About the Authors

Michael H. Merson, MD, is the Wolfgang Joklik Professor of Global Health at Duke University. He joined the Duke faculty in November 2006 as the founding director of the Duke Global Health Institute and served in that role through 2017. In addition, Dr. Merson was Vice President and Vice Provost for Global Affairs from 2011 until 2018, and Vice Chancellor for Duke-National University of Singapore Affairs from 2010 until 2016.

Dr. Merson has held leadership positions at the Centers for Disease Control and Prevention and the International Center for Diarrheal Diseases Research, Bangladesh; served as Director of the World Health Organization's Diarrheal and Acute Respiratory Control Programs and Global Program on AIDS; and was the first Dean of Public Health at Yale University. Dr. Merson's research and writings have been primarily on the etiology of diarrheal diseases in low- and middle-income countries, AIDS prevention and policy, and academic global health. He has served as an advisor to a number of international organizations and advisory bodies; is an elected member of the National Academy of Medicine; and has received two honorary degrees and the U.S. Surgeon General's Exemplary Service Medal.

Robert E. Black, MD, MPH, is Professor and Director of the Institute for International Programs of the Johns Hopkins Bloomberg School of Public Health in Baltimore, Maryland. Dr. Black is trained in medicine, infectious diseases, and epidemiology. He has served as a medical epidemiologist at the Centers for Disease Control and Prevention and worked at institutions in Bangladesh and Peru on research related to childhood infectious diseases and nutritional problems. He was Chair of the Department of International Health of the Bloomberg School of Public Health from 1985 to 2013.

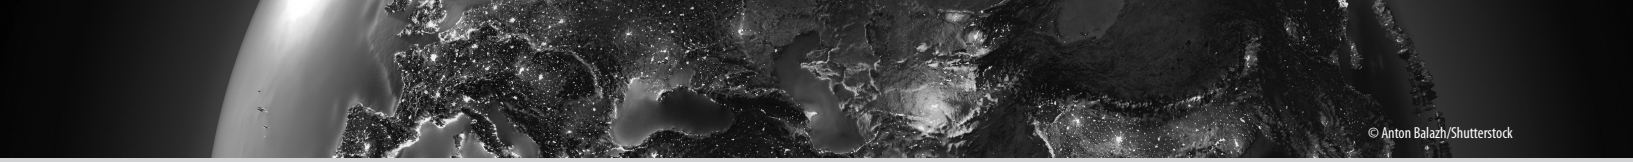
Dr. Black's current research includes field trials of vaccines, micronutrients, and other interventions; effectiveness studies of health programs; and evaluation of preventive and curative health service programs in low- and middle-income countries. In the last 20 years, he has led work that demonstrated the benefits of zinc supplements in prevention and treatment of childhood diarrhea and pneumonia. His other interests are related to the use of evidence in policy and programs, including estimates of the causes of child mortality, the development of research capacity, and the strengthening of public health training.

As a member of the U.S. National Academy of Medicine and advisory bodies of the World Health Organization, the International Center for Diarrheal Diseases Research, Bangladesh, and other international organizations, Dr. Black assists with the development of research and policies intended to improve child health. He chaired the Child Health and Nutrition Research Initiative and serves on the governing boards of Nutrition International and Vitamin Angels. He has more than 700 scientific journal publications. Dr. Black is the recipient of the Programme for Global Paediatric Research Award for Outstanding Contributions to Global Child Health in 2010, the Prince Mahidol Award for Public Health in 2010, the Canada Gairdner Global Health Award in 2011, the Nutrition Leadership Award from Sight and Life in 2013, and the Jimmy and Rosalynn Carter Humanitarian Award in 2016.

Anne J. Mills, PhD, is Deputy Director and Provost of the London School of Hygiene & Tropical Medicine (LSHTM), and Professor of Health Economics and Policy. She has degrees from Oxford University (MA), Leeds University (Diploma), and London University (PhD). After two years as Overseas Development Institute Fellow and Economist in the Ministry of Health in Malawi, she spent three years at the University of Leeds studying health planning in the National Health Service; she moved to the LSHTM in 1979.

Dr. Mills has researched and published widely in the fields of health economics and health systems in low- and middle-income countries and continues to be involved in research on financial protection in South Africa, Tanzania, India, and Thailand. She has had continuing involvement in supporting capacity development in health economics in universities, research institutes, and governments. She has been

involved in numerous policy initiatives, including the World Health Organization's Commission on Macroeconomics and Health. She is a Foreign Associate of the U.S. Institute of Medicine and a Fellow of the U.K. Academy of Medical Sciences. In 2009, Dr. Mills received the Prince Mahidol Award in the field of medicine. In 2013, she was elected a Fellow of the Royal Society; and in 2015, she was made a Dame in the Queen's New Year's Honours, for services to international health.



Foreword

The philosophy, skills, and knowledge essential for global health practice continue to improve with experience. The objective, of course, is the improvement of health for everyone in the world, or global health equity. The means to achieve that objective require harnessing every resource and skill possible in every country. When it comes to health, no country is more important than any other.

The United States has direct experience with the returns of global investment in health. When President Lyndon Johnson provided funds for global smallpox eradication in 1966, the United States had not had a case of smallpox for 17 years. It would have been easy to say this was not an American problem. Yet the investment to eliminate smallpox in the rest of the world had immediate financial benefits because treating Americans with adverse effects caused by the vaccine was no longer necessary. We did not have to tolerate 6 to 8 deaths each year due to the vaccine. And savings were realized in foreign quarantine procedures as well. This country recoups its investment in smallpox eradication every 3 months—more than 150-fold, to date, and it will continue forever, an infinite benefit–cost ratio.

Because of the increasing number of global health programs, health benefits continue to accrue for every country. More than 35,000 deaths are averted each day in children younger than the age of 5, as compared to 60 years ago, when my interest in global health was kindled. In addition to smallpox, we stand at the brink of eradicating Guinea worm disease and polio. The number of measles deaths has declined by more than 95% and, according to the World Bank, 250,000 people move out of poverty every day. It is a miraculous time for global health.

And science marches on, in ways that promise even more benefits in the next decade. Immunization rates are improving, new vaccines are becoming available, and the world is slowly moving to address chronic diseases, environmental health problems, and injury control in larger geographic areas. Even the health problems associated with global warming now engage many countries, including the largest polluters of the environment. Evolution is evident in humanity's responses to its global health problems.

No global health decision stands alone. Instead, such decisions are always dependent on political decisions and compromises. It is difficult enough to gain agreement on a local level, where groups are acquainted and share many experiences. It is many times more difficult to achieve agreement across political and cultural divides. Global health workers are forced to learn diplomatic skills and to understand the art of cross-cultural transactions. Despite such difficulties, some of my best professional memories involve meetings, discussions, and field activities involving people of various cultures and languages. Successful approaches thrive on the shared knowledge of people with different life experiences.

For all of the improvements, there are, nevertheless, areas of concern. The rapid expansion of academic programs in global health presents practical problems for students. We need more teachers who have actually worked in resource-poor situations. I attended a superb tropical public health program 50 years ago, but not a single faculty member had actually lived in tropical areas, although they were frequent consultants to field programs. The training of pediatricians, surgeons, or internists involves hands-on experiences. Likewise, we need to increase the ability of students to have problem-solving experiences in poor areas, while they are still in school.

