonly used meaning attached to the term "globalization," referring to the process of closer interaction and exchange between people located in different countries. Various cross-border measures, such as trade and investment, communications, and migration, are cited as evidence of the increase in exchanges across national borders. Because the focus of these interactions and exchanges is how they occur across countries (or nations), the term "internationalization" is the appropriate term. Historically, since the establishment of the international system of sovereign states some 500 years ago, there have been a growing scope and frequency of economic, political, and social connections across groups of two or more countries.
- *Liberalization.* This is another commonly used meaning attached to "globalization." Liberalization concerns the process, in a world composed of sovereign states, of lessening government "regulatory barriers to transfers of resources between countries." Historically, the various rounds of negotiations under the General Agreement on Tariffs and Trade (GATT), spanning from the end of World War II to 1995 and including the creation of the World Trade Organization (WTO), led to successive reductions in trade tariffs. The continuation of this process since the mid-1990s, under multilateral, regional, and bilateral trade and investment agreements, has frequently been referred to as globalization. However, Scholte argues that the term "liberalization" is more accurate, with "little need now to invent a new vocabulary for this old phenomenon."
- *Universalization.* This term, which refers to the process of a social phenomenon spreading to all parts of the world, is often the intended meaning of "globalization" for some users of this term. When defined in this way, however, it might be argued that many examples of universalization predate globalization. Several world religions, for example, have won followers worldwide over the centuries. In this sense, Scholte argues that the term "universalization" is deemed adequate.
- *Westernization.* This term describes the process by which culture, values, ideas, and behaviors characteristic of Western societies, and particularly American society, are increasingly adopted in other countries worldwide. In this sense, globalization refers to a largely negative process of cultural colonization, and even homogenization, through a steady diet of American media, fashion, language, and consumer products. Although it is undoubtedly the case that Westernization is taking place, Scholte (2008) argues that "intercontinental westernization . . . has unfolded since long before the recent emergence of globe-talk." He suggests that the concepts of modernization and imperialism readily capture the ideas of Westernization and "[w]e do not need a new vocabulary of globalization to remake an old analysis."

Scholte (2008) casts aside these "redundant" terms and reserves the term "globalization" to describe social phenomena that do not simply cross national borders, but rather transcend them. Only when territorial boundaries, based on physical geography, are circumvented or become irrelevant can we speak of globalization. Satellite communications, climate change, social media, illicit drug trafficking, and undocumented migration are examples of globalization in this strict sense. It is this strict definition of globalization, as the accelerated transcendence of territorial boundaries, that distinguishes the changes being experienced across human societies since the late 20th century.

Thus, globalization is a historical process characterized by changes in the nature of human interaction across a range of social spheres, including the economic, political, technological, cultural, and environmental arenas. These changes are globalizing in the sense that boundaries hitherto separating us from each other are being transformed. These boundaries—spatial, temporal, and cognitive—can be described as the dimensions of globalization. Briefly, the spatial dimension concerns changes in how we perceive and experience physical space or geographical territory, the temporal dimension concerns changes in how we perceive and experience time, and the cognitive dimension concerns changes in how we think about ourselves and the world around us (Lee, 2003).

The loose and varied uses of the term "globalization" in public health have led to similar imprecision in the application of the term "global health." The diverse definitions of global health, in tandem with its prevalent use, risk rendering this term meaningless. Although such definitions abound, many lack conceptual rigor. As a result, the term "global health" is also now associated with a broad range of other meanings. Some are redundant, given preexisting terms with the same meaning, such as health cooperation between governments (international health) or health in low- and middle-income countries (LMICs) (health development). Others are based on seeing the world from a self-centric (largely Western) viewpoint, such that domestic health issues in one's home country are considered separate from those of all other countries. The problem with adopting this perspective, in which "global" is viewed as everywhere but home, is that global health becomes completely relative. Moreover, this view supports the "othering" of nondomestic populations, and overlooks the key defining feature of globalization—namely, the closer linkages and interconnections among populations across territorial space. Other definitions focus on normative goals such as reducing differences in health status or distribution of health determinants caused by an increasingly globalized world (health inequalities) or the systematic, socially produced and unfair causes of health inequalities (health inequities). Thus, the understanding of the term "global health" can depend as much on normative frameworks and aspirations as it does material reality.

In sum, "global health" has become an umbrella term, subsuming previously used terms describing existing health needs, as well as embracing emerging kinds of health issues arising from contemporary globalization. It is important to recognize and interrogate these varying definitions as a key part of the task of strengthening global health governance and diplomacy.

An alternative approach is to focus on the nature or characteristics of a health issue, and then to categorize it as a certain type of "global health" problem requiring collective action. Building on the previously described distinction between globalization, as strictly defined, and other common uses of the term, we can arrive at a clearer understanding of the health needs arising within an increasingly globalized world that require collective action. Within the public health community, there has been a broad shift in nomenclature between the terms "international health" and "global health." The reasons for this shift, and the conceptual difference between the two terms, have elicited much discussion. Brown et al. (2006) locate the historical roots of international health in 19th century European imperialism, when the priority for collective health action was controlling epidemic diseases spreading from colonized territories. In contrast, global health encompasses a shift to putting "the health needs of the people of the whole planet above the concerns of particular nations." Koplan et al. (2009) distinguish among public (or population), international (interstate) health, and global health, with the last variably "thought of as a notion (the current state of global health), an objective (a world of health people, a condition of global health), or a mix of scholarship, research, and practice (with many questions, issues, skills, and competencies)."

Following Scholte's work, a strict definition of global health would limit the term to issues characterized by the transcendence of territorial boundaries. The issue must be caused by factors that transcend territorial geography, or possess the capability to occur or spread in ways that do so—that is, it must be "transboundary"—to be classified as a global health problem. Needless to say, not every health problem qualifies. Guinea worm infection, for example, remains a residual health threat in many parts of Africa. By comparison, significant political and financial capital has been expended on human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS). The distinction drawn might be explained, at least in part, by the fact that the former is transmitted via an animal vector that is prevalent only in certain parts of the world. The other is a disease spread by close contact with infected bodily fluids, an event that can occur in any part of the world.

Another good example is communicable diseases having the potential to become pandemic. The migration of wild birds across territorial boundaries on a regional and even planetary scale, for instance, makes avian influenza a global health issue. The increased distribution of the *Aedes aegypti* mosquito over the past 25 years, due to global climate change, local environmental

conditions, and increased transport links (e.g., ship, airplanes) worldwide (European Centre for Disease Prevention and Control, n.d.), means that associated diseases such as yellow fever, dengue, and chikungunya should be considered global health issues.

The large-scale trade in illicit goods such as counterfeit medicines, tobacco products, and narcotics, enabled by a worldwide network of criminal organizations, represents another example of a global health issue. Likewise, the use of social media—whose content is accessible worldwide and pose challenges for national authorities to regulate—to promote unhealthy lifestyles and health-harming products can be considered a global health issue.

Focusing on health determinants, lung cancer and liver cirrhosis could be described as global health issues because their causal factors are transboundary (i.e., transnational tobacco and alcohol companies). In contrast, the nutritional taboos practiced in some cultures, which may lead to nutritional deficiencies in pregnant women and children, pose a serious problem but are not a global health issue by virtue of their localized practice.

Collectively, these examples, when a stricter definition of globalization is applied, suggest that there are relatively few truly global health issues. In this chapter, by balancing the stricter and looser definitions of globalization and global health, we can describe health issues requiring collective action in a globalizing world as falling into four main categories (Lee, Hawkins, & Wiist, 2016):

- *Cross-border or transborder problems* originate in one locale but have wider ramifications for other locales (e.g., large-scale communicable disease outbreaks; advertising, marketing, and promotion of health-harming products via social media).
- *Commons problems* concern disputed access to or use of shared resources across societies (e.g., intellectual property rights over genetic sequencing, access to vaccines and other essential medicines).
- *Shared problems* are widely experienced across geographies due to changes to social and natural environments from intensifying globalization (e.g., increased popularity of computer gaming and childhood obesity, lack of safe water and sanitation).
- *Planetary problems* arise from the cumulative actions of individuals and populations in many countries (e.g., spread of antibiotic resistance, impact of climate change on distribution of disease vectors).

The forms of collective action needed to address these categories of global health issues are discussed in the next section.

What Is Global Health Governance?

Governance concerns the agreed rules for interaction and procedures for decision making adopted by an organized society to address its collective needs and deliver shared solutions. The agreed rules and procedures relate to such considerations as membership in the society, obligations and responsibilities of members, forms of engagement and decision making, mobilization and distribution of resources, dispute settlement, and implementation and evaluation of actions taken. Defined in this way, governance should be recognized as occurring across many types, and at many different levels, of social organization (Dodgson, Lee, & Drager, 2002). In global health, governance is essential to groups ranging from local community groups (e.g., patient advocacy groups, community health centers) to globally operating organizations (e.g., global public–private partnerships, transnational corporations).

Importantly, as Rosenau (1995, p. 4) writes, governance is not the same as government:

> Both refer to purposive behavior, to goal oriented activities, to systems of rule; but government suggests activities that are backed by formal authority . . . whereas governance refers to activities backed by shared goals that may or may not derive from legal and formally prescribed responsibilities and that do not necessarily rely on police powers to overcome defiance and attain compliance.

Government, in other words, is a particular form of governance, where a recognized body applies agreed rules and procedures in ways that are binding on the society's members. The formation of the international states system during the mid-17th century, for example, is based on the principle that national governments are sovereign, having ultimate authority over their own territories and populations. Above the state, where formally binding authority exists to a more limited degree, collective action is heavily reliant on governance. International law exists but is circumscribed in scope and authority. Where formal authority to govern does not exist, compliance is based on custom, common law, cultural norms and values, and public opinion.

Health governance, in turn, can be defined as the agreed rules for interaction and procedures for decision making adopted by an organized society to address collective health needs and deliver shared health solutions. Such rules and procedures can be

binding, such as various types of health-related legislation adopted and enforced by governments, or they can be reliant on nonbinding mechanisms (e.g., Hippocratic Oath, resolutions, codes of practice). Historically, the locus of health governance has been at the national level (and delegated to the subnational level), as the governments of sovereign states have held primary responsibility for protecting and promoting the health and well-being of their own populations. Where health determinants and outcomes spill over national borders and create cross-border or transborder impacts, international (intergovernmental or interstate) governance mechanisms have facilitated cooperation between two or more governments.

Indeed, there is a long and established history of *international health governance*. For example, the recurrence of bubonic plague, which caused as many as 50 million deaths during the 6th to 8th centuries, resulted from burgeoning trade links between Asia and Europe. The disease was spread by rat-infested ships along the Mediterranean coast and then inland via transported goods. The disease returned during the 14th century, transported by trade from Asia; it reached first Italy and then the rest of Europe, eventually killing one-third of the continent's population. The outbreaks led to closer cooperation among ruling authorities, including the introduction of quarantines (Cohn, 2002; Watts, 2003).

Similarly, the transition of cholera from an endemic disease limited to South Asia, to a pandemic disease reaching Europe in the 1830s, and then recurring on various continents over the next two centuries, was initially caused by the social, political, and economic upheavals of European imperialism (Lee & Dodgson, 2000). The cholera epidemics of the 19th century prompted European countries and the United States to hold a series of International Sanitary Conferences and adopt the International Sanitary Conventions (forerunner of the International Health Regulations). The formation of the League of Nations Health Organization in 1919 after World War I, amid the devastating 1918–1920 influenza pandemic, and then the founding of WHO after World War II, are other key examples of institutional arrangements for international health governance led by sovereign states (for more on this history, see the Introduction to this text).

The term *global health governance* was coined in the late 1990s to describe the diversity of governance mechanisms that go beyond intergovernmental health cooperation (Dodgson et al., 2002). In large part, these new institutional arrangements have been prompted by the "real world" of accelerating and intensifying globalization. These impacts are challenging the capacity of states, acting alone or collectively, to protect and promote the health of their domestic populations. As Aginam (2005, p. 58) writes:

> Transboundary disease spread now constitutes a global crisis that requires the pooling of efforts and resources by nation states in a multilateral context. In no other sphere of global relations is the global village metaphor more practical . . . [in view of] the permeation of national boundaries by disease pathogens and the consequent vulnerability of populations within those boundaries to microbial threats.

The forms of health governance that have emerged in response to these challenges are distinct in several ways. First, given the scale and scope of cross-border and transborder health risks faced, GHG is characterized by *collective action less focused on national borders*. International health governance is built on practices such as screening at ports of entry, quarantine measures, and national disease surveillance and reporting. The global geographies of health and disease, which create new spatial distributions and dynamics of health determinants and outcomes, require different forms of governance. Disease surveillance, monitoring, and reporting systems, which do not rely wholly on data collected by and about states, now provide valuable supplements to the International Health Regulations (IHRs), which were revised in 2005 (see the *Public Health Infrastructure* chapter for more information on the IHR). The Global Public Health Intelligence Network (GPHIN), created in 1997 by Health Canada, analyzes 20,000 online news reports worldwide in 9 languages each day, to alert WHO of potential outbreak risks (Dion, AbdelMalik, & Mawudeku, 2015). The concept of *planetary health*, based on an understanding that human health depends on the wise stewardship of natural systems, raises concerns about "present systems of governance" as "inadequate to address the threats to planetary health" (Whitmee et al., 2015, p. 1974) (see the *Environmental and Occupational Health* chapter for more on planetary health).