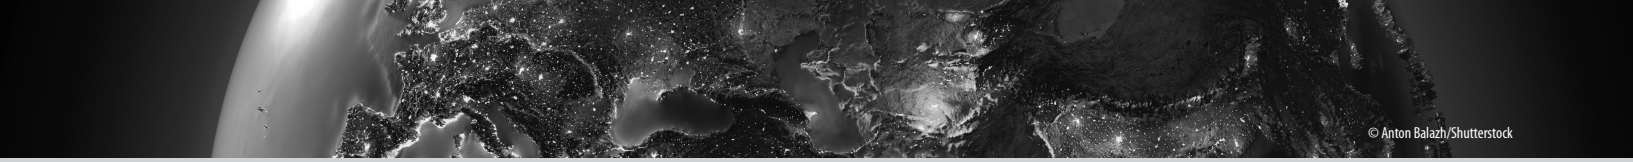
This text also addresses the very real shortcomings of how global health is organized. We are often critical of the World Health Organization (WHO) and other agencies without acknowledging that we organized them to be dysfunctional. WHO has regional offices that can undercut the WHO headquarters decisions because the United States insisted, 70 years ago, on strong regional offices in its attempt to protect the Pan American Health Organization. We imposed the burden of 195 health ministers as WHO's board of directors, and annually tell WHO to reduce its budget. Then we condemn WHO for an inadequate response to the Ebola virus. It is time to ask what has been learned in 70 years and how we can use that experience to

improve our global organizations to better protect the health of all.

Finally, WHO promoted primary health care at the Alma Ata conference 40 years ago, yet we are still struggling to implement village-level interventions and better understand the social determinants of health. This year the world will again come together at a conference in Kazakhstan to recommit to strengthening primary health care in order to achieve universal health coverage and the Sustainable Development Goals. No risk factor is as great as poverty. Nevertheless, while progress *is* being made and the World Bank has championed the cause, deliberate action to reduce poverty is still an underdeveloped tool in the daily lives of health departments in every country. Moreover, keeping people healthy helps to keep them productive. The world will not be a great place for any of us until it is a great place for all of us.

Drs. Merson, Black, and Mills have again brought us a comprehensive text that helps to make sense of an enlarging and challenging field. It is an enormously valuable guide for students, teachers, practitioners, and researchers alike, which helps to map out the journeys of those who will change the future and make our planet a healthier one.

William Foege
Professor Emeritus, Rollins School of Public Health,
Emory University



Introduction

Michael H. Merson, Robert E. Black, and Anne J. Mills

The three of us are privileged to serve as faculty at universities that provide education every year to hundreds of graduate and undergraduate students motivated to learn about global health issues and challenges. Many of these students plan to or have already begun careers in global health research, policy, practice, teaching, or administration. This text is written for these students around the world, as well as for those who teach and mentor them. In this Introduction, we define global health, provide a brief history of the field, and summarize its many accomplishments and challenges. We then explain how we put this *Fourth Edition* together and how we think it can best be used.

What Is Global Health?

Global health is a burgeoning field, which has seen a major surge of interest as an area of academic study in the last decade. Essentially, global health has replaced international public health in both concept and reality. International public health focuses on the application of the principles of public health to health problems and challenges that affect low- and middle-income countries (LMICs) and to the complex array of global and local determinants that influence them. Global health maintains this focus, but places much greater emphasis on health issues that concern many countries or that are affected greatly by transnational determinants, such as climate change or urbanization. This greater emphasis on the scope and location of health problems provides the opportunity to address cross-border issues as well as domestic health disparities in high-income countries.

While international public health primarily applies the principles of public health, there is now agreement that success and progress in improving health around the world requires a multidisciplinary and interdisciplinary approach that includes, yet extends beyond, public health. Professionals from many disciplines and academic fields possess the skills and knowledge needed to understand the various determinants of health and develop strategies that will address these determinants, thereby sharing goals to improve the health of populations. These disciplines and professional fields include social and behavioral sciences (including sociology, economics, psychology, anthropology, political science, and international relations), biomedical and environmental sciences, engineering, business and management, public policy, law, history, and divinity. Furthermore, while efforts to reduce health disparities should focus on prevention, treatment, care, and curative strategies must also be addressed when developing solutions to global health challenges. This call for multipronged action further emphasizes the need for a multidisciplinary approach.

In addition, while social justice must continue to be a central pillar of health, the approach to achieving health equity and finding solutions to reducing health disparities must now much more strongly emphasize global cooperation. Rather than following a model that transfers ideas and resources from high-income countries, organizations, or funding agencies to low- and middle-income settings, it is imperative to pursue "a real partnership, a pooling of experience and knowledge, and a two-way flow between developed and developing countries" when implementing health interventions or programs (Koplan et al., 2009, p. 1995).

Today we live in an increasingly connected world, but the challenges to reduce health disparities are considerable, and the tenets of global health provide a unique insight and strategic approach to addressing them. Given this evolution in our thinking, there has been an understandable interest in defining global health. In 1997, the U.S. Institute of Medicine (IOM) released a report that broadly defined global health as "health problems, issues, and concerns that transcend national boundaries, may be influenced by circumstances or experiences in other countries, and are best addressed by cooperative actions and solutions" (Board on International Health, 1997, p. 1). More than 10 years later, IOM amended its definition, describing

global health "not just as a state but also as the *goal of improving health for all people by reducing avoidable disease, disabilities, and deaths*" (Committee on the U.S. Commitment to Global Health, 2009, p. 5).

Although a number of other definitions for global health have been proposed, we prefer the definition of global health that was adopted by the Consortium of Universities for Global Health (CUGH). CUGH was formed to promote, facilitate, and enhance the growth of global health as an academic field of study. It has defined global health as follows:

> [A]n area for study, research, and practice that places a priority on improving health and achieving equity in health for all people worldwide. Global health emphasizes transnational health issues, determinants, and solutions; involves many disciplines within and beyond the health sciences and promotes interdisciplinary collaboration; and is a synthesis of population-based prevention with individual-level clinical care. (Koplan et al., 2009, p. 1995)

When providing this definition, an effort was made to explain the differences between public health, international health, and global health. While these terms certainly share areas of overlap, this comparison helps to draw out global health's distinctive qualities. (**EXHIBIT I-1**).

A Brief History of Global Health

Tracing the roots of global health brings us to the history of international public health. This history encompasses the origins of public health and can be viewed as the story of how populations experience health and illness; how social, economic, and political systems create the possibilities for healthy or unhealthy lives; how societies create the preconditions for the production and transmission of disease; and how people, both as individuals and as social groups, attempt to promote their own health or avoid illness (Rosen & Morman, 1993). A number of authors have documented this history (Arnold, 1988; Basch, 1999; Leff & Leff, 1958; Rosen & Morman, 1993; Winslow & Hallock, 1933). A brief history is presented here primarily to provide a perspective for the challenges that face us today (**EXHIBIT I-2**).

The Origins of Public Health

It is difficult to select a date for the origins of the field of public health. Some would begin with Hippocrates, whose book *Airs, Waters, and Places*, published around

EXHIBIT I-1 Global Health, International Health, and Public Health

Global Health	International Health	Public Health
Focuses on issues that directly or indirectly impact health but can transcend national boundaries.	Focuses on health issues of countries *other* than one's own, especially those of LMICs.	Focuses on issues that impact the health of the *population* of a particular community or nation.
Development and implementation of solutions often require global cooperation.	Development and implementation of solutions usually involve binational cooperation.	Development and implementation of solutions usually do not involve global cooperation.
Embraces both prevention in populations and clinical care of individuals.	Embraces both prevention in populations and clinical care of individuals.	Mainly focused on prevention programs for populations.
Health equity among nations and for all people is a major objective.	Seeks to help people of other nations.	Health equity within a nation or community is a major objective.
Highly interdisciplinary and multidisciplinary within and beyond health sciences.	Embraces but has not emphasized multidisciplinarity.	Encourages multidisciplinary approaches, particularly within health sciences and with social sciences.

EXHIBIT I-2 History of Global Health: A Summary

400 BC: Hippocrates presents the causal relationship between environment and disease.

First century AD: Romans introduce public sanitation and organize a water supply system.

14th century: The "Black Death" (bubonic plague) leads to quarantine and *cordon sanitaire*.

Middle Ages: Colonial expansion spreads infectious diseases around the world.

1750–1850: The Industrial Revolution results in extensive health and social improvements in cities in Europe and the United States.

1850–1910: Knowledge about the causes and transmission of communicable diseases is greatly expanded.

1910–1945: Significant reductions in child mortality occur. Schools of public health and international foundations and intergovernmental agencies interested in public health are established.

1945–1990: The World Bank, World Health Organization (WHO), and other United Nations agencies are created. WHO eradicates smallpox. The Alma Ata conference gives emphasis to primary health care. The HIV/AIDS pandemic begins. The United Nations Children's Fund (UNICEF) leads efforts to ensure universal childhood immunization. Greater attention is given to noncommunicable diseases (NCDs).

1990–2000: Priority is given to health-sector reform, the impact of and responses to globalization, cost-effectiveness, and public–private partnerships in health.

2000–2010: Priority is given to equity, social determinants of health, health and development, use of innovative information and communications technologies, declaration of the Millennium Development Goals (MDGs), and response to influenza.

2010–2020: Priority is given to climate change's impact on health, growing burden of NCDs, increasing threat of emerging and re-emerging diseases, global health security, universal health coverage, proliferation of innovative technologies for delivery of prevention and care services, and the declaration of the Sustainable Development Goals (SDGs).

400 BC, was the first systematic effort to present the causal relationships between environmental factors and disease and offer a theoretical basis for an understanding of endemic and epidemic diseases. Others would cite the introduction of public sanitation and an organized water supply system by the Romans in the first century AD. Many would select the bubonic plague ("Black Death") pandemic of the 14th century, which began in Central Asia; was carried on ships to Constantinople, Genoa, and other European ports; and then spread inland, killing 25 million persons in Europe alone. In responding to this devastating infectious disease, the Great Council of the city of Ragusa (now Dubrovnik, Croatia) followed a contagion theory, which recommended the separation of healthy and sick populations; it issued a document stating that outsiders entering the city must spend 30 days in the restricted location of nearby islands (Stuard & NetLibrary, 1992). The length of time for this isolation period, dubbed *trentino*, was eventually increased from 30 to 40 days, introducing the concept of the modern quarantine (Gensini, Yacoub, & Conti, 2004).

The Middle Ages was also the period when many cities in Europe, particularly through the formation of guilds, took an active part in establishing hospitals and other institutions to provide medical care and social assistance. At the same time, many European countries began to expand their horizons abroad, by exploring and colonizing new lands. The travelers brought some diseases with them (e.g., influenza, measles, smallpox), and those who settled in these colonial outposts were forced to confront diseases that had never been seen in Europe (such as syphilis, dysentery, malaria, and sleeping sickness). European explorers also carried pathogens from one part of Africa to another, and from one area of the globe to another (e.g., from Africa to North America through the slave trade). On long voyages, the greatest enemy of the sailor was often scurvy—at least until 1875, when the British government issued its famous order that all men-of-war should carry a supply of lemon juice as a preventive measure.

The Age of Enlightenment (1750–1830) was a pivotal period in the evolution of public health. It was a time of social action in relation to health, as reflected by the new interest taken in the health problems of specific population groups. During this period, rapid advances in technology led to the development of factories. In England and elsewhere, this industrialization was paralleled by expansion of the coal mines. The Industrial Revolution had arrived. During this period,

sanitaire the populations of the cities of England and other industrialized nations grew enormously, with overcrowded, unsanitary conditions in these urban areas leading to outbreaks of cholera and other epidemic diseases, which ultimately resulted in high rates of child mortality. Near the end of this period, significant efforts were made to address these problems. Improvements were made in urban water supplies and sewerage systems, municipal hospitals arose throughout cities in Europe and the east coast of the United States, laws were enacted limiting children's ability to work, and data on deaths and births began to be systematically collected in many places.

As industrialization continued, it became obvious that more efforts to protect the health of the public were needed. These changes occurred first in England, regarded as the first modern industrial country, through the efforts of the noted social reformer Edwin Chadwick. Beginning in 1832, he headed up the royal Poor Law Commission, which undertook an extensive survey of health and sanitation conditions throughout the country. The work of this commission led in 1848 to the Public Health Act, which created a General Board of Health that was empowered to appoint local boards of health and medical officers of health to deal effectively with public health problems. The impact of these developments was felt throughout Europe and especially in the United States, where it stimulated creation of health departments in many cities and states.

Cholera, which in the first half of the 19th century spread in waves from South Asia to the Middle East and then to Europe and the United States, did the most to stimulate the formal internationalization of public health. The policy of establishing a *cordon sanitaire*—an action applied by many European nations in an effort to control the disease—had become a major restraint on trade, necessitating an international agreement. In 1851, the First International Sanitary Conference was convened in Paris to discuss the role of quarantine in the control of cholera, plague and yellow fever, which were causing epidemics throughout Europe. Although no real agreement was reached, the conference laid the foundations for international cooperation in health.

The latter part of the 19th century was distinguished by the enormous growth of knowledge in the area of microbiology, as exemplified by Louis Pasteur's proof of the germ theory of disease, Robert Koch's discovery of the tubercle bacillus, and Walter Reed's demonstration of the role of the mosquito in transmitting yellow fever. Between 1880 and 1910, the etiologic causes and means of transmission of many communicable diseases were discovered in laboratories in North America and Europe. The development of this knowledge base was paralleled by related discoveries in the sciences of physiology, metabolism, endocrinology, and nutrition. Dramatic decreases were soon seen in child and adult mortality thanks to improvements in social and economic conditions, discovery of vaccines, and implementation of programs in health education. The way was now clear for the development of public health administration based on a scientific understanding of the principles involved in the transmission of communicable diseases.

The first two decades of the 20th century witnessed the establishment of three formal intergovernmental public health bodies: the International Sanitary Bureau to serve nations in the western hemisphere (in 1904); l'Office Internationale d'Hygiene Publique in Paris, which was concerned with prevention and control of the main quarantinable diseases (in 1909); and the League of Nations Health Office (LNHO) in Geneva, Switzerland, which provided assistance to countries on technical matters related to health (in 1920). In 1926, LNHO commenced publication of *Weekly Epidemiological Record*, which evolved into a weekly publication of the World Health Organization (WHO) and still is published today. LNHO also established many scientific and technical commissions, issued reports on the status of many infectious and chronic diseases, and sent its staff around the world to assist national governments in dealing with their health problems.