Second, GHG is characterized by a *growth in the number, and degree of influence, of non-state actors*. Non-state actors are organizations operating outside of the state or governmental sphere. They can be either for-profit or not-for-profit entities, depending on how they earn and use their financial resources. In general, *for-profit organizations* (e.g., private businesses, industry associations, consultancy firms) seek to maximize their financial returns, and use the earned proceeds to benefit private owners and shareholders. In contrast, *not-for-profit organizations* (e.g., patient groups, charities, religious groups, healthcare cooperatives) seek

financial returns to serve shared or public interests. The boundaries dividing these two categories are not entirely clear cut, with ongoing debates concerning the vested interests served by some non-state actors such as trade unions, think tanks, and private foundations.

What is notable, in global health and other spheres of global governance, is that the number of non-state actors has grown more rapidly than the number of governmental actors. Using data from the *Yearbook of International Organizations*, Weiss et al. (2013) describes a dramatically changing landscape over the 20th and early 21st centuries (**FIGURE 21-1**). Since 1950, more than 33,000 international governmental organizations (IGOs) and international nongovernmental organizations (INGOs) have been founded—more than one per day. INGOs grew especially rapidly during the final decades of the 20th century, to the point that they outnumbered IGOs by 9.5 to 1 by 2000.

As well as becoming more numerous, some non-state actors now bring substantial resources to global health and, by extension, can command a louder voice in GHG. The most prominent example is the Bill & Melinda Gates Foundation (BMGF), which was launched in 2000. By 2016, private foundations tracked by the Institute for Health Metrics and Evaluation provided $2.3 billion to global health development, of which 78.5% as disbursed by the BMGF (Institute for Health Metrics and Evaluation, 2017). This undeniable generosity brings vital new funding for a variety of health needs, and has been especially welcomed amid flagging aid commitments by donor governments since the late 2000s. As the relative size of funding by private foundations has grown, however, important questions about their governance have been raised. Whereas international (governmental) organizations are accountable to member states, in principle, and in turn the citizens of those member states, concerns have arisen about the public accountability of private foundations. The BMGF, for example, is headed by an Executive Leadership Team that "oversees all of the foundation's efforts" (BMGF, n.d.). As Harman (2016, p. 350) points out, this arrangement has led to concerns about the "sources of its money, how and where it spends its money, its partnerships, and the 'Bill Chill' effect of the foundation on global health institutions." The last concern includes the tendency to support, and therefore skew global health initiatives toward, disease-focused and technology-based approaches. Birn (2014), for example, goes further by arguing that its "pervasive influence . . . [is of] grave concern both to democratic global health governance and to scientific independence." In response, efforts are being made to improve the transparency and accountability of all non-state actors, especially those as influential as the BMGF (Youde, 2013).

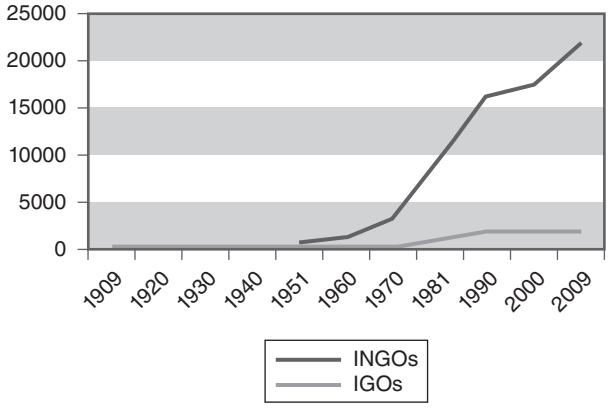

FIGURE 21-1 Number of intergovernmental and international nongovernmental organizations, 1909–2009.

Reproduced from Weiss, T., Seyle, D., & Coolidge, K. (2013). *The rise of non-state actors in global governance opportunities and limitations* [Discussion paper]. Broomfield, CO: One Earth Future Foundation. Retrieved from http://acuns.org/wp-content/uploads/2013/11/gg-weiss.pdf

The way that non-state actors are governed and their role in governing global health relate to the wider range of functions they now perform in GHG. As Haas (2004) describes, global governance comprises a range of functions, with state and non-state actors performing these functions either formally and directly, or informally and indirectly (**TABLE 21-1**). In GHG, traditionally non-state actors have played a supplementary role where government institutions have been weak or nonexistent, where there are gaps in funding and resources, or where neglected issues or constituencies require advocacy. However, a review of the functions performed by civil society organizations (CSOs) in relation to four GHG instruments—the International Code on the Marketing of Breastmilk Substitutes, the Framework Convention on Tobacco Control (FCTC), the International Health Regulations, and Codex Alimentarius—noted that they now play a critical watchdog role, ensuring that formally mandated governmental institutions fulfill their responsibilities appropriately, and keep a watchful eye on corporate actors exerting undue influence or engaging in health-harming activities (Lee, 2010). These functions have been essential to the International Code on the Marketing of Breastmilk Substitutes, where ongoing campaigning and advocacy by CSOs have been critical to achieving policy attention. CSOs play an even more significant role in the negotiation and implementation of the FCTC, fulfilling an unusually wide range of functions traditionally dominated by governments. By comparison, CSOs have been less involved in formal proceedings of the Codex Alimentarius Commission or the revision process for the IHR (2005). In regard to the latter, there is now formal recognition of the

TABLE 21-1 Matrix of Global Governance Functions

Function	Formal/Direct	Informal Indirect
Issue linkage	■ Intergovernmental negotiations ■ New information provided by epistemic communities ■ Through financial mechanisms (GEF) ■ IOs (GEO/WEO)	■ Scientists ■ Business/industry
Agenda setting	■ IOs and member states ■ Scientists	■ NGOs ■ Media ■ Scientists
Developing usable knowledge	■ Scientists	■ Scientists ■ NGOs ■ Business/industry
Monitoring	■ IOs ■ Commitees nominated by MEA secretariat ■ MEA signatory governments	■ NGOs (particularly in developing countries) ■ Scientists
Rule making	■ Negotiations by governments ■ NGOs (principled standards)	■ Business/industry (de facto standards) ■ NGOs (principled standards)
Norm development	■ Epistemic communities	■ NGOs (equity & environmental preservation) ■ Business/industry (efficiency)
Policy verification	■ Governments	■ NGOs ■ IOs
Enforcement	■ (Hard) Law ■ WTO and MEA rules	■ NGO campaigns
Capacity building (tech transfer)	■ Official technical assistance (national and local government) ■ Business/industry ■ Science community (education/ training)	■ Business/industry (joint venture)
Capacity building (organizational skills)	■ IOs ■ NGs ■ Scientific community (education/training)	■ Business/industry
Promote vertical linkage	■ IOs ■ National and local governments	■ NGO ■ Scientific community
Financing	■ Government (ODA) ■ Regional development banks ■ Multilateral bodies	■ Business/industry

importance of CSOs in effective disease surveillance, as these organizations may play a supplementary role when state institutions cannot or will not report to WHO promptly.

Moreover, new combinations of state and non-state actors, in a myriad of partnerships, alliances, coalitions, networks, and joint ventures, now populate the field of health cooperation. These institutional arrangements for GHG reflect the search for collective action that can overcome the limitations of state authority. In a few cases, they also mark a shift in the role of non-state actors from being the subject of governance (i.e., law takers) to being participants in governance (i.e., law makers) (Ryngaert, 2016). The board of the Global Fund to Fight AIDS, Tuberculosis and Malaria (GFATM), for example, is "designed to incorporate leading stakeholders in an inclusive and effective way"; consequently, nongovernmental organizations (NGOs), communities affected by the three diseases, the private sector, and private foundations are represented as voting members of the board (GFATM, 2017). In addition, "a broad range of stakeholders, moving beyond the usual participants to reach those who are not normally involved in Global Fund processes" contribute "critical input, suggestions and views about the development of the strategy that guides the Global Fund's mission" through a Partnership Forum (GFATM, 2017). Similarly, the decision-making body of UNITAID (Executive Board), an international organization that raises and grants funds to prevent, diagnose, and treat the same three diseases, includes two representatives of relevant civil society networks (NGOs and communities living with HIV/AIDS, malaria, or tuberculosis [TB]) and one representative of private foundations (UNITAID, 2017).

Third, GHG is characterized by *binding and nonbinding instruments*. Binding instruments, in the form of treaties (sometimes known as conventions), are written agreements concluded by two or more states, and governed by international law. Signatories to binding treaties are legally required to comply with the measures contained within them and, in return, are themselves protected by their provisions. Nonbinding instruments come in diverse forms (e.g., declarations, principles, resolutions, voluntary codes, communiqués) and, given the primacy afforded to the sovereign authority of states, tend to be far more numerous (Taylor, 2013). Although these types of instruments cannot compel compliance by state and non-state actors, their power to shape collective action in global health can stem from their political or moral weight (Kates & Katz, 2010).

In global health cooperation, there are relatively few binding instruments, each of which has required substantial diplomatic efforts to achieve. **TABLE 21-2** provides examples of binding and nonbinding instruments related to GHG. In addition to the treaties leading to the creation of WHO and other international health organizations, WHO member states have agreed to the IHR and FCTC as binding treaties. Professor Lawrence Gostin and others have advocated for the adoption of a binding Framework Convention on Global Health to underpin GHG. As Gostin et al. (2012, p. 790) write:

> A framework convention would establish a health financing framework with clear obligations, and would create an accountability regime with robust standards, monitoring, and enforcement. It would advance health justice through engaging marginalized and underserved populations in making and evaluating policies and through comprehensive strategies and targeted interventions designed to overcome the barriers that prevent these populations from enjoying the conditions required for good health. Governments would be held to high standards of good governance, namely inclusive participation, transparency, honesty, accountability and stewardship. The framework convention would empower people to claim their right to health.

A number of treaties concluded by other international organizations have health-related provisions, such as the International UNICEF Convention on the Rights of the Child (1989) and the World Trade Organization's (WTO) Doha Declaration on the TRIPS Agreement and Public Health (1994). More common are the large number of nonbinding instruments that encourage state and non-state actors to adopt agreed standards, norms, and practices. **EXHIBIT 21-1** describes the WHO Global Code of Practice on the International Recruitment of Health Personnel (2010), which seeks to address the serious problem of health worker migration causing "brain drain" from LMICs to high-income countries. Overall, whether the global health community seeks to achieve a binding or nonbinding instrument depends on the perceived importance and priority of an issue, which in turn shapes the instrument's political feasibility. The decision by a government to become party to a binding instrument is taken after careful consideration of the country's foreign policy as a whole, and not just its health policy. There is generally a tradeoff when agreeing to be bound by international law, between

TABLE 21-2 Examples of Binding and Nonbinding Intergovernmental Agreements Related to Global Health Governance

Binding Instruments	Nonbinding Instruments
UN Convention Relating to the Status of Refugees (1967)	WHO/UNICEF Declaration of Alma Ata on Primary Health Care (1978)
Convention on the Elimination of All Forms of Discrimination Against Women (1981)	WHO Code on the International Marketing of Breastmilk Substitutes (1981)
UNICEF Convention on the Rights of the Child (1989)	UN Principles for the Protection of Persons with Mental Illness and for the Improvement of Mental Health Care (1991)
WTO Doha Declaration on the TRIPS Agreement and Public Health (1994)	ILO Code of Practice Management of Alcohol- and Drug-Related Issues in the Workplace (1999)
Cartagena Protocol on Biosafety to the UN Convention on Biological Diversity (2003)	UN Millennium Development Goals (2000)
Stockholm Convention on Persistent Organic Pollutants (2004)	UN Declaration of Commitment on HIV/AIDS (2001)
WHO Framework Convention on Tobacco Control (2005)	FAO Guidelines on the Right to Food (2004)
WHO FCTC Protocol to Eliminate Trade in Illicit Tobacco Products (2012)*	OECD Paris Declaration on Aid Effectiveness (2005)
WHO Revised International Health Regulations (2005)	WHO Global Code of Practice on the International Recruitment of Health Personnel (2010)
UN Convention on the Rights of Persons with Disabilities (2008)	WHO Global Recommendations on Physical Activity for Health (2010)
	UN Political Declaration of the High-Level Meeting of the General Assembly on the Prevention and Control of Non-communicable Diseases (2012)
	UN Sustainable Development Goals (2015)
	Shanghai Declaration on Promoting Health in the 2030 Agenda for Sustainable Development (2016)
	UN Political Declaration on Antimicrobial Resistance (2016)

Abbreviations: FAO = Food and Agriculture Organization; ILO = International Labour Organization; OECD = Organisation for Economic Co-operation and Development; UN = United Nations; WHO = World Health Organization; WTO = World Trade Organization.

* The agreement was signed on November 12, 2012, and will come into force when 41 states party to the FCTC have ratified and acceded to the protocol.

a lessened ability to act unilaterally, and the benefits accrued when other countries are bound in the same way. Negotiating binding instruments, therefore, requires governments to accept a shared interest in concluding such an agreement. Nonbinding instruments can raise attention to an issue, create agreement on new norms and practices, and thus be effective means of GHG. In some cases, nonbinding instruments can progress to the negotiation of binding agreements as perspectives change within the global health community.