In North America and countries in Europe, the explosion of scientific knowledge in the latter part of the 19th century and the belief that social problems could be solved stimulated universities, such as Johns Hopkins, to establish schools of public health. In France, public subscriptions helped to fund the Institut Pasteur (named in honor of Louis Pasteur) in Paris, which subsequently developed a network of institutes throughout the francophone world that produced sera and vaccines and conducted research on a wide variety of tropical diseases. Another significant development during this period was the founding of the Rockefeller Foundation (in 1909) and its International Health Commission (in 1913). During its 38 years of operation, the commission cooperated with many governments in campaigns against endemic diseases such as hookworm, malaria, and yellow fever. The Rockefeller Foundation also provided essential financial support to help establish medical and public health schools around the world; and later international health programs in a number of American and European

schools of medicine and public health. All of these developments were paralleled by the development and strengthening of competencies in public health among the militaries of the United States and the countries of Europe, stimulated in great part by the buildup to and realities of World War I. Following the war, there was increasing recognition that much ill health in the colonial world was not easily solvable with medical interventions alone, but rather was intractably linked to malnutrition and poverty.

Some historians would date the beginning of international public health to the end of World War II. The ending of European colonialism, the need to reconstruct the economies of the United States and the countries of Western Europe, and the rapid emergence of newly independent countries in Africa and Asia were all forces that led to the creation of many new intergovernmental organizations. The United Nations Monetary and Financial Conference, held in Bretton Woods, New Hampshire, in 1944 and attended by representatives from 43 countries, resulted in the establishment of the International Bank for Reconstruction and Development (more commonly known as the World Bank) and the International Monetary Fund. The former initially lent money to countries only at prevailing market interest rates, but in 1960 it began to provide loans to poorer countries at much lower interest rates and with far better terms through its International Development Association. It was not until the early 1980s, however, that the World Bank began to accelerate greatly its provision of loans to countries for programs in health and education. By the end of that decade, these loans had become the greatest source of foreign assistance to LMICs (Ruger, 2005).

In the decade after World War II, many other United Nations organizations (e.g., UNICEF) and specialized agencies (such as WHO) were formed to assist countries in strengthening their health, social, and economic sectors. In addition, most of the wealthier industrialized countries established agencies or bureaus that funded bilateral projects in specific LMICs. Among the historical colonial powers, such assistance was most often provided to their former colonies.

Many of the international health efforts in the 1960s and 1970s were dedicated to the control of specific diseases. A global effort to control malaria was hampered by a number of operational and technical difficulties, including the vector's increasing resistance to insecticides and the parasite's resistance to available antimalarial drugs. In contrast, the campaign to eradicate smallpox, led by WHO, successfully eliminated the disease in 1981 and stimulated the establishment of the Expanded Program on Immunization, which focused on the delivery of effective vaccines to infants. Also, during the 1970s, two large international research programs were initiated under the co-sponsorship of various United Nations agencies: The Special Program for Research on Human Reproduction (focusing on development and testing of new contraceptive technologies) and the Tropical Disease Research Program (providing support for the development of better means of diagnosis, treatment, and prevention of six tropical diseases, including malaria). Greater attention also was gradually given to chronic diseases, commonly known as noncommunicable diseases (NCDs), such as cardiovascular and cerebrovascular diseases and cancer.

In 1978, WHO organized a conference in Alma Ata in the former Soviet Union that prioritized the delivery of primary healthcare services and set the goal of "health for all by the year 2000." Rather than focusing solely on control of specific diseases, this conference called for international efforts to strengthen the capacities of LMICs to extend their health services to populations with poor access to prevention and care. The concerns of tropical medicine, which were concentrated on the infectious diseases of warm climates, were replaced by an emphasis on the provision of health services to reduce morbidity and premature mortality in resource-poor settings (De Cock, Lucas, Mabey, & Parry, 1995). Given the limited financial and managerial capacities of many governments, increased attention was paid to the role of nongovernmental organizations (NGOs) in providing these services. As a result, many mission hospitals, particularly in sub-Saharan Africa, expanded their activities in their local communities, the number of local NGOs began to increase, and a number of international NGOs (e.g., Save the Children, Oxfam, Médecins Sans Frontières) greatly expanded their services, often with support from bilateral agencies. Disease-specific efforts—most notably UNICEF's Child Survival Program, with its acronym GOBI (growth charts, oral rehydration, breastfeeding, immunization) and its goal of universal childhood immunization by 1990—were seen by many as programs that both focused on specific health problems and provided a means of strengthening health systems.

The emergence of what is sometimes called "the new public health" was heralded by the Ottawa Charter of 1986, which was meant to provide a plan of action to achieve the "health for all" targets set forth at Alma Ata. The Ottawa Charter pioneered the

definition of health as a resource for development, rather than merely a desirable outcome of development. The prerequisites for health that were outlined in the charter were diverse and included peace, shelter, education, food, income, a stable ecosystem, sustainable resources, social justice, and equity. Moreover, the charter emphasized the importance of structural factors that affect health on a societal level, rather than focusing only on the risk behaviors of individuals. It called on the worldwide health community to address health disparities by engaging and enabling people to take charge of their health at community and policy-making levels. This shift from a "risk behavior" focus to an emphasis on "risk environment" continues to resonate in contemporary public health practice and research.

One hugely influential development in the 1980s was the onset of the human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) pandemic. By the time a simple laboratory test to detect HIV was discovered in 1985, more than 2 million persons in sub-Saharan Africa had been infected. In 1987, WHO formed the Global Programme on AIDS, which within 2 years became the largest international public health effort ever established, with an annual budget of $90 million and 500 staff working in Geneva, Switzerland, and in more than 80 LMICs. In 1995, with some 20 million persons infected with HIV (mostly living in LMICs), and with the understanding that the pandemic could be brought under control only through a multisectoral effort, the program was transformed into a joint effort of UN agencies known as the Joint United Nations Programme on HIV/AIDS (UNAIDS). The global response to HIV/AIDS helped to shape the field of global health from its emphasis on intersectoral collaboration, health and human rights, global advocacy for health, and focus on prevention and treatment.

The Origin and Growth of Global Health

The end of the Cold War ushered in dramatic changes that stimulated the development of the new concept of global health. Major shifts in political and economic ideologies led to a reconsideration of the role of governments, including how they should finance and deliver public services. Greater attention was given to increasing the role of civil society and the private sector in achieving universal health coverage. Indeed, global health as it relates to health systems in the last decade of the 20th century and the first two decades of the 21st century can be characterized by its emphasis on health-sector reform, cost-effectiveness as an important principle in the choice of interventions, and public–private partnerships in health, paralleled by a rapid expansion of innovative technologies.

Although rising incomes have long been known to improve health status, increased attention has been paid to the relationship between health and poverty, and the importance of a healthy population for achieving economic development. Participation of sectors other than the health sector is now viewed as essential for achieving a healthy population. More and more countries are experiencing the demographic transition to societies with rapidly increasing numbers of middle-aged and older adults, and in turn are being challenged with providing preventive and care services that address health problems of both the poor and the wealthy simultaneously. Increasing life expectancy, urbanization, and resultant changing lifestyles have contributed to an ever-increasing burden of NCDs. India and China, for example, now have high rates of cardiovascular disease, stroke, and diabetes. Not surprisingly, issues regarding equity in the availability of drugs and vaccines and in access to other technological advances have drawn greater attention. Healthy populations are also now viewed as essential for domestic security.