In summary, GHG concerns the agreed rules for interaction and procedures for decision making to address collective health needs and deliver shared health solutions in a global context. These rules and procedures are negotiated and upheld by state and non-state actors, serving formal and informal roles, and are embodied in binding and nonbinding instruments, resulting in direct and indirect impacts on global health. Importantly, in the early 21st century, a transition from *international* to *global* health governance has begun. The design and adoption of a wholly new "architecture" of GHG is unlikely given the complex political, technical, and practical challenges posed. Instead, the world is likely to be governed by diverse and complex institutional arrangements varying across geography, constituency, and issue-area. It is from this starting point that this chapter now turns to describing the existing institutional arrangements commonly referred to as GHG.

EXHIBIT 21-1 WHO Global Code of Practice on the International Recruitment of Health Personnel

According to the *World Social Protection Report 2014/15,* countries need at least 41.1 health workers per 10,000 people to be able to provide essential health care to their own populations. For many low-income countries, however, the available personnel fall far short of this ratio. For example, in countries such as Haiti, Niger, Senegal, and Sierra Leone, there are 5 or fewer health workers available per 10,000 people, compared to 269 in Finland. In 2014, it was estimated that there was a total shortfall of 10.3 million health workers worldwide (International Labour Organization [ILO], 2015). This situation has arisen for many reasons, but one key factor is certainly health worker migration.

Global patterns of health worker migration are complex and dynamic, producing a mixture of costs and benefits at the individual and population levels. The effects are also felt differently across the diverse source and destination countries. In general, the pattern of flow is from low-income countries to higher-income countries. The problem is most acute in sub-Saharan Africa, which has 24% of the global disease burden but only 3% of the health workforce (Taylor, Hwenda, Larsen, & Daulaire, 2011). This "brain drain" ultimately weakens the health systems capacity in the source countries that bear a disproportionate share of the costs. While destination countries benefit from such migration by filling gaps in human resources and strengthening their capacity to deliver health services, source countries lose valuable human capital and, in turn, face gaps in their health services.

Health worker migration has been the subject of longstanding discussions within the global health community. The issue requires collective action across countries because of the cross-border dynamics (i.e., the "pull" factors attracting health workers to migrate stem from outside of affected countries) and the shared experience of brain drain (i.e., 57 low-income countries face critical shortages in their healthcare workforces [WHO, 2006]). Moreover, health worker migration is arguably a planetary problem. As Taylor et al. (2011) write:

> These shortages . . . contribute substantially to the weakness of health systems and obstruct the achievement of public health goals such as reductions in maternal and child mortality; they also hinder implementation of such international legal agreements as the WHO 2005 International Health Regulations, which aim to protect populations from the international spread of disease and to enhance public health security. Strong health systems are essential to improving health outcomes in underserved populations. Without effective health systems employing enough skilled, motivated, well-supported, and adequately supervised health workers, it's unlikely that vaccines and other important medical interventions can improve global health outcomes in any sustainable way. *

Recognizing that countries cannot address this problem alone, the global health community has developed a variety of strategies to improve the governance of health worker migration. Alongside strategies to increase the supply of health workers, deploy available resources more effectively (e.g., task-shifting), and change the incentive structures supporting migration, codes of practice have been adopted to regulate the active recruitment of workers from low-income settings. These governance instruments include the Kampala Declaration adopted at the First Global Forum on Human Resources for Health, the World Medical Association Statement on Ethical Guidelines for the International Recruitment of Physicians (2003), and a large number of bilateral agreements (Pagett & Padarath, 2007). For the most part, these voluntary codes have had limited scope and ultimately minimal effects in stemming the outward flow of healthcare workers (Mackey & Liang, 2013).

In May 2010, the WHO Global Code of Practice on the International Recruitment of Health Personnel was adopted as a framework for cooperation and platform for continuing dialogue on the critical problem of health worker migration. Siyam et al. (2013, p. 820) describe the process of negotiation as "vigorous" and displaying "maturity and a favourable evolution in global health diplomacy." The Global Code is based on the agreed principle, embedded in the WHO Constitution, that all people have a right to the highest attainable standard of health. At the same time, it recognized that health workers have the right to migrate from one country to another in search of employment. As a nonbinding instrument, the Global Code calls upon member states to voluntarily implement and report on measures that uphold these principles.

While a voluntary code might seem to be a limited advance from previous efforts to address international recruiting of healthcare personnel (Tankwanchi, Vermund, & Perkins 2014), some have argued that the Global Code's approach signals a shift in the debate based on recognition of health worker migration as a social problem requiring global solidarity. The adoption of the Global Code by all 193 member states also reflects universal support among all countries for collectively addressing the issue more effectively. WHO describes the code as a "groundbreaking instrument [that] marks the first time that WHO member states have used the constitutional authority of the Organization to develop a code in thirty years" (WHO, n.d.).

With the Global Code now in place, attention has shifted to promoting its implementation, which has so far been limited. The need for more robust reporting by member states on their progress in the implementation of the code has been identified as an unresolved issue (Siyam et al., 2013).

Mapping Existing Institutional Arrangements Governing Global Health

The complex and diverse institutional arrangements that currently constitute GHG have evolved over time into a mixture of international organizations, mechanisms, and instruments. This evolution has not been guided by an overarching plan, but rather has been characterized by a *laissez-faire* approach to institutional building, largely driven by powerful state and non-state actors. Moreover, differing opinions among these powerful actors regarding which global health goals should be given priority, and how best to achieve them, have led to the formation of numerous initiatives focused on specific diseases, populations, and geographic locales. While there are interconnections and complementarities among some of these initiatives, there are also gaps, overlaps, and even working at cross purposes. In this context, mapping these numerous institutional arrangements, and the ways in which they have evolved over time, is not a straightforward task.

One way of mapping GHG is to understand it as a process of cumulatively adding new actors over time. A familiar starting point is to locate WHO as the beginning, and at the center, as the "directing and coordinating authority on international health work" (WHO, 1946). The period from the end of World War II to the late 1990s saw WHO's program of work expand in breadth and depth, alongside the establishment of other United Nations bodies concerned with health, including the UN Children's Fund (UNICEF), UN Development Program (UNDP), and UN Population Program. In the 1980s, the World Bank began to take an active role in health as part of its development financing role. In the 1990s, a broader range of other sectors began to be involved, including trade and investment, finance, customs and excise, education, and public works (water and sanitation). Globalization was broadening the factors affecting health determinants and outcomes, and health was impacting on other policy spheres. Health became more prominent on the agendas of the Organisation for Economic Co-operation and Development (OECD), the Group of Eight (G8), and the Group of 20 (G20). New global health partnerships were formed soon after, involving state and non-state actors, alongside emerging economies such as Brazil, Russia, India, China, and South Africa (i.e., the BRICS countries). Thus, GHG is seen as evolving from WHO's foundational role, with succeeding layers adding different actors and institutional arrangements over time (**FIGURE 21-2**).

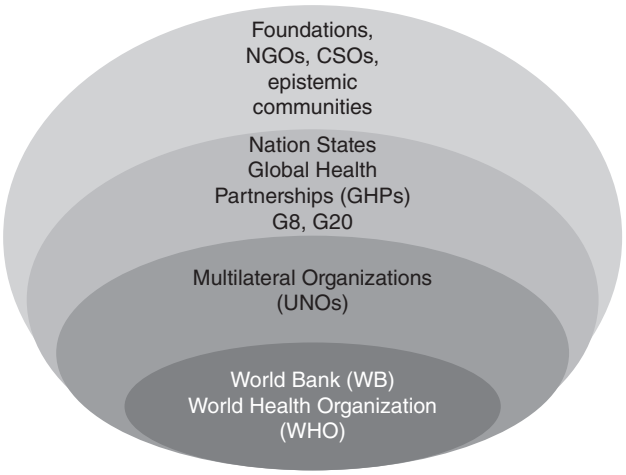

FIGURE 21-2 Prominent global health governance actors in the 21st century.

Used with permission from Okello, A., Vandersmissen, A., & Welburn, S. (2014). One health into action: Integrating global health governance with national priorities in a globalized world. In K. Zomsstag, E. Schelling, M. Whittaker, M. Tanner, & D. Waltner-Toews, (Eds.), *The theory and practice of integrated health approaches* (pp. 283–303). Wallingford, UK: CABI.

A second way of mapping GHG is to understand the changing roles and relationships played by the state, market, and civil society. State actors consist of governmental bodies, led by ministries or departments, service providers, and other agencies that serve the public interest. In GHG, this concept embraces national-level bodies concerned with health security (e.g., centers for disease control, public health agencies), health development (e.g., U.S. Agency for International Development, German Technical Cooperation Agency), and foreign policy (e.g., Global Affairs Canada), and along with international-level bodies with membership primarily composed of governmental actors (e.g., WHO, World Bank, UNICEF).

The distinctiveness of the state sphere, and therefore the central role and authority of states configured into intergovernmental organizations, is seen as changing with the advent of GHG. Since the 1990s, GHG can be mapped as an increasing overlap of the three spheres under shared institutional arrangements for the purpose of governing global health. As discussed in the previous section, non-state actors traditionally operate separately from the governmental (state) sphere, and can be divided into for-profit (market) and not-for-profit (civil society) entities. Both types of non-state actors have grown substantially in number and influence since the late 20th century. GHG can be described as bringing together the three spheres, in different configurations, to realize new resources, comparative advantages, and, ultimately, greater effectiveness (**FIGURE 21-3**). The formation of

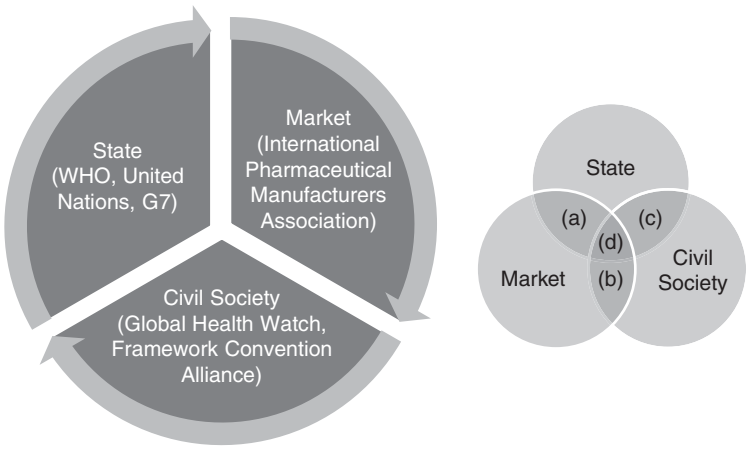

FIGURE 21-3 Transition from distinct to overlapping spheres of state, market, and civil society in global health governance.

dozens of global public–private partnerships between governments and the pharmaceutical sector, such as the Innovative Medicines Initiative between the European Commission and the European Federation of Pharmaceutical Industries and Associations, can be located in section (a) of Figure 21-3. Charitable foundations, which some argue should be located in either the market or civil society sector, might be more accurately fall between the two spheres into (b). The collaboration by Médecins sans Frontières with WHO to provide logistics for sleeping sickness (human African trypanosomiasis) drug distribution in endemic countries, is an example of section (c) of Figure 21-3. Finally, section (d) is where all three spheres come together, as exemplified by the GFATM, the Global Alliance for Vaccines and Immunization (GAVI), and UNITAID.

A third way of mapping institutional arrangements for GHG is by specific function. As described in Table 21-1, global governance fulfills a variety of functions (e.g., issue linkage, monitoring, financing) to which state and non-state actors may contribute formally or informally, with direct or indirect effects (Haas, 2004). Historically, WHO was tasked with fulfilling a broad range of these functions, including taking a lead role in agenda setting. By the 1990s, growing demands on that organization's capacities, and severe limitations of an essentially frozen budget, alongside internal challenges posed by a bureaucratic structure and weak leadership, elicited debate about the appropriate scope of WHO's mandate (Godlee, 1994). At the heart of the question of "who should be doing what in health" among UN bodies (Lee, Collinson, Walt, & Gilson, 1996) was defining the core or essential functions to be retained by WHO. Despite reforms to address some of the structural and procedural problems hindering WHO's capacity, the organization faced a growing number of "work-arounds" by dissatisfied donors who supported the creation of new initiatives. The result was a supply-driven expansion of global health initiatives, some located within WHO, but most governing their own operations.

By the early 2000s, GHG had become a varied collection of institutional arrangements that were fulfilling different functions, but not acting collectively as a whole. **FIGURE 21-4** illustrates the many state and non-state actors involved in the financing of global health (mobilization, allocation, and implementation) during this era. In this environment, despite its designation as the "directing and coordinating authority," WHO was now seen as one potential partner in a crowded GHG landscape.

While debate continues about WHO's mandate, other players have shifted their attention to the broader question of what should be the core functions of GHG more generally. For example, the concept of global public goods takes a residual view of GHG functions, considering those areas of concern to arise from "market failures" or to be undersupplied without collective action (Smith & MacKellar, 2007). Similarly, the Oslo–*The Lancet* Commission on Global Health Governance has suggested how different functions might be distributed across a restructured GHG system (Ottersen et al., 2014).