The first decade of the 21st century witnessed the addition of new multifaceted and complex issues to the list of global health challenges—among them, human migration and displacement, bioterrorism, emerging pathogens, climate change, and disaster preparedness. It was within this context that the United Nations General Assembly adopted the Millennium Declaration in September 2000 as a set of guiding principles and key objectives for international cooperation. The declaration underscored the need to address inequities that have been created or worsened by globalization, and to form new international linkages to achieve and protect peace, disarmament, poverty eradication, gender equality, a healthy environment, human rights, and good governance. The goals dealing specifically with development and poverty eradication become known as the Millennium Development Goals (MDGs); three of them pertained primarily to health (shown in bold in **EXHIBIT I-3**). In addition, Goal 1 included reduction in childhood undernutrition. All 191 member states of the UN pledged to meet the MDGs by 2015.

Building on the achievements of the MDGs (covered later), as well as learning from their limitations, the United Nations adopted the 2030 Agenda for Sustainable Development in 2015. Central to this agenda are the SDGs which comprise 17 goals, 169 associated

EXHIBIT I-3 Millennium Development Goals

1. Reduce extreme poverty and hunger by one-half
2. Achieve universal primary education
3. Promote gender equality and empower women
4. **Reduce under-5 mortality by two-thirds**
5. **Reduce maternal mortality by three-fourths**
6. **Reverse the spread of HIV/AIDS, malaria, tuberculosis, and other major diseases**
7. Ensure environmental sustainability
8. Develop a global partnership for development, with targets for aid, trade, and debt relief

EXHIBIT I-4 Sustainable Development Goals

Goal 1: End poverty in all its forms everywhere
Goal 2: End hunger, achieve food security and improved nutrition, and promote sustainable agriculture
Goal 3: Ensure healthy lives and promote well-being for all at all ages
Goal 4: Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all
Goal 5: Achieve gender equality and empower all women and girls
Goal 6: Ensure availability and sustainable management of water and sanitation for all
Goal 7: Ensure access to affordable, reliable, sustainable, and modern energy for all
Goal 8: Promote sustained, inclusive, and sustainable economic growth, full and productive employment, and decent work for all
Goal 9: Build resilient infrastructure, promote inclusive and sustainable industrialization, and foster innovation
Goal 10: Reduce inequality within and among countries
Goal 11: Make cities and human settlements inclusive, safe, resilient, and sustainable
Goal 12: Ensure sustainable consumption and production patterns
Goal 13: Take urgent action to combat climate change and its impacts
Goal 14: Conserve and sustainably use the oceans, seas, and marine resources for sustainable development
Goal 15: Protect, restore, and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, halt and reverse land degradation, and halt biodiversity loss
Goal 16: Promote peaceful and inclusive societies for sustainable development, provide access to justice for all, and build effective, accountable, and inclusive institutions at all levels
Goal 17: Strengthen the means of implementation and revitalize the global partnership for sustainable development

targets, and 230 indicators to guide global sustainable development through to 2030; the goals are shown in **EXHIBIT I-4**. The SDGs seek a more integrated approach to address the challenges of an increasingly global and integrated world. While there is only one health-specific goal—Goal 3: "Good health and well-being"—it has 13 associated targets and there are many linkages between health and the other SDGs and associated targets. For example, Goal 2 includes elimination of nutritional deficiencies. Achieving the SDGs will require consistent monitoring and evaluation and both global and national commitment.

In the years since the previous edition of this text was published, there have been a number of noteworthy successes in global health, partly due to the MDGs. Notably, substantial progress was made in achieving the three health-related MDG goals cited earlier. First, mortality among children younger than age 5 dropped 56%, from 12.6 million deaths in 1990 to 5.6 million deaths in 2016 (WHO, 2017a). Second, maternal mortality worldwide decreased by 44% between 1990 and 2015 (WHO, 2016b). Third, there was an almost 26% reduction in malaria deaths between 2006 and 2016 (Global Burden of Disease [GBD] Causes of Death Collaborators, 2017). In addition, in 2016, the number of people who were infected annually with HIV declined to 1.8 million—a more than 50% reduction since 1996, when there were 3.5 million new infections. The number of AIDS-related deaths fell by 48% (to 1 million deaths) since the peak in 2005 (UNAIDS, 2017a. In addition, for the first time since the eradication of smallpox, we are

on the verge of eliminating another major global disease from the world: 2017 saw the lowest case count of polio in recorded history (Polio Global Eradication Initiative, 2017).

The recent successes in fighting malaria and HIV/AIDS are attributable in great part to the expansion of access to treatment, financed primarily by the Global Fund to Fight AIDS, Tuberculosis and Malaria (the Global Fund), and the President's Emergency Plan for AIDS Relief (PEPFAR). Moreover, the Global Fund's performance-based funding and decision-making processes have made important contributions to the practice of aid, particularly in encouraging management for results, participation of civil society, mutual accountability, and broad-based country and local ownership.

Current Challenges in Global Health

We have witnessed major improvements in the health of populations over the past century, with the pace of change increasing rapidly in LMICs since the Bretton Woods Conference. Global health—and, more broadly, an improved understanding of how social, behavioral, economic, and environmental factors influence the health of populations—has contributed to these improvements to a greater extent than expanded access to medical care. Nevertheless, these improvements have not been universal, disparities between rich and poor both between and within countries remain, and the challenges of global health have never been greater.

Despite recent progress, we still have far to go in terms of maternal and child health. Millions of children still die before reaching the age of 5 due to diseases that could be simply and affordably prevented and treated (UNICEF, 2016). Hundreds of thousands of women continue to die annually from preventable complications of pregnancy and childbirth, and most of these deaths occur in LMICs (WHO, 2016b).

> Infectious diseases—once thought to have been vanquished as major killers—have emerged or reemerged around the world as top threats to health and well-being. Despite recent progress, the AIDS pandemic is far from over. In particular, prevention efforts need to be targeted toward vulnerable populations who are still at high risk for HIV/AIDS, such as girls and young women in sub-Saharan Africa—a population that accounts for more than 70% of new HIV infections among adolescents. (USAID, 2017)

We have seen infectious diseases travel from endemic regions to previously unaffected areas (e.g., Zika virus), and others newly emerge. The 2013-2016 Ebola outbreak in West Africa was an alarming wake-up call regarding the danger of epidemics in urban areas and the frail state of our global health security. The underlying causes of many emerging infectious diseases can be traced to human-initiated social and environmental changes, including climatic and ecosystem disturbances, trends in food consumption and production, close proximity of humans and animals in household settings, and unsafe medical practices (Kuiken, Fouchier, Rimmelzwaan, & Osterhaus, 2003). This relationship has given rise to the disciplines of One Health, an approach that seeks to address and mitigate the effects on health arising from the interfaces between humans, animals, and environments (Gibbs, 2014) and Planetary Health, which studies the health of human civilizations and the systems—political, economic, and social—on which they depend (The Lancet Planetary Health, 2017). Furthermore, globalization forces, including increased trade and movement of people, have led to far greater opportunities for infectious disease to spread around the world quickly, as evidenced by the severe acute respiratory syndrome (SARS) epidemic in 2002–2003. In 2012, an estimated 12.6 million deaths were attributable to environmental factors, many of which were related to effects of climate change (Pruss-Ustun, Wolf, Corvalan, Bos, & Neira, 2016). Other health consequences of climate change and environmental biodegradation will be experienced through increased water and food insecurity, extreme climactic events, displaced populations, and vulnerable human settlements (Jamison et al., 2013). Resistance to antibiotics is also rising among populations around the globe, making infections harder and more expensive to treat and threatening the gains we have made in combatting infectious diseases.

NCDs were once considered a problem afflicting only high-income nations whose populations had achieved long life expectancies. Today, NCDs are the leading causes of death worldwide; they accounted for more than 70% of global deaths in 2016, an increase of 16% since 2006 (GBD Causes of Death Collaborators, 2017). Ischemic heart disease and stroke are the leading causes of death globally, accounting for 15 million deaths in 2015 (WHO, 2017b). The rise of

NCDs is especially apparent in LMICs, where 78% of global NCD deaths occurred in 2015 (WHO, 2017b). Globalizing forces that have imported Western lifestyle habits, such as increased trade and trade liberalization, tobacco use, and increased consumption of processed foods, have fueled these disease trends. In addition, despite the high burden imposed by mental illness, and especially depressive disorders, and the high percentage of global disability and mortality attributable to them, only recently have these disorders been given the attention they deserve (Summergrad, 2016). As a result of the overall increase in all types of NCDs and the lingering problem of infectious diseases, many LMICs face a double burden of disease, putting more strain on their already frail healthcare systems.

The importance of improving the performance of health systems to achieve reductions in mortality and morbidity has become widely accepted, including the need to address the global health workforce crisis (WHO, 2006). Health systems need adequate resources to meet the changing and growing needs of the populations they serve. An estimated 40 to 50 million new health and social care workers will be needed by 2030 to reach the SDGs, 18 million of whom are needed in LMICs (WHO, 2016a). WHO has identified the critical need to strengthen health systems so as to fight poverty, foster development, and maintain and improve the health of people around the world. It has set the goal of achieving universal health coverage, meaning that all persons can access needed health services of sufficient quality to be effective and not cause financial hardship. As the world faces increasing threats from emerging and re-emerging infectious diseases, strong basic healthcare systems will also be essential to support global health security and to avoid crippling national and global pandemics (Horton, 2018).

One means for expanding access to health services has been the use of mobile phone technology. By 2021, 5.5 billion people are predicted to have access to mobile phones, and more people in Africa will have access to mobile phones than to running water (Thornton, 2017). Mobile phone initiatives are now aimed at improving healthcare services in many countries, as they are increasingly being used for disaster management, reminders for people to get vaccinations, health screening tests, and social marketing. Emerging drone technology also has been harnessed to improve access to health care by transporting blood, contraceptive products, and medical supplies to remote areas, or during natural disasters. These technologies, and others like them, will surely play a pivotal role in the future of global health.

In recent years, the growth in the number of refugees and displaced persons around the world has been startling. By the middle of June 2017, more than 65 million people had been forced to leave their homes (United Nations High Commissioner for Refugees, 2017)— the highest number recorded in 70 years (Mohammadi, 2016). In addition to humanitarian and economic repercussions, this population upheaval puts displaced populations at increased risk for both infectious and NCDs due to overcrowding, poor sanitation, and lack of access to health care, and overburdens the health systems in the refugees' host countries.

There is a broad consensus that poverty is the most important underlying cause of preventable death, disease, and disability on a global level. While the number of people living in poverty remains unacceptably high, progress has been made in reducing the global poverty rate: 10.7% of the world population lived below the poverty line in 2013, compared to 42% in 1981 (*The Economist*, 2017). This progress has been partly due to advances made in literacy, access to housing, safe water, sanitation, food supplies, and urbanization. Even so, 50% of the world's extremely poor live in sub-Saharan Africa (Hollenhorst, 2016), reflecting the particular challenges of social and economic development in that region.

Meeting the global health challenges we face today and in the future will require new forms of financing and cooperation. Changing global economies have altered traditional global health funding mechanisms. Contributions to health assistance from donor countries have more or less flattened in recent years, while LMICs are rightfully taking on more responsibility for financing their domestic health sector due in part to the increasing economic growth in these countries. In 2015, for example, domestic resources accounted for 57% of total HIV/AIDS funding (UNAIDS, 2017b). However, many low-income countries are far from being able to raise enough domestic revenue to replace development assistance for health. International and intersectoral cooperation between UN agencies with an established health role, other international bodies such as the World Trade Organization, regional bodies such as the European Union, bilateral agencies, NGOs, foundations, and the private sector, including pharmaceutical companies, will need to be enhanced. Global organizations such as the Bill & Melinda Gates Foundation, the Global Fund, and GAVI, the Vaccine Alliance, have taken on significant leadership roles and in many cases have surpassed the older,

more traditional actors in global health governance. These organizations have not only injected significant amounts of funds into the global system, but also brought a new, more informal and personal style of operation. Ensuring the ideal structure, effective functioning, and financing of this global health system will itself be an enormous challenge for the next decade of global health (National Academies of Sciences, Engineering, and Medicine, 2017).

Use and Content of This Text

This text has been prepared with future global health challenges foremost in mind. Its focus is on diseases, programs, health systems, and health policies in LMICs, making reference to and using examples from the United States, Western Europe, and other high-income countries as appropriate.[1] Individual chapters present information on health issues that transcend national boundaries and are of concern to many countries.

Our intent has been, first and foremost, to provide a text for graduate students from various disciplines and professions who are studying global health. Given its broad range of content, the text as a whole may serve as the main source for an introductory graduate course on global health. Experience with the previous editions has shown that it also can be used as a reference text for undergraduate courses in global health. Alternatively, some chapters (or parts of chapters) can be used in graduate or undergraduate courses dedicated to more specific subjects and topics. Ideally, students who use the text in this way will be stimulated to explore other chapters once they have read the assigned material. Moreover, the text can serve as a useful reference for those already working in the field of global health in government agencies, health and development agencies, NGOs, or the private sector.

Because of the many dynamic areas and subjects we wanted to cover, we chose to prepare an edited text. We selected content experts for each chapter rather than presuming to have the expertise to write the entire text ourselves. We recognize that an edited text has its shortcomings, such as some inconsistencies in style and presentation and occasional overlap in chapter content. We have done our best to limit these disadvantages, and hope the reader will agree that those that remain are a small price to pay for fulfilling our goal of providing the reader with the highest-quality content.

Another consequence of the dynamic nature of global health is the occasional difficulty in providing the most up-to-date epidemiologic information on all causes of mortality and morbidity. To assist the reader in obtaining this information, we have provided salient references in various chapters, including internet resources.

This is the fourth edition of the text. In planning its preparation, we sought advice on how to improve it from those who prepared chapters in the first three editions, as well as from faculty in various countries who were using the text in their courses; we also examined important current and emerging trends in global health. The text has 21 chapters, including four new chapters that have been added in response to feedback from these reviewers.