In sum, what is presently referred to as GHG is, in actuality, a less than perfect patchwork of institutional arrangements that have evolved, in *laissez-faire* fashion, from a combination of supply-driven donor dissatisfaction and demand-driven health needs arising from globalization. Truly *global* governance in the health sphere is so far limited in scope, authority, and function. It would thus be misleading to refer to GHG

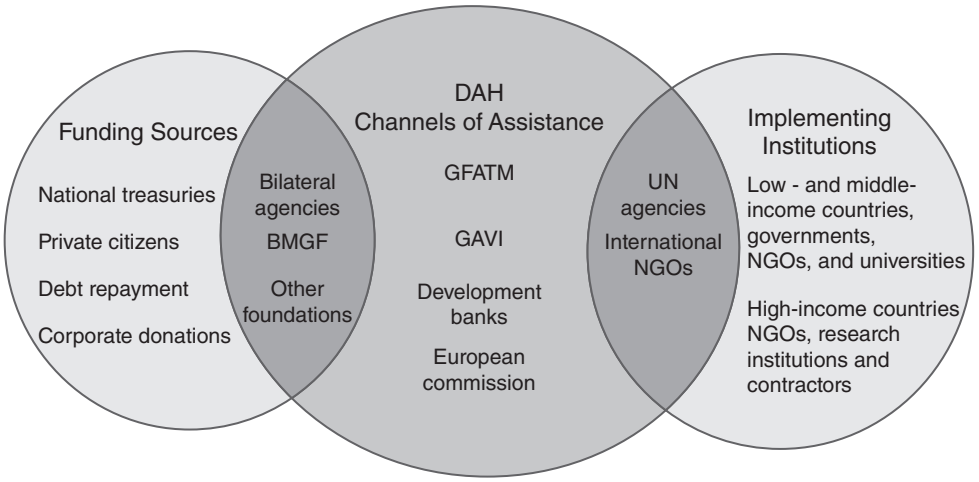

FIGURE 21-4 Overlapping roles of state and non-state actors in financing of global health governance.

Reproduced from Institute for Health Metrics and Evaluation. (2009). *Financing global health 2009: Tracking development assistance for health*. Seattle, WA: IHME.

as a "system" or "architecture" in its present form, as this would suggest an agreed strategy or vision to guide its construction or evolution. Rather, what we have is a partial transitioning from international to global health governance, for selected areas of collective action such as AIDS, TB, and malaria, and to prevent and control major communicable disease outbreaks (**EXHIBIT 21-2**). For most other issue areas, national and international health governance remains the basis for collective action.

The Role of Global Health Diplomacy

The building of effective GHG relies on the conduct of global health diplomacy. *Diplomacy* is the art or practice of conducting international relations through negotiating alliances, treaties, and other agreements. It is concerned with dialogue "designed to identify common interests and areas of conflict between the parties" (Evans & Newham, 1992). This discussion, in turn, is guided by a country's *foreign policy*, the activity whereby state actors act, react, and interact at the boundary between the internal (domestic) and external (foreign) environments. Thus, while foreign policy is "the substance, aims and attitudes of a state's relations with others," diplomacy is "one of the instruments employed to put these into effect" (Reynolds, 1980, p. 36). The term "new diplomacy" describes shifts in foreign policy that challenge how diplomatic practice is carried out. More recently, it has been used to describe the global context, diverse actors, and innovative processes shaping contemporary international relations. Another key feature of new diplomacy has been a shift in the participants, from highly trained officials within foreign affairs ministries to a broader range of political actors (Heine, 2006).

Importantly, new diplomacy has been shaped by non-state actors. While diplomats formally interact with their counterparts, their constituencies are increasingly broad based. Bayne and Woolcock (2007) argue that globalization, and the growing influence of non-state actors, is transforming foreign policy in the 21st century. As Davenport (2002, p. 19) writes, "thousands of nongovernmental organizations have come on stage in recent years, driving their own issues to the top of the diplomatic agenda." Solana (2009) argues, therefore, that "diplomacy is about more than mobilizing states. We need to find ways to harness the expertise and resources of nongovernmental organizations and companies and energize individuals towards shared goals." This diversification of a diplomat's constituencies is illustrated by the "explosion of multilateral negotiations aimed at addressing the new global environmental issues" (Benedick, 1998, p. 4). While the diplomat's formal role is to serve as an official representative of a state, new diplomacy requires engagement with wider constituencies. Thus, it requires what Riordan (2002) calls a "radical restructuring of diplomatic services, replacing hierarchical with networked structures, and the creation of new forms of interaction." New diplomacy, for example, seeks to harness new technologies, altering negotiations through enhanced consultation, coordination, information gathering, and analytical capabilities.

More broadly, social/cultural activities are seen by public diplomacy advocates as important means of promoting understanding and influence. Governments are not alone in the use of such technologies. Non-state actors see new technologies, including social networking, as means for exerting "soft power," especially when they lack military and economic resources. Consequently, there has been growing

EXHIBIT 21-2 The Global Governance of Pandemic Influenza

Influenza is a respiratory infection characterized by the rapid onset of symptoms such as fever, chills, body ache, and unproductive cough. Influenza can cause severe health problems for the elderly and the young, as well as for people with weakened immune systems. Of the three types of influenza viruses (A, B, and C), type A is of greatest public health concern. Type A viruses infect both human and various animal species, which expands the pathogens' reservoir. These viruses are unstable because they regularly mutate in minor ways (antigenic drift), but periodically mutate in major ways (antigenic shift). Genetic reassortments occur when a human influenza virus and zoonotic influenza virus coinfect a human or animal (e.g., pig, bird) host, exchange RNA, and produce a novel virus. Depending on its characteristics, the novel virus could trigger human or animal epidemics or wider pandemics.

Governments have long recognized that influenza requires collective action given the enduring risks posed by the disease and the substantial human and social impacts caused by outbreaks. For these reasons, WHO member states have agreed that global influenza governance must fulfill four core functions: surveillance and reporting, preventive measures, effective response, and public communication.

First, *surveillance and reporting* provides vital knowledge of which influenza strains are circulating, thereby enabling the planning and implementation of interventions such as vaccines. This function is carried out by the WHO Global Influenza Surveillance and Response System (GISRS), established in 1951 and operating in 83 countries. The GISRS consists of 112 national influenza centers, 4 Collaborating Centers for Reference and Research (Australia, Japan, United Kingdom, and United States), and the Collaborating Center for Studies on the Ecology of Influenza in Animals (United States). In addition, the GISRS operates FluNet, a global web-based tool for influenza virologic surveillance that was launched in 1997. The virologic data entered into FluNet (e.g., number of influenza viruses detected by subtype) are critical for tracking the movement of viruses globally and interpreting the epidemiologic data. FluNet recommends, twice annually, the content of the influenza vaccine for the coming season, and serves as an early alert mechanism for the emergence of a virus with pandemic potential. FluNet also forms part of the WHO Global Outbreak Alert and Response Network (GOARN), established in 2000, to combat the worldwide spread of disease.

Second, an important function of effective global influenza governance is to *undertake preventive measures that reduce the disease burden on populations*. Given that influenza viruses, including H5N1, are endemic in a growing number of countries, and contact between human and animal populations remains difficult to control, most experts agree that no form of governance can prevent the emergence of new influenza strains. However, public health agencies, in cooperation with animal health experts and the agricultural sector, can control the spread of the virus and mitigate its impact through rapid diagnosis, isolation of cases, and vaccination (Gerdil, 2003). Among healthy adults, influenza vaccine provides protection from infection, even when the circulating viruses do not exactly match the vaccine viruses. Unfortunately, supply limitations and the cost of vaccines put them out of reach of most populations worldwide. Other measures, such as good husbandry practices, can be supported through guidelines published by WHO and World Animal Health Organization.

Third, influenza can still cause significant disease burdens even when the preceding measures are implemented, so it requires *effective public health responses*. Seasonal epidemics are estimated to result in 3 to 5 million cases of severe illness each year, and 250,000 to 500,000 deaths annually. The morbidity and mortality for pandemic influenza vary depending on the virulence of the virus involved; for example, mortality from this cause was approximately 575,400 deaths in 2009 but 50 million to 100 million deaths in 1918–1919. The infrequency of influenza pandemics, combined with the potentially major severe public health impacts of such events, pose challenges for preparedness planning. The role of GHG, in this respect, focuses on enhancing the surge capacity of national-level health systems to cope with increased demands for diagnostic and clinical treatment, notably control of infection and administration of antiviral drugs. This effort is guided by the Pandemic Influenza Preparedness (PIP) Framework adopted by WHO member states in 2011 following growing concerns about the risks from highly pathogenic avian influenza (HPAI). More broadly, influenza governance seeks to maintain the functioning of societies, including public services and economic activity.

Finally, *public communication* is a key function of global influenza governance. Accurate and timely information is essential for ensuring an appropriate perception of risk among the public. This task is especially challenging during influenza pandemic because when and where it begins, which specific strain emerges, and how severe the health impact is can be unknown. An unduly high level of risk perception can prompt irrational behavior, which then adversely affects collective interests. The private stockpiling of antiviral drugs, for example, contributes to shortages in world supply. Maintaining a high level of alert can lead to "risk fatigue" and public skepticism when a pandemic does not materialize. At the same time, failure to raise sufficient awareness and concern may create problems in securing needed resources or public compliance with response measures.

(continues)

EXHIBIT 21-2 The Global Governance of Pandemic Influenza *(continued)*

Today, surveillance and reporting is the most developed function under global influenza governance, although data gaps remain for many LMICs. Web-based monitoring and reporting systems, integrating both state and non-state sources, and new technologies (e.g., web trawling) have further enhanced the delivery of this function. Global influenza governance remains most vulnerable in relation to the three core functions of preventive measures, response, and public communication. Despite recognition of the need to implement the PIP Framework, much of the effort to prepare for pandemic influenza remains focused at the national level. Pharmacologic interventions are, at present, available in only some countries. In addition, the stockpiling of antiviral medications and vaccines by individual countries causes shortages and increased prices worldwide. This practice is especially problematic if such drugs are needed, for example, to contain an outbreak during the initial stages. By undermining GHG capacity to ring-fence an outbreak, governments can actually reduce the health security of their domestic populations. As Coker and Mounier-Jack (2006, p. 889) argue, "The next pandemic will test notions of global solidarity."

Excerpted from Lee, K., & Fidler, D. (2007). Avian and pandemic influenza: Progress and problems for global governance. *Global Public Health 2*(3): 215.

recognition of the importance of *netpolitik* and *media-politik* (in contrast to *realpolitik*), a "new style of diplomacy that seeks to exploit the powerful capabilities of the Internet to shape politics, culture, values, and personal identity" (Bollier, 2003, p. 2).

Global change, in turn, is creating new problems ripe for collective action (e.g., climate change, population migration, economic instability, disease pandemics) through foreign policy and, consequently, diplomats. The new diplomacy agenda, then, includes a broader range of issue-areas deemed relevant to foreign policy (McInnes & Lee, 2006). This has given rise to new specialty areas of diplomacy such as *resource diplomacy* (the cultivation of relations with resource-rich countries), *Internet diplomacy* (negotiation of rules governing the Internet), and *disaster diplomacy* (understanding and addressing risks in a complex global system).

It is within this context that growing attention has been paid to global health diplomacy. Much of the GHD literature is overtly normative in advocating the use of global health activities to further foreign policy. For example, the U.K. government's *Health Is Global Strategy* seeks to "use health as an agent for good in foreign policy, recognizing that improving the health of the world's population can make a strong contribution towards promoting a low-carbon, high-growth global economy" (United Kingdom Department of Health, 2008). Similarly, Suleman et al. (2014, p. 1) propose that "[t]houghtful Health Diplomacy . . . has the potential to bridge the perceived divides between Western and predominantly Muslim nations." In the United States, GHD is often cast as a counterpart to military-backed "hard power" in the search for "what other tools are available to advance U.S. interests in the world" ("Health Diplomacy," 2007, p. B4).

In summary, GHD can be defined as "policy-shaping processes through which States, intergovernmental organizations, and non-state actors negotiate responses to health challenges or utilize health concepts or mechanisms in policy-shaping and negotiation strategies to achieve other political, economic, or social objectives" (Smith, Lee, & Fidler, 2009, p. 1). Such processes recognize that the changing roles and responsibilities of the increasingly diverse public and private actors concerned with global health require a range of approaches to collective action. Of significance is the absence of an overarching authority to adopt and enforce legally binding measures. Yet the world's experiences with severe acute respiratory syndrome (SARS) and H1N1 influenza, for example, have reemphasized the shared nature of global health challenges. To date, the focus has largely centered on negotiating global governance mechanisms to deal with acute public health threats—notably, infectious diseases outbreaks. However, greater attention needs to be given to how state and non-state actors at different policy levels can work more effectively together to address other global health issues, such as strengthening of health systems, health worker migration, access to medicines, and prevention and control of the rapid increase in chronic diseases.