The first four chapters set the background. The *Measures of Health and Disease in Populations* chapter reviews the importance of using quantitative indicators for decision making in health. It presents the latest developments in the measurement of health status and the global burden of disease, including the increasing use of composite measures of health that combine the effects of disease-specific morbidity and mortality on populations. It then reviews current estimates and future trends in selected countries and regions, as well as the global burden of disease.

The *Culture, Behavior, and Health* chapter examines the social, cultural, and behavioral parameters that are essential to understanding public health efforts. This chapter describes key concepts in the field of anthropology, particularly as they relate to health belief systems. It presents theories of health behavior that are relevant to behavior change with examples of specific national and community programs in various areas of health. The importance of combining qualitative and quantitative methodologies in measuring and assessing health status and programs is emphasized.

The 1946 WHO constitution established that "the highest attainable standard for health as a fundamental right of every human being" (WHO, 2014, p. 1). The *Global Health, Human Rights and Ethics* chapter is new to this edition of the text in recognition of the inextricable link between human rights and health.

[1]A classification of countries can be found on the World Bank's website: https://datahelpdesk.worldbank.org/knowledgebase/topics/19280-country-classification.

It begins by defining global health in the context of human rights and ethics and by describing the importance of these concepts in global health approaches. Ebola, Zika, HIV/AIDS, and sugar-sweetened beverages are used as case studies to explore the role of human rights and ethics in a global health response. Finally, the chapter discusses the many challenges faced in implementing these approaches.

Addressing the underlying causes of ill health that stem from complex social, political, historical, economic, and environmental factors is crucial to improving health and addressing health inequity.

The *Understanding and Acting on Social Determinants of Health and Health Equity* chapter presents and explains these determinants. It focuses on the development and application of conceptual frameworks for understanding the social determinants of health, the implications of social determinants on health systems and services, the role of social determinants of health in an increasingly globalized world, and the importance of evaluating actions that address social determinants and health equity.

The next three chapters are devoted to the three greatest public health challenges traditionally faced by LMICs: reproductive health, infectious diseases, and nutrition. Reproductive health has long been addressed primarily through family planning programs directly intended to reduce fertility, and through programs that prevent sexually transmitted infections. The *Reproductive Health* chapter presents more current views of this area that broaden the concept to include empowerment of women in making decisions about their health and fertility. It provides information on population growth and demographic changes around the world, reviews how women control their fertility, indexes the effects of various social and biological determinants of fertility, and examines the impact of family-planning services and programs.

Collectively, infectious diseases have historically been the most important causes of premature mortality and morbidity in LMICs. The *Infectious Diseases* chapter presents the descriptive epidemiologic features and available prevention and control strategies for the infectious diseases that are of greatest public health significance in these countries today—namely, vaccine-preventable diseases; diarrhea and acute respiratory infections in children; tuberculosis, influenza, malaria, and other parasitic diseases; HIV/AIDS and other sexually transmitted diseases; and emerging infectious diseases and new disease threats, including Zika and Ebola. The chapter also addresses concerns about antimicrobial resistance. Examples of successful control programs are described, as are the challenges and obstacles that confront LMICs in implementing them.

Nutritional concerns in LMICs are diverse, ranging from deprivation and hunger to consequent deficiencies in health, survival, and quality of life in some regions. The *Nutrition* chapter focuses on several spheres of nutrition that are of utmost concern in these countries, including undernutrition and its components of protein- and energy-related malnutrition and micronutrient deficiencies at various stages of life; food insecurity; the interaction of nutrition and infections; the role of breastfeeding and complementary feeding in ensuring healthy children; and currently implemented nutrition-specific interventions and programs. It also considers the nutrition transition and the growing problem of overweight and related metabolic diseases in adults observed in more affluent segments of populations in rapidly developing countries. Finally, the chapter discusses the cost-effectiveness of nutritional interventions.

The next four chapters address the shifting and emerging global health priorities in NCDs, injury, mental health, environmental and occupational health, and complex emergencies.

NCDs are generally characterized by a long latency period, prolonged course of illness, noncontagious origin, functional impairment or disability, and incurability. The *Chronic Diseases and Risks* chapter covers the global epidemiology of these diseases, particularly their prevalence in LMICs, as well as the impact they have on health and economies. The chapter also discusses the four key risk factors—poor diet, tobacco, alcohol and substance abuse, and low physical activity—that serve as determinants and proposes approaches, programs, and policies required to adequately prevent and manage these diseases at national and global levels.

The *Unintentional Injuries and Violence* chapter discusses both unintentional injuries (ones for which there is no evidence of predetermined intent, such as road accidents and occupational injuries) and intentional injuries or violence that is planned or intended (including injuries related to self-directed, interpersonal, and collective violence). The chapter provides an overview of the global burden of injuries, outlines the causes of and risk factors for them, describes evidence-based interventions that can successfully reduce their impact, and considers the opportunities and challenges that can move forward an injury prevention agenda at the global level.

Mental health is finally starting to receive the attention commensurate with its great importance to the disability and disease burden in LMICs. The *Global Mental Health* chapter charts the historical development of public mental health; considers various concepts and classifications of mental disorders, taking into account the influence of cultural factors in the development of psychiatric classifications; and reviews what is known about the epidemiology and etiology of the more common disorders, including anxiety and mood disorders, psychotic disorders, substance abuse disorders, epilepsy, developmental disabilities, and dementia. The chapter reviews mental health policies, human resources for mental health care, and the evidence for the prevention and treatment of major mental disorders, and provides guidance on implementing mental health services into health systems. Lastly, the chapter addresses the importance of research and emerging research priorities.

The *Environmental and Occupational Health* chapter provides a comprehensive review of environmental and occupational health issues in LMICs, and its new title reflects an increased focus on occupational health and its link to environmental health. The chapter examines the global burden of environmental health hazards in five categories: household (e.g., water and sanitation), workplace (e.g., on farms, in mines, and in factories), community (e.g., outdoor air pollution), and regional and global levels (e.g., climate change, ozone depletion, and biodiversity). It covers important methodology issues in the field and provides several case studies on the most pressing issues. The chapter concludes with a discussion on future priorities for environmental health research and policy.

The *Complex Emergencies* chapter focuses on the global health challenges that characterize conflicts that occur within and across state boundaries, have political antecedents, and are protracted in duration. It considers the causes of complex emergencies (particularly the political causes) and their impact on populations and health systems, and reviews the technical interventions that can limit their adverse effects on the health of populations. Attention is drawn to the importance of an effective and efficient early response in influencing the long-term survival of populations and health systems and the nature of any post-conflict society that is established. The chapter also reviews the impact of natural disasters.

The next three chapters are concerned with the development and implementation of effective health systems, which have a crucial influence on the ability of countries to address their disease burden and improve the health of their populations. The *Design of Health Systems* chapter focuses mainly on the healthcare system. It provides a conceptual map of the health system along with its key elements; addresses the fundamental and often controversial question as to the role of the state; and considers the key functions of any health system—namely, regulation, financing, resource allocation, and services provision. It includes extensive references to country experiences in strengthening the various dimensions of health systems, and reviews current issues. Five country examples are used throughout the chapter to illustrate key differences in health systems across the world.

Public Health Infrastructure is a new chapter that defines public health functions and the tangible and intangible aspects that make up the public health infrastructure. These include the institutions, knowledge, and commodities involved in supporting public health at local, national, and global levels. The chapter discusses ways to strengthen the public health system, including universal health coverage, human and material resources, and emergency response systems. It also examines issues surrounding global health security, the International Health Regulations, and the need for research and development to improve public health practice.