Over the past six decades, WHO has been at the forefront of global health diplomacy as the United Nations' specialized agency for health. The World Health Assembly (WHA) has served as a valued forum for debating issues and encouraging consensus among member states. The post–Cold War era, however, has seen the rise of the G8 (reduced to G7 with suspension of Russia since 2014) countries as a core influence in international relations. Since the 2000s, the rising influence of the BRICS countries, along

with other "emerging economies," has been a notable development on the world stage. The most remarkable change among these countries is the transformation of China from an aid recipient to a leading aid donor over the past three decades. While there are limited official data sources on Chinese global health funding, a study by Grepin et al. (2014) reports that health has increased as a development aid priority for China. This change in perspective is reflected in the steady increase in the number of health, population, water, and sanitation projects supported in Africa since 2000, with China ranking among the top 10 bilateral global health donors to that continent. Beyond bilateral aid, China has been an active participant in the annual BRICS Health Ministers meetings that have held since 2011. These meetings include six roundtables and two Ministerial Forums on China–Africa Health Development, involving 40 African countries as well as representatives from the African Union, WHO, and UNAIDS (Röhren, 2017). In January 2017, China and WHO signed a memorandum of understanding on health issues related to the so-called Belt and Road Initiative, a monumental development strategy focused on strengthening land and sea trade routes between Europe and China. The agreement deals with health emergencies and with the certification of Chinese medicines and vaccines. This rapid growth of China's role in global health, in large part driven by the country's foreign and economic policy goals, has led to observations that China will soon overtake the United States as "the next leader in global health" (Dahl, 2017).

During the 21st century, it is likely that further geopolitical shifts will lead emerging economies, individually and collectively, to have greater prominence in GHD. The New Development Bank, formed by BRICS countries in 2014, intends to pursue the objective of "financing infrastructure and sustainable development projects in BRICS and other emerging economies and developing countries, complementing the efforts of multilateral and regional financial institutions toward global growth and development" (New Development Bank, n.d.). The G20 (the world's 20 leading industrial countries and emerging economies) is also poised to take a more active global health role. Its Berlin Declaration, issued in May 2017, recognizes health as "one of the most valuable resources for building a sustainable future" (Group of 20, 2017). The declaration, which follows the first G20 Health Ministers Meeting, focuses on antimicrobial resistance and health systems strengthening.

Along with state-based diplomacy, as discussed earlier in this chapter, global health actors embrace a broad range of non-state actors. For example, watching the G20 closely has been a coalition of civil society organizations known as the C20, which aims to facilitate "a structured and sustained exchange of critical reflection and political perspectives amongst civil society in G20 countries and beyond on the G20 agenda" (C20, n.d.). The diversity of actors concerned with global health is extended further by the influence of other sectors, including trade, security, environment, migration, and agriculture, upon the health sector. This is illustrated by the negotiation process to move from the MDGs to SDGs (**EXHIBIT 21.3**). Together, the greater diversity of actors and the complexity of issues gives the role of GHD even greater importance (Kickbusch & Kökény, 2013). Far greater understanding is needed concerning how GHD can best be conducted, which skills are needed for effective negotiation, and which ends GHD should seek to achieve. In response to calls for more information on these topics, there has been a blossoming of GHD literature and training programs focused on the skills and processes needed for the negotiation of global health-related agreements (Kickbusch & Kökény, 2013). As former WHO Director Margaret Chan (2007) noted, health negotiators need to assert themselves more effectively in new policy arenas:

> [D]ue to the impact of globalization on public health, a new type of diplomacy is necessary to navigate the changing landscape of international affairs and politics. The emergence of cross-border disease, bio-terrorism, shifting geopolitical environments, and the linkages between health, trade, intellectual property, and human rights, present stakeholders with a complex matrix of technical and relational challenges.

Key Tasks for Strengthening Global Health Governance

Debates over the past two decades about the present weaknesses of GHG have often focused on dissatisfaction with specific international organizations' willingness and ability to fulfill their mandates, notably WHO. A substantial amount of intellectual and practical energy has been expended searching for effective options for reforming, rebuilding, or even replacing WHO. From concerns during the mid-1990s about weak leadership, lack of nimbleness, and poor leadership, to the crisis of confidence following the Ebola virus outbreak of 2013–2016, there are clear frustrations with the process of "fixing" WHO. Even the reform recommendations prompted by the Ebola

EXHIBIT 21-3 Negotiating the Role of Health Within the UN Sustainable Development Goals

The 2030 Agenda for Sustainable Development was adopted by the UN General Assembly in September 2015 to replace the Millennium Development Goals (MDGs) as the central UN platform for achieving "integrated and indivisible" development across three dimensions: social, environmental, and economic. Encompassing 17 Sustainable Development Goals (SDGs) and 169 targets, which require national, regional, and local efforts across all sectors of society, the purpose of the SDG agenda is to serve as a broad and inclusive framework for ending poverty worldwide.

The SDGs differ from the MDGs in two important respects. First, the UN Secretary General's High-Level Panel on Sustainable Development highlights the importance of addressing the determinants of development and well-being within a "universal framework" in which goals apply to every country and across all sectors of society. While the MDGs applied to developing countries, the SDGs are framed to address poverty alleviation in all countries. Second, the SDGs place sustainability at the heart of the development agenda, recognizing the need to address the complex links between development and the environment. Of particular concern is the need to move away from a narrow set of quantitative goals and targets and toward a broader range of more "integrated and indivisible" goals and targets.

Before consensus could be achieved on these differences, however, negotiators had to navigate a broad range of sector-specific interests. This included the health sector, which enjoyed particular prominence under the MDGs. Three out of eight MDGs focused directly on health-related issues: reducing child mortality (MDG 4), improving maternal health (MDG 5), and combating HIV/AIDS, malaria, and other diseases (MDG 6). Three others were indirectly related to health: eradicating extreme poverty and hunger (MDG 1), ensuring environmental sustainability (MDG 7), and developing a global partnership for development (MDG 8). This emphasis arose because, at the time the MDGs were negotiated during the late 1990s, major donor agencies heavily favored support for addressing global health needs. During this period, increased funding was directed to global health, with the sector receiving substantial new resources and political support (Nunes, Lee, & O'Riordan, 2016).

A detailed comparison of the negotiation of the MDGs and SDGs is difficult given the "absence of contemporaneous, empirical documentation of the agenda-setting and decision-making process resulting in the MDGs" (Brolan & Hill, 2016, p. 514). Nevertheless, it appears that the processes were different. The MDGs arose from the Millennium Summit, described as the "largest gathering of world leaders in history" (UN Millennium Project, 2006). According to McArthur (2014, p. 7), the text of the UN Millennium Declaration was the product of an "intergovernmental drafting process . . . led by John Ruggie, Kofi Annan's advisor and assistant secretary-general. Mark Malloch Brown, the UNDP administrator. . . . In the end, world leaders signed off on a historic Millennium Declaration text that distilled a wide-ranging global agenda down to a relatively pithy framework of global priorities. . . . The text was ultimately drafted in a UN conference room, but its contents had roots in the outcomes from the 1990s conferences."

While the SDGs were supported by almost 200 UN member states, they were the product of a process facilitated by a Sustainable Development Solutions Network (SDSN), overseen by a Leadership Council, operating "under the auspices of the UN Secretary-General . . . [to mobilize] global scientific and technological expertise to promote practical solutions for sustainable development." The SDSN formed 12 Thematic Groups (TGs), including the Thematic Group on Health for All, whose members comprised leading scientists, engineers, academics, and practitioners from civil society and the business community (SDSN, 2014). As Wagner (2015) describes:

> Several elements combined to deliver a different negotiation process on the SDGs. A critical change was the fact that North–South differences were not as pronounced. The SDG negotiation process was conducted in a manner that reduced delegation rigidity, both of individual member states and within coalitions. Based on the Rio+20 instructions for how the SDGs would be developed, negotiations were conducted by an "Open Working Group" [OWG] in which 70 countries developed a sharing arrangement for the designated 30 "seats" for participants. The sharing arrangement broke up traditional coalitions, and facilitated discussions in which seat partners sought to identify what they shared in common with each other's position, rather than to strategize over how to elevate their different positions.

This new negotiating format led to a shift away from the prominence previously given to the health sector. During the negotiations, some argued that the MDGs had been too focused on quantifiable targets, which were closely associated with health targets such as reducing child mortality rates; those targets then became goals in themselves, rather than achieving overall development. As Hill et al. (2014, p. 1) describe, the "global context and framing of the new agenda is substantially different, and health advocates cannot automatically assume the same prominence." Instead, health needs to be reframed within a social sustainability paradigm, be universally relevant to all countries, and be asserted across all themes, rather than being identified as stand-alone goals and targets. On this basis, they suggest that "health advocates need to overtly explore what global governance structures will be needed to finance and implement these universal Sustainable Development Goals" (p. 1).

The end result of the negotiation process was that, among the 17 SDGs, only one is directly a health goal (SDG 3) including universal health coverage. For some, this outcome signals a downgrading of health on the global agenda. For others, the broader approach represents an improvement over the MDG targets, but questions remain about its achievability without a clear commitment to the right to health, collective responsibility (beyond individual societies) to uphold this commitment, and accountability mechanisms to ensure the delivery of the right to health as an entitlement (Go4Health, 2013).

outbreak (**EXHIBIT 21-4**)—an event in which WHO's conduct faced unprecedented criticism—have once again led to disappointment that real change remains elusive (Horton, 2015).

WHO is not alone in drawing reformers' attention: Other international organizations have also faced criticism. For example, the impacts on health equity and status in LMICs of the World Bank's market-driven policies and conditionalities have raised major concerns since the early 1990s (Birn & Dmitrienko, 2005). In 2011, the GFATM faced criticism regarding its governance and financial oversight, confirmed by findings of a high-level independent review panel. The review, chaired by former U.S. Health Secretary Michael Leavitt and former President of Botswana Festus Mogae, acknowledged the important work and achievements of the Global Fund, but noted that inadequate fiduciary controls resulted in misappropriation of funds in recipient countries (Boseley, 2011).

Beyond the governance of individual organizations, many challenges stem from the way that existing institutional arrangements together serve to govern global health. As discussed in this chapter, the need to strengthen collective action has been driven by impacts wrought by globalization (e.g., technological change, increased capital flows, intensifying population mobility) that existing forms of governance cannot address in an effective manner. Can existing bodies, individually and collectively, govern in ways that meet the health needs of a globalizing world, or is there need to design a new "system"? The latter task, of achieving a better "system" of GHG, must resolve a number of challenges.

Which Normative Frameworks Should GHG Seek to Uphold?

Any redesign of GHG requires agreement among those governed about the shared values and ethics underlying collective action and institution building. The normative frameworks shaping global affairs are, of course, diverse and sometimes at odds. Nevertheless, a substantial part of the global health community has moved toward the adoption of some values as the starting point for GHG, beginning with the basic right to health. A commitment to addressing health inequities, within and across countries, and to building universal health coverage, also forms important parts of the SDGs. What does fairness and justice look like in GHG?

Which Core Functions Should GHG Fulfill?

Among the many functions that can be performed by global governance (Table 21-1), there is a need for agreement on which functions should form part of GHG, and how they should be carried out. Today, health governance is exercised at many different institutional levels: local/subnational (e.g., district health authority), national (e.g., ministry of health), regional (e.g., Pan American Health Organization), international (e.g., WHO), and global (GFATM). Should GHG be considered residually, as comprising only those functions that cannot be performed by other levels of health governance? Or should GHG be considered holistically, as comprising all levels of health governance scaffolded in an interconnected and complementary way? For both visions of GHG, it is clear that building stronger global institutions is not a zero-sum game, whereby new institutional arrangements necessarily seek to replace existing ones. Rather, by focusing on the functions to be performed, effective GHG could be viewed as an enabling structure built upon strong institutions from the ground up.

What Should Be the Relative Roles of State and Non-state (For-Profit and Not-for-Profit) Actors?

This chapter has described how GHG increasingly involves state (e.g., ministry of health) and non-state (e.g., International Federation of Pharmaceutical Manufacturers Association) actors, sometimes operating separately, but increasing working in combination (e.g., Project Last Mile, Malaria for Medicines Venture). Pragmatism has been a major factor in the proliferation of global public–private partnerships. However, their roles have also raised questions about whose interests are served by GHG. Can GHG serve

EXHIBIT 21-4 Ten Recommendations for Strengthening Global Health Governance After the 2013–2016 Ebola Virus Outbreak

Recommendation 1: Develop a global strategy to invest in, monitor, and sustain national core capacities.
WHO should convene governments and other major stakeholders within 6 months to begin developing a clear global strategy to ensure that governments invest domestically in building core capacities and to mobilize adequate external support to supplement efforts in poorer countries.

Recommendation 2: Strengthen incentives for early reporting of outbreaks and science-based justifications for trade and travel restrictions.
Political leaders, governments, and international organizations must strengthen the set of incentives and disincentives so that governments report disease outbreaks early. Among these should be stronger disincentives for implementing trade and travel restrictions without a scientific or public health basis.

Recommendation 3: Create a unified WHO Center for Emergency Preparedness and Response with clear responsibility, adequate capacity, and strong lines of accountability.
High-level political leaders must clearly designate who is responsible for responding when disease outbreaks outstrip national capacities, invest in the capacity to respond, and ensure accountability for fulfillment of these responsibilities.

Recommendation 4: Broaden responsibility for emergency declarations to a transparent, politically protected Standing Emergency Committee.
Member states should amend the International Health Regulations to broaden responsibility for declaring a public health emergency of international concern. The Director-General convenes, and is advised by, an ad hoc Emergency Committee constituted from a list of independent experts; however, authority and responsibility to declare a public health emergency of international concern rest exclusively with the Director-General. We recommend the creation of a Standing Emergency Committee that meets regularly, with the mandate to declare a public health emergency of international concern by a majority vote of its members. The emergency declaration should trigger other actions, such as financial disbursements by development banks, emergency data-sharing and specimen-sharing rules, and emergency regulatory procedures for new drugs, vaccines, and diagnostics (recommendations 6 and 7). The Director-General should chair, communicate, and explain the Standing Emergency Committee's decisions. Following an open call for nominations, the Director-General would appoint the first members; thereafter, the Standing Emergency Committee itself would periodically vote in new members to preserve its independent character. Minutes and votes of Standing Emergency Committee members should be published immediately following each meeting for the sake of transparency, to build external confidence, reduce political interference, and strengthen the committee's hand against resistant states. Similarly to other institutions responsible for technically complex, yet politically consequential decisions, such as central banks or drug regulatory authorities, the Standing Emergency Committee must be protected from political pressure that might interfere with its judgment.

Recommendation 5: Institutionalize accountability by creating an independent Accountability Commission for Disease Outbreak Prevention and Response (Accountability Commission).
The UN Secretary General should create an Accountability Commission as an independent body composed of civil society, academia, and independent experts doing real-time and retrospective system-wide assessment of global responses to major disease outbreaks. The Accountability Commission would track and analyze the contributions and results achieved by national governments, donors, UN agencies, international and national nongovernmental organizations, and the private sector. All major actors would be expected to share information promptly with the Accountability Commission about financial, in-kind, or operational contributions; the Accountability Commission should publish the names of organizations unwilling to share such information. The Accountability Commission would assess aid effectiveness, including funds committed, paid, disbursed, and spent; both short-term and long-term accomplishments achieved with those funds; and the timeliness, effectiveness, cultural appropriateness, and equity of the response for intended beneficiaries. The Accountability Commission should liaise directly with and provide a forum for representatives of communities directly affected by outbreaks. Finally, it should monitor efforts to build and sustain national core capacities.

Recommendation 6: Develop a framework of rules to enable, govern, and ensure access to the benefits of research.
Before the 2016 World Health Assembly, WHO should convene governments, the scientific research community, industry and nongovernmental organizations to begin developing a framework of norms and rules for research relevant to disease outbreaks. The framework's goal would be to provide guidance on three interrelated issues: (a) access to data and samples to enable and accelerate research; (b) improved ethical standards; and (c) equitable access to the benefits of research such as priority and affordable access to newly developed technologies and treatments.

Recommendation 7: Establish a global facility to finance, accelerate, and prioritize research and development.
The UN Secretary General and the WHO Director-General should convene in 2016 a high-level summit of public, private, and not-for-profit research funders to establish a global financing facility for research and development for health technology relevant for major disease outbreaks. The facility would support manufacturing, research, and development for drugs, vaccines, diagnostics, and other nonpharmaceutical supplies (such as personal protective equipment) where the commercial market does not offer appropriate incentives. For known pathogens, the facility could invest in bringing candidate drugs, vaccines, technology platforms, and other relevant products through proof of concept, phase 1, and phase 2 testing in humans, so that they are ready for wider testing, manufacturing, and distribution when an outbreak strikes. During an outbreak the facility would rapidly mobilize finance for priority research and development projects, such as diagnostics for novel pathogens.

Recommendation 8: Sustain high-level political attention through a Global Health Committee of the Security Council.
In recognition of health as an essential facet of human and national security, the UN Security Council should establish a Global Health Committee consisting of government representatives. The Committee's main goal would be to expedite and elevate political attention to health issues posing a serious risk to international peace and security and provide a prominent arena to mobilize political leadership. Specifically, the Committee would monitor and publish an annual report on progress in building a strong and effective global health security system, taking into account analyses from the Accountability Commission and WHO. The Committee would also address alleged noncompliance with International Health Regulation provisions on trade and travel measures. The Committee would not declare public health emergencies of international concern. That decision would remain technically driven and under the authority of WHO. The Committee would not be able to veto WHO decisions or reports of the Accountability Commission. Rather, the Committee's main role would be as an arena for high-level attention to health threats and a forum for problems not adequately resolved by the WHO governing bodies.

Recommendation 9: A new deal for a more focused, appropriately financed WHO.
To rebuild trust, respect, and confidence within the international community, WHO should maintain its broad definition of health, but substantially scale back its expansive range of activities to focus on core functions. The scope of WHO's work would thus continue to embrace the full range of health issues, but its functions should be far more circumscribed. We restrict our analysis to core functions in infectious disease outbreaks. However, there remains the need to define WHO's core functions in other key areas of work, such as noncommunicable diseases, injuries, environmental health, health systems, and social determinants of health. For this purpose, the January 2016 Executive Board should launch a fundamental review of the organization's constitution and mandate to define its core functions. This review should identify and hand over noncore activities to other actors, thereby streamlining WHO's activities. It should also examine which core functions are not being fulfilled or adequately funded.

Recommendation 10: Good governance of WHO through decisive, time-bound reform, and assertive leadership.
Restoring credibility demands that WHO institutionalizes accountability mechanisms, strengthens and clarifies how it works with other actors, and fosters strong leadership. The January 2016 Executive Board should launch a process to implement four new policies for WHO to meet basic principles of good governance: establish a freedom of information policy, with appropriate safeguards; create a permanent Inspector General's office to monitor overall performance of the organization and its entities, reporting to the Executive Board; conclude continuing work on the Framework of Engagement with Non-State Actors to better govern the way WHO interacts with civil society, academia, foundations, and the private sector; and revise human resources policies to attract or retain well-qualified staff, including for leadership positions, while letting go of chronic underperformers.

Extracted from Moon, S., Sridhar, D., Pate, M., Jha, A., Clinton, C., Delauney, S., . . . Piot, P. (2015). Will Ebola change the game? Ten essential reforms before the next pandemic. The report of the Harvard-LSHTM Independent Panel on the Global Response to Ebola. *The Lancet, 386*: 2204–2221.

public interests with the participation of both state and non-state actors? Which institutional arrangements are needed to ensure appropriate "checks and balances" to protect public interests in GHG? The adoption of the WHO Framework for Engagement with Non-State Actors (FENSA) in May 2016 followed a long and "difficult gestation" (Buse & Hawkes, 2016) amid concerns regarding the organization's relationship with the private for-profit sector (**EXHIBIT 21-5**). While FENSA "recognizes the risks of potential conflicts of interest from engagement with non-state actors, including undue influence in setting or applying policies, norms, and standards," and "WHO and its governing body have taken an important step in democratizing the invite list to the policy table and establishing the dining etiquette," (p. 5) Buse and Hawkes (2016, p. 5) argue that this was a lost opportunity for the organization to "leverage its mandate and authority to address the larger issue of governing the activities of industry."

EXHIBIT 21-5 WHO Framework of Engagement with Non-State Actors

Introduction

1. The overarching framework of engagement with non-state actors and the WHO policy and operational procedures on management of engagement with non-state actors apply to all engagements with non-state actors at all levels of the Organization, whereas the four specific policies and operational procedures on engagement are limited in application to, respectively, nongovernmental organizations, private sector entities, philanthropic foundations and academic institutions.

Engagement: Rationale, Principles, Benefits, and Risks

Rationale

2. WHO is the directing and coordinating authority in global health in line with its constitutional mandate. The global health landscape has become more complex in many respects; among other things, there has been an increase in the number of players including non-state actors. WHO engages with non-state actors in view of their significant role in global health for the advancement and promotion of public health and to encourage non-state actors to use their own activities to protect and promote public health.
3. The functions of WHO, as set out in Article 2 of its Constitution, include: to act as the directing and coordinating authority on international health work; to establish and maintain effective collaboration with diverse organizations; and to promote cooperation among scientific and professional groups which contribute to the advancement of health. The Constitution further mandates the Health Assembly or the Executive Board, and the Director-General, to enter into specific engagements with other organizations. WHO shall, in relation to non-state actors, act in conformity with its Constitution and resolutions and decisions of the Health Assembly, and bearing in mind those of the United Nations General Assembly or the Economic and Social Council of the United Nations, if applicable.
4. WHO's engagement with non-state actors supports implementation of the Organization's policies and recommendations as decided by the governing bodies, as well as the application of WHO's technical norms and standards. Such an effective engagement with non-state actors at global, regional, and country levels, also calls for due diligence and transparency measures applicable to non-state actors under this framework. In order to be able to strengthen its engagement with non-state actors for the benefit and interest of global public health, WHO needs simultaneously to strengthen its management of the associated potential risks. This requires a robust framework that enables engagement and serves also as an instrument to identify the risks, balancing them against the expected benefits, while protecting and preserving WHO's integrity, reputation, and public health mandate.

Principles

5. WHO's engagement with non-state actors is guided by the following overarching principles.
   Any engagement must:
   a. demonstrate a clear benefit to public health;
   b. conform with WHO's Constitution, mandate, and General Programme of Work;
   c. respect the intergovernmental nature of WHO and the decision-making authority of member states as set out in the WHO's Constitution;
   d. support and enhance, without compromising, the scientific and evidence-based approach that underpins WHO's work;
   e. protect WHO from any undue influence, in particular on the processes in setting and applying policies, norms, and standards;
   f. not compromise WHO's integrity, independence, credibility, and reputation;
   g. be effectively managed, including by, where possible, avoiding conflict of interest and other forms of risks to WHO;
   h. be conducted on the basis of transparency, openness, inclusiveness, accountability, integrity, and mutual respect.

How Should GHG Intersect with, or Be Integrated with, Other Spheres of Governance?

Health determinants and outcomes, in a globalizing world, are affected by a broad range of factors. As a consequence, effective GHG cannot be limited to the health sector, but rather must operate within a larger ecosystem of global governance. How should GHG engage with non-health sectors (e.g., trade, environment, law enforcement, education, transportation)? How can this be achieved at all levels of health governance to achieve policy coherence (Silberschmidt & Zeltner, 2013)? The formulation of the SDGs has adopted this approach and offer opportunities to embed GHG more deeply in other sectors. Similarly, *The Lancet*–University of Oslo Commission on Global Governance for Health proposed a UN Multistakeholder Platform on Global Governance for Health that would "engage governments, intergovernmental organizations (in the areas of finance, trade, labor, food, environment, human rights, migration, and peace and security), and non-state actors including civil society, academic experts, and business" (Ottersen et al., 2014, p. 630). The Platform (**FIGURE 21-5**) would address the problem of what the Commission calls "institutional stickiness," whereby it becomes "difficult to reform institutions to evolve with the times" because power becomes entrenched. The Commission has argued that the Platform would enable "more inclusive, better integrated, and more coherent policy dialogue across institutions and arenas."

How Should Decisions Be Made Within a System of GHG?

Decision-making processes are central to governance—that is, who participates and how decisions are made. International health governance gives formal power and authority for decision making largely to state actors. This chapter describes how non-state actors have become increasingly involved in global health and, to a growing extent, in decision making, both formally and informally. Proponents argue that this "opening up" of participation enables a broader range of stakeholders to be represented in GHG decisions and, by extension, facilitates better decisions. Others, however, question whether more voices are necessarily the right voices. To what extent are the voices of big business and CSOs necessarily representative of local people, notably the poor and vulnerable? More voices also do not necessarily mean better decision making. Indeed, lessons from the Occupy Movement and the UN Climate Change Conference suggest that too many diverse voices coalescing around "amorphous structures" can be a hindrance to effective global change (Klein, 2014). Who should be enfranchised in decision making and how should they meaningfully participate in GHG? How can dissenting voices be

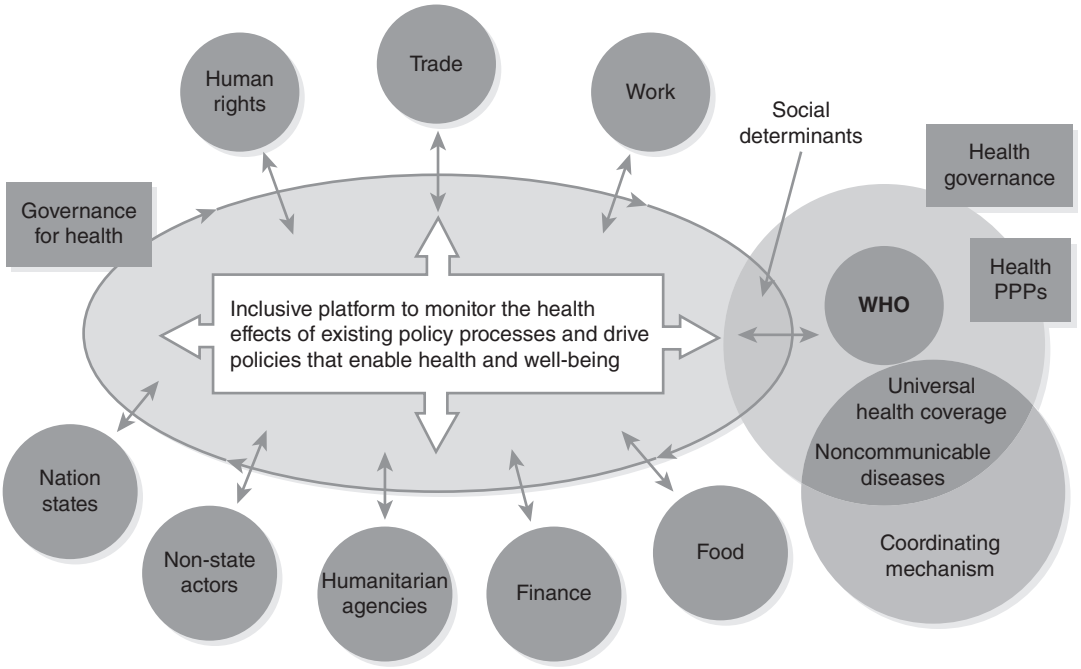

FIGURE 21-5 United Nations stakeholder platform.

heard but, most importantly, reconciled in ways that allow legitimate collective action?

Ultimately, the challenges faced by GHG cannot be reduced to technical or administrative fixes. If only a new vaccine could be developed, if only new technology could be applied more widely, if only a financial oversight committee could be formed to watch over the disbursing of available resources—these are all important achievements in GHG but will not deliver the kinds of changes needed. The key challenges in GHG are fundamentally political: They do not deal with interferences with scientific or rational action, but rather with building institutions that enable the agreed exercise of power for collective action. The proposal to create a Committee C (**EXHIBIT 21-6**), for example, would retain the primary role of WHO member states, while enabling "major stakeholders in global health—international agencies, philanthropic organizations, multinational health initiatives, and representatives from major civil-society groups, particularly those who legitimately represent the most vulnerable populations"—to feed more actively into state-led decision making (Silberschmidt, Matheson, & Kickbusch, 2008, p. 1485).

Supporting Institutional Innovation in Global Health Governance

As described in the previous section, while there is broad agreement that existing institutions face many problems, agreed ways of moving forward to address them are lacking. Proposals to strengthen GHG to date have ranged from the reform of selected international organizations (notably focused on WHO) to the design of an entirely new GHG architecture. On the one hand, numerous, and largely unsuccessful, efforts to "fix" WHO since the 1990s have produced "reform fatigue." On the other hand, the design of an entirely new system has not been supported by a clear and agreed vision of what it should look like (Gill & Benatar, 2016; Lee & Pang, 2015; Youde, 2012).

To get beyond this impasse, after so much debate and numerous initiatives, a potentially useful way forward is to draw on thinking about institutional innovation. Institutional innovation is defined by Raffaelli and Glynn (2015, p. 1) as "novel, useful, and legitimate change that disrupts the cognitive, normative or regulative mainstays of an organizational field." Institutional innovation can occur along a continuum ranging from incremental change within existing institutions (modification) to more radical change in the form of creating new institutions (disruptive innovation). Institutional innovation theory has received substantial attention in business studies in the context of explaining success and failure in companies' adaptation to fast-paced globalization. Thus, by the mid-2000s, institutional theory had shifted from a focus on explaining stability, permanence, and homogeneity, to increased attention to change and variation.

EXHIBIT 21-6 Proposal to Create a Committee C of the World Health Assembly

Currently the formal work of the WHA is focused on determining the policies of WHO itself and on making recommendations for member states. The assembly is the key annual event of global health, sometimes more because of the many informal and formal side-meetings than for its agenda. The consequence is that many major decisions in global health are taken unlinked to the formal business of the assembly. . . . The mechanism we propose is to consider the establishment of a committee C of the WHA. This committee would debate major health initiatives by other key players in the global-health arena. It would provide the opportunity for these organizations to present their plans and achievements to the delegates of the WHA and the nongovernmental organizations in official relations with WHO. It would also provide an opportunity to address coordination and common concerns of different partners in global health. Organizations wishing to make use of this mechanism would send their proposal to WHO's executive board, which would set the agenda for this committee as it does with the existing committees.

A committee C would need rules of procedures that give sufficient space to the other groups involved while fully respecting the role of governmental delegations. This double requirement could be met by proposing resolutions for adoption by the plenary of WHA as in committees A and B, but to explicitly welcome within such resolutions commitments independently taken by other partners that would be annexed to the resolution (panel). With such a procedure the other entities keep their full independence by autonomously adopting—according to their internal rules—their declarations to be annexed. There is an interaction between the member states and the other entities in committee C on the conditions and methods under which to annex a declaration and the core of the resolution. Member states keep their sovereignty in the final adoption of the resolution in the WHA plenary where other stakeholders cannot vote or intervene.

Institutional innovation has so far received limited attention in the study of public institutions, particularly international organizations. Nevertheless, some examples can be cited of institutional innovation occurring to support GHG in response to the disconnect between the forms of governance needed in a globalizing world and the institutional arrangements presently available (Smith & Lee, 2017).

One important example is innovative financing mechanisms. The two traditional sources of healthcare financing at the national level have largely been various forms of taxation and out-of-pocket payments. At the international level, financing of health governance functions has been through assessed contributions by governments according to their size and ability to pay (a form of taxation) and voluntary donations from individuals, states, and non-state actors. While funding for global health initiatives increased to unprecedented levels from the late 1990s until the global financial crisis beginning in 2008, available resources have fallen short of need. Where available funds through these two sources have not been sufficient, innovative financing mechanisms have been developed. Many alternative financing mechanisms have emerged to fill the funding gap, such as taxation of global transactions (e.g., air travel, foreign currency exchange) and crowdsourcing. Relatedly, efforts to reduce the costs of global health activities have led to important innovations such as forward purchasing, generic pricing, and guaranteed contracts.

Another area where institutional innovation is occurring is disease surveillance, monitoring, and reporting using web-based technologies. In some ways, strengthening existing capacities is likely to be most appropriate in this area of focus. A good example is the revised International Health Regulations (2005). To prevent smaller-scale outbreaks from becoming larger-scale emergencies, all WHO member states need to have a minimum level of core capacities to detect, report, and respond to such events rapidly. Governments agreed to develop these core capacities by 2012 under the revised IHR following the SARS outbreak of 2002–2003. A failure to meet this deadline by many countries led to an extension of the target time frame to 2014. Following the Ebola virus outbreak, the deadline was further extended to 2019 (Moon et al., 2015). As of 2016, and based on self-assessments, approximately half of WHO member states had yet to comply, exposing the world to similar risks in future (Lillywhite, 2016).

To support these efforts, the Global Health Security Agenda (GHSA) was launched in 2014 "to advance a world safe and secure from infectious disease threats, to bring together nations from all over the world to make new, concrete commitments, and to elevate global health security as a national leadership priority." The GHSA was subsequently endorsed by the G7, with the governments of Finland and Indonesia hosting commitment development meetings (see the *Public Health Infrastructure* chapter for more information on the GHSA). A 10-year strategic plan has also been set out by WHO to enable compliance by LMICs (WHO, 2016b). The overall lessons from the Ebola virus outbreak has been that noncompliance by LMICs needs to be addressed through financial support, rather than through changes to the IHR, which is considered "technically sound" (Lillywhite, 2016).

For other functions, however, innovations applying information and communication technologies (ICTs), open source learning, and big data offer opportunities to improve the capacity to identify, track, and even predict disease outbreaks of global concern. An early example of ICT-based innovation is ProMed (Program for Monitoring Emerging Diseases), an Internet-based reporting system established in 1994 to rapidly disseminate information on outbreaks of infectious diseases and acute exposures to toxins that affect human health, including those in animals and in plants grown for food or animal feed. ProMed currently reaches more than 70,000 subscribers in at least 185 countries. It is open to all sources of information, including media reports, official reports, online summaries, local observers, and ProMed subscribers. A team of expert human, plant, and animal disease moderators screen, review, and investigate reports before posting them to the network. Reports are then distributed by email to direct subscribers and posted immediately on the ProMed website (ProMed, n.d.).

The Global Public Health Intelligence Network operates in a similar way by identifying outbreaks from websites, news wires, and local and national newspapers retrieved through news aggregators. Global Pulse is a flagship initiative of the United Nations Secretary-General that is seeking to harness big data safely and responsibly as a public good. A good example of the innovative use of big data (extremely large data sets that require analysis computationally to reveal patterns, trends, and associations, especially related to human behavior and interactions) for global health is GermTracker (**EXHIBIT 21-7**).

Another example of institutional innovation has been representation in decision making. At the heart of GHG innovation is finding appropriate ways for decisions to be made collectively to identify and achieve shared goals. A longstanding concern with WHO has been the limited voice given to civil society organizations, which have become increasingly

EXHIBIT 21-7 GermTracker

Researchers at the University of Rochester showed last year how Twitter can be used to predict how likely it is for a Twitter user to become sick. They have now used Twitter to model how other factors—social status, exposure to pollution, interpersonal interaction, and others—influence health.

"If you want to know, down to the individual level, how many people are sick in a population, you would have to survey the population, which is costly and time-consuming," said Adam Sadilek, postdoctoral researcher at the University of Rochester. "Twitter and the technology we have developed allow us to do this passively, quickly, and inexpensively; we can listen in to what people are saying and mine this data to make predictions."

Many tweets are geo-tagged, which means they carry Global Positioning System (GPS) information that shows exactly where the user was when he or she tweeted. Collating all this information allows the researchers to map out, in space and in time, what people said in their tweets, as well as where they were and when they were there. By following thousands of users as they tweet and go about their lives, researchers also could estimate interactions between two users and between users and their environment.

Using tweets collected in New York City over a period of a month, the researchers looked at factors such as how often a person takes the subway, goes to the gym, or visits a particular restaurant; proximity to a pollution source; and online social status. They examined 70 factors in total. They then looked at whether these factors had a positive, negative, or neutral impact on the users' health.

Some of their results are perhaps not surprising. For example, pollution sources seem to have a negative effect on health. However, the study marked the first time that this impact has been extracted from the online behavior of a large online population. The paper also reveals a broader pattern, in which almost any activity that involves human contact leads to significantly increased health risks. For example, even people who regularly go to the gym get sick marginally more often than less active individuals. Nevertheless, people who merely talk about going to the gym, but actually never go (verified based on their GPS data), get sick significantly more often. Thus, interesting confounding factors can now be studied at scale.

The technology that Sadilek and his colleague Professor Henry Kautz developed has led to a web application called GermTracker. The application color-codes users (from red to green) according to their health by mining information from their tweets for 10 cities worldwide. Using the GPS data encoded in the tweets, the app can then place people on a map, which allows anyone using the application to see their distribution.

"This app can be used by people to make personal decisions about their health. For example, they might want to avoid a subway station if it's full of sick people," Sadilek suggested. "It could also be used in conjunction with other methods by governments or local authorities to try to understand outbursts of the flu."

During flu season, as the number of people with the flu across the United States increases, so do the number of people monitoring GermTracker. On some days in January, as many as 10,000 people visit http://fount.in where the app is hosted.

The model that Sadilek and his colleagues developed is based on machine learning. At the heart of their work is an algorithm that can distinguish between tweets that suggest the person tweeting is sick and those that do not.

"It's like teaching a baby a new language," Sadilek said. He explained that they first generated a training set of data—5,000 tweets that had been manually categorized and from which the algorithm can start to distinguish what words and phrases are associated with someone being sick. He added, "We need the algorithm to understand that someone who tweets 'I'm sick and have been in bed all day' should be characterized as sick, but 'I'm sick of driving around in this traffic' shouldn't be."

The application is also improving the algorithm. Every time users access the app and click on one of the colored dots that represent the tweeting users, they can see the specific tweet that led someone to be classified in a specific way. The application asks users to assess the tweet and say whether they agree with the classification. These data are fed back into the algorithm, which continues to learn from its mistakes.

University of Rochester. (2013). Using Twitter to predict the influence of lifestyle on health. http://www.rochester.edu/news/show.php?id=5532

important in global health activities. Historically, WHA has been the plenary body through which governments set priorities. Officially recognized non-state actors can be given observer status at the WHA, for example, but obtaining this status is a highly selective process controlled by states.

Overall, change has been too slow and too limited for many CSOs seeking to inject a more critical voice in WHO deliberations. The previously described limitations of WHO as an authoritative decision-making body raise the question of what kind of body is needed. Some have suggested an enhanced WHA through a committee C involving additional constituencies beyond member state delegations, such as CSOs, charitable foundations, and other non-state actors (Exhibit 21-6). The People's Health Assembly, a consortium of CSOs, was initiated by organizations that did not feel represented by existing institutional

arrangements, which focused on WHO and member states. The four *Global Health Watch* (2014) reports were published as an alternative to the *World Health Report* published by WHO—they sought to offer a critical voice. Each report was intended to serve as

> the definitive voice for an alternative discourse on health and health care. It covers a range of issues that currently impact on health, including the present political and economic architecture in a fast-changing and globalized world; a political assessment of the drive towards Universal Health Coverage; broader determinants of health, such as gender-based violence and access to water; stories of struggles, actions and change; and a scrutiny of a range of global institutions and processes. It integrates rigorous analysis, alternative proposals and stories of struggle and change to present a compelling case for a radical transformation of the way we approach actions and policies on health (Global Health Watch, 2014, Overview).

Conclusion

The health impacts of contemporary globalization are now widely documented, and are recognized as being more extensive and intensive than the impacts that occurred in earlier periods of social change. The resultant effects on health determinants and outcomes, affecting individuals and populations worldwide, pose fundamental challenges to how we govern health from the local level to the planetary level. "Global health" is now a widely used and accepted term, albeit one laden with imprecision and redundant meanings. A full transition in thinking and practice entails more than a change in nomenclature; it requires embracing a paradigmatic shift about health determinants and outcomes. An understanding of the distinct meaning of global health, in turn, leads to different expectations about collective active to govern the health impacts of globalization.

The transition from international to global health governance is also a work in progress, characterized by conceptual fuzziness and contested views about what should be achieved and how to achieve it. Numerous challenges remain to be addressed, but many opportunities are available to approach these challenges using institutional innovation. This is already beginning to happen, resulting in the strengthening of some GHG functions in selected issue areas. It is more likely that the global health community will continue to move incrementally in this way, rather than adopt a wholesale redesign of existing institutional arrangements.

Discussion Questions

1. Which core functions do you believe an effective system of global health governance should serve?
2. How might the concept of network governance be used to link together existing institutional arrangements for global health? Are there any governance gaps that need filling?
3. Which stakeholders should be involved in making decisions concerning global health? How should participation in decision making be governed?
4. Which functions might non-state actors perform in global health governance?

Acronyms

ACC/SCN	Administrative Committee on Coordination/Sub-Committee on Nutrition (UN)
ACF	Action Contre la Faim
ACSD	Accelerated Child Survival and Development program (UNICEF)
ACT	artemisinin-based combination therapy
ADDO	accredited drug dispensing outlet
ADE	adverse drug event
ADHD	attention-deficit/hyperactivity disorder
ADLs	activities of daily living
ADR	adverse drug reaction
AFENET	African Field Epidemiology Network
AGA	appropriate weight for gestational age
AGP	alpha-1 acid glycoprotein
AI	Adequate Intake
AIDS	acquired immunodeficiency syndrome
ALRI	acute lower respiratory infection
ALT	alanine aminotransferase
AMC	advance market commitment
AMR	antimicrobial resistance
ANC	antenatal care
APA	American Psychiatric Association
ARI	acute respiratory infection
ART/ARV	antiretroviral therapy
ASEAN	Association of Southeast Asian Nations
ASEOWA	African Union Support for the Ebola Outbreak in West Africa
ASMR	age-specific mortality rates
ASP	antimicrobial stewardship program
AST	aspartate aminotransferase
AYUSH	Ayurveda, yoga and naturopathy, Unani, Siddha, homeopathy
AZT	Azidothymidine
BAC	blood alcohol concentration
BCC	behavioral change communication
BCG	bacillus Calmette-Guérin (vaccine)
BMGF	Bill and Melinda Gates Foundation
BMI	body mass index
BOP	balance of payments
BP	*British Pharmacopoeia*
BRICS	Brazil, Russia, India, China, and South Africa
CAPI	computer-assisted personal interviewing
CARA	Conscience of Antimicrobial Resistance Accountability (initiative)
CARIFTA	Caribbean Free Trade Agreement
CBH	community-based health
CBHI	community-based health insurance
CBR	community-based rehabilitation
CBRN	chemical, biological, radiological, and nuclear
CBT	cognitive-behavioral therapy
CCD	cultural concept of distress
CCM	country coordination mechanism
CCMD	Chinese Classification of Mental Disorders
CCT	conditional cash transfer
CDC	Centers for Disease Control and Prevention (U.S.)
CDR	case disability ratio
CE	complex emergency
CECA	Comprehensive Economic Cooperation Agreement (India–Singapore)
CEF	Contingency Fund for Emergencies (WHO)
CETA	Common Elements Treatment Approach
CFI	cultural formulation interview
CFR	case fatality ratio
CERF	Central Emergency Response Fund (UN)
CHD	coronary heart disease
CHE	complex humanitarian emergency
CHeSS	Country Health Systems Surveillance
CHF	Community Health Fund (Tanzania)
CHW	community health worker
CI	confidence interval
CIDT	Community Informant Detection Tool

CIT	crisis intervention team
CITEM	Center for International Trade Expositions and Missions (Philippines)
CKD	chronic kidney disease
CLAS	*Cultural and Linguistically Appropriate Services* guidelines
CMAM	community management of acute malnutrition
CMD	common mental disorder
CMR	crude mortality rate
CMS	central medical store
COPD	chronic obstructive pulmonary disease
CPAP	continuous positive airway pressure
CRA	comparative risk assessment
CRC	child-resistant container
CRP	C-reactive protein
CSDH	Commission on Social Determinants of Health (WHO)
CSO	civil society organization
CSR	corporate social responsibility
CVD	cardiovascular disease
cVDPV	circulating, vaccine-derived polio viruses
CVI	Childhood Vaccine Initiative
DAH	development assistance for health
DALE	disability-adjusted life expectancy
DALY	disability-adjusted life year
DBT	dialectical behavioral therapy
DCP	*Disease Control Priorities*, third edition
DDT	dichlorodiphenyltrichloroethane
DFATD	Department of Foreign Affairs, Trade and Development (Canada)
DFID	Department for International Development (U.K.)
DFLE	disability-free life expectancy
DHHS	Department of Health and Human Services (U.S.)
DHMT	district health management team
DHS	demographic and health survey; district health system
DOTS	directly observed treatment, short course
DPP	Diabetes Prevention Program
DPSEEA	driving forces, pressures, state of environment, exposures, effects, and actions (model)
DPT	diphtheria, pertussis, tetanus vaccine
DRC	Democratic Republic of Congo
DRR	disaster risk reduction
DSM-IV	*Diagnostic Statistical Manual of Mental Disorders, Fourth Edition* (American Psychiatric Association)
DSM-5	*Diagnostic Statistical Manual of Mental Disorders, Fifth Edition* (American Psychiatric Association)
DSS	demographic surveillance site/system
EAR	Estimated Average Requirement
ECD	early childhood development
ECDC	European Centres for Disease Control
ECOWAS	Economic Community of West African States
EDCTP	European and Developing Countries Clinical Trials Partnership
EHRA	environmental health risk assessment
EI	extractive industry
EIA	environmental impact assessment
EIS	Epidemic Intelligence Service (CDC)
ELISA	enzyme-linked immunosorbent assay
EMA	European Medicines Agency
EMERALD	Emerging Mental Health Systems in Low- and Middle-Income Settings
EMRO	Eastern Mediterranean Regional Office (WHO)
EMT	Emergency Medical Team
ENACT	Enhancing Assessment of Common Therapeutic Factors
ENMR	early neonatal mortality rate
EOC	emergency operations center
EPEC	enteropathogenic *Escherichia coli*
EPHF	essential public health functions
EPI	Expanded Program on Immunization
EPIDOS	European Patent Information and Documentation Systems
EPIET	European Programme for Intervention Epidemiology Training (ECDC)
EQ-5D	European Quality of Life with Five Domains
ERA	environmental risk assessment
ERC	Emergency Relief Coordinator (UN)
ERHI	employment-related health insurance
ESG	environmental, social, and governance (indicators)
ESKAPE	*Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter*
ETS	environmental tobacco smoke
EU	European Union
FAO	Food and Agriculture Organization

NPHW	non-physician healthcare worker
NTD	neglected tropical disease
OCHA	Office for the Coordination of Humanitarian Affairs (UN)
ODA	official development assistance
OECD	Organization for Economic Cooperation and Development
OOP	out of pocket
OOS	out of specification
OP	outpatient
OPV	oral polio vaccine
OR	odds ratio
ORS	oral rehydration solution
ORT	oral rehydration therapy
P4P	pay for performance
PAF	population-attributable factor
PAHO	Pan American Health Organization
PATH	Program for Appropriate Technology in Health
PCBs	polychlorinated biphenyls
PCIS	patient care information system
PCR	polymerase chain reaction
PDP	productive development partnership
PEF	Pandemic Emergency Financing Facility (World Bank)
PEM	protein-energy malnutrition
PEN	Package of Essential Medicines and Technologies for Non-Communicable Disease Interventions
PEP	post-exposure prophylaxis (for HIV)
PEPFAR	President's Emergency Plan for AIDS Relief
PEV	Expanded Program on Immunization (French)
PHC	primary health care
PHE	Public Health England
PHEIC	public health emergency of international concern
PHFI	Public Health Foundation of India
PHR	Physicians for Human Rights
PIEA	political and institutional economy analysis
PLHIV	people living with HIV
PLWHA	people living with HIV and AIDS
PMNCH	Partnership for Maternal, Newborn, and Child Health
POC	point of care
POLHN	Pacific Open Learning Health Net
PPI	Private Participation in Infrastructure
PPM	public–private mix
PPP	purchasing power parity; public–private partnership
PPTC	Pacific Paramedical Training Centre
PRA	participatory reflection and action; probabilistic risk assessment
PrEP	pre-exposure prophylaxis (for HIV)

PRIME	Program for Improving Mental Health Care
PRSP	Poverty Reduction Strategy Paper
PSAC	Policy Strategy Advisory Committee
PSR	pressure–state–response
PTSD	post-traumatic stress disorder
QA	quality assurance
QALY	quality-adjusted life year
QC	quality control
QWB	quality of well-being
RAE	retinol activity equivalent
RAP	Rapid Assessment Procedure
RARE	Rapid Assessment, Response, and Evaluation
RBM	Roll Back Malaria Partnership
RBP	retinol binding protein
RCT	randomized controlled trial
R&D	research and development
RDA	Recommended Dietary Allowance
RDoC	Research Domain Criteria (U.S.)
REDISSE	Regional Disease Surveillance Systems Enhancement (African program)
REQA	Regional External Quality Assessment
RHU	Refugee Health Unit (Somalia)
RR	relative risk
RSV	respiratory syncytial virus
RTA	regional trade agreement
RUTF	ready-to-use therapeutic food
RWJF	Robert Wood Johnson Foundation
SAARC	South Asian Association for Regional Cooperation
SAM	severe acute malnutrition
SARS	severe acute respiratory syndrome
SD	standard deviation
SDGs	Sustainable Development Goals
SDH	social determinants of health
SDHE	social determinants of health equity
SEA-EU-NET	Southeast Asia–Europe Joint Funding Scheme for Research and Innovation
SFP	supplementary feeding program
SGA	small for gestational age
SIP	sector investment program
SMART	specific, measurable, attainable, relevant, and time bound (objectives)
SPS	Agreement on the Application of Sanitary and Phytosanitary Measures (WTO)
SSB	sugar-sweetened beverage
STEM	science/technology/engineering/mathematics
STEPS	STEPwise approach to Surveillance
STI	sexually transmitted infection
SWAp	sector-wide approach
SWOT	strengths, weaknesses, opportunities, and threats
TAC	Treatment Action Campaign
TB	tuberculosis
TBT	Agreement on Technical Barriers to Trade (WTO)
TCM	traditional Chinese medicine
TDR	WHO-based Special Programme for Research and Training in Tropical Diseases
TEA	total exposure assessment
TEHIP	Tanzania Essential Health Interventions Project
TFC	transnational food company
TFP	therapeutic feeding program
TFR	total fertility rate
THET	Tropical Health and Education Trust
TIA	trade and investment agreement
TNC	transnational corporation
TPP	Trans-Pacific Partnership
TRAP	traffic-related air pollution
TRIPS	Trade-Related Intellectual Property Rights (WTO)
TRL	Transport Research Laboratory
TSH	thyroid-stimulating hormone
TTIP	Transatlantic Trade and Investment Partnership
UCT	unconditional cash transfer
UDHR	Universal Declaration of Human Rights
UHC	universal health coverage
UI	urinary iodine
UK PHRST	U.K. Public Health Rapid Support Team
UN	United Nations
UNAIDS	United Nations Programme on HIV/AIDS
UNAMID	United Nations–African Union Mission in Darfur
UNCED	United Nations Conference on Environment and Development
UNCHR	United Nations Commission on Human Rights

UNCPRD	United Nations' Convention on the Rights of Persons with Disability
UNCTAD	United Nations Conference on Trade and Development
UNDP	United Nations Development Program
UNEP	United Nations Environment Program
UNESCO	United Nations Educational, Scientific and Cultural Organization
UNFPA	United Nations Population Fund
UNGC	United Nations Global Compact
UNHCR	United Nations High Commissioner for Refugees
UNICEF	United Nations Children's Fund
UNISDR	United Nations Office for Disaster Risk Reduction
USAID	U.S. Agency for International Development
USP	*United States Pharmacopoeia*
UV	ultraviolet
UVR	ultraviolet radiation
VA	verbal autopsy
VAT	value-added tax
VVM	vaccine vial monitor
WASH	water, sanitation, and hygiene
WAZ	weight-for-age *z*-score
WCH	women's and children's health
WEIRD	Western, educated, industrialized, rich, and democratic
WFP	World Food Program
WHA	World Health Assembly
WHO	World Health Organization
WHZ	weight-for-height *z*-score
WIPO	World Intellectual Property Organization
WLZ	Weight-for-length *z*-score
WPRO	Western Pacific Regional Office (WHO)
WTO	World Trade Organization
XDR-TB	extremely drug-resistant tuberculosis
YLD	years of life lived with disability
YLL	years of life lost
YP-CDN	Young Professionals Chronic Disease Network