As multipurpose and multidisciplinary endeavors, health systems require coordination among numerous individuals and units. Thus they require effective and efficient management and planning. The *Management and Planning for Global Health* chapter is dedicated to this topic. It details the important aspects of the political, social, and economic context in which a management process must operate; discusses the organizational structures under which healthcare systems may be organized, including the role of the private sector; examines the critical processes of planning and priority setting; looks at issues in the management of resources, focusing on finance, resource allocation, staffing, transport, and information; and concludes by discussing some cross-cutting themes, such as management style, accountability, and sustainability.

The *Pharmaceuticals* chapter is dedicated to this key element of a health system. It focuses on access, availability (both upstream issues and country-level distribution and management systems), and affordability of pharmaceuticals and their safe and effective use. It also discusses the pharmaceutical system architecture and reflects on coordination and priority setting in a complex global environment.

Health technology and innovation resources have grown exponentially in recent years and have the ability

to transform healthcare delivery. The newly added *Innovation, Technology, and Design* chapter examines the process of technical innovation and design, and explores the impact it can have on health. The chapter focuses on three critical areas of innovation in global health: mobile health technologies; point-of-care diagnostics; and improved access technologies. As innovative technologies achieve their full potential only when they are successfully scaled up, the chapter outlines methods on how to ensure technologies can be translated into the field. It concludes by discussing some of the gaps in health care that might potentially be addressed by new innovations.

The *Evaluations of Large-Scale Health Programs* chapter covers the important area of evaluation science and addresses the rationale for and the design of summative impact evaluation of programs being scaled up and delivered to large populations and aimed at delivering several biological and behavioral interventions together. To describe the planning, design, and execution of program evaluations and data analyses, the authors use three evaluations as examples: An Integrated Community Case Management of Childhood Illness program, an accelerated child survival development initiative, and a voucher scheme for insecticide-treated bed nets.

Health and health systems interrelate with a nation's economy in two main ways. The first, as noted earlier, comprises the bidirectional relationships between health status and national income and development. For example, health affects income through its impact on labor productivity, saving rates, and age structure; in turn, a higher income improves health by increasing the capacity to produce food and have adequate housing and education, and through incentives for fertility limitation. The second type of interaction concerns linkages among healthcare delivery institutions, health financing (including insurance) policies, and economic outcomes. The *Health and "The Economy"* chapter reviews both of these challenging and closely related topics, which are critical to government policy makers seeking the best ways to improve the quality of life of their populations, and are particularly important for those countries transitioning between low-, middle-, and high-income status.

The global trading system has both direct and indirect impacts on the health of populations, but is a factor that is often overlooked by health professionals and was addressed only tangentially in the previous edition of this text. Given its importance, we have added a new *International Trade and Health* chapter that examines the relationships among international trade, determinants of health, and health care. It outlines international trade agreements, describes the surrounding political context, and reviews the global health community's involvement in this field.

Finally, the *Global Health Governance and Diplomacy* chapter addresses the role of governance and globalization in global health, bringing together material included in the previous edition's two chapters on cooperation in global health and globalization and health. It covers the various institutional arrangements that respond to global health needs through collective action, considers how these have shifted over time, and assesses the governance challenges faced by the global health community. It concludes with thoughts on how to strengthen global health governance and its institutional architecture in the future.

Many case studies can be found in exhibits scattered throughout the text. They provide concrete examples and illustrations of key points and concepts covered in each chapter. At the conclusion of each chapter is a list of questions that can help course instructors stimulate classroom discussions about important issues covered in the chapter.

The editors recognize that this text could include separate chapters on many other topics—maternal and child health and implementation or delivery science, for example. We have opted instead to provide in-depth information on the core subjects that were selected, although we did our best to cover some aspects of these and other topics in one or more chapters.

In many ways, global health stands today at an important crossroads. Its greatest challenge is to confront global forces, while at the same time promoting local, evidence-based, cost-effective, and responsive programs that deal with both disease-specific problems and more general issues, such as poverty and gender inequality. Global health–related research is essential to gain a better understanding of the determinants of illness and of innovative approaches to prevention and care, as well as to find means of improving the efficiency and coverage of health systems. Whether as practitioners, policy makers, or researchers, global health professionals can make an enormous difference by being well trained and sensitive to the beliefs, culture, and value systems of the populations with whom they collaborate or serve. We hope this text will aid in this process.

CHAPTER 1

Measures of Health and Disease in Populations

Abdulgafoor M. Bachani and Adnan A. Hyder

In its 1948 charter, the World Health Organization (WHO) defined health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." Although this is an important ideological conceptualization, for most practical purposes, objectives of health programs are more readily defined in terms of prevention or treatment of disease. Disease has been defined in many ways and for a variety of reasons; distinctions may be made between disease, sickness, and illness. For purposes of defining and measuring disease burden, a general definition will be used in this text: *Disease* is anything that a person experiences that causes, literally, "dis-ease"—that is, anything that leads to discomfort, pain, distress, disability of any kind, or death constitutes disease. It may be due to any cause, including injuries or psychiatric conditions.

It is also important to be able to diagnose and classify specific diseases to the extent that such classification aids in determining which health intervention programs would be most useful. Thus, defining disease, understanding the pathogenesis of the disease process, and knowing which underlying risk factors lead to this process are critical for understanding and classifying causes so as to determine the most effective prevention and treatment strategies for reducing the effects of a disease or risk factor. Just as the purpose of diagnosis of a disease in an individual patient is to provide the right treatment, so the major purpose of working through a burden of disease analysis in a population is to provide the basis for the most effective mix of health and social program interventions.

Developments in the measurement of population health status and disease burden over the past two decades include the increasing use of summary, composite measures of health that combine the mortality and morbidity effects of diseases into a single indicator; the availability of results of Global Burden of Disease (GBD) studies, which make use of such summary indicators; and developments in the measurement of disability and risk factors. The more traditional approaches to measuring health are widely available in other public health textbooks and will be used for illustrative and comparative purposes here.

This chapter is divided into five sections. The first section explains the reasons for and approaches to measuring disease burden in populations, describes the need for using quantitative indicators, highlights the importance of using data for decision making in health, and lists a variety of major health indicators currently in widespread use. The second section critically reviews methods for developing and using composite measures that combine the mortality and morbidity from diseases in populations at national and regional levels. It explores the potential utility of these measures and discusses their limitations

and implications. The third section demonstrates the application of these methods for measurement of health status and assessment of global health trends. It reviews current estimates and forecasts trends in selected countries and regions, as well as examines the global burden of disease. The fourth section reviews important underlying risk factors of disease and discusses recent efforts to measure the prevalence of major risk factors and to determine their contributions to regional and global disease burdens. The final section provides conclusions for the chapter.

Reasons for and Approaches to Measuring Health and Disease

Rationale

The many reasons for obtaining health-related information all hinge on the need for data to guide efforts toward reducing the consequences of disease and enhancing the benefits of good health. These include the need to identify which interventions will have the greatest beneficial effect, to identify emerging trends and anticipate future needs, to assist in determining priorities for expenditures, to provide information for education to the public, and to help in setting health research agendas. The primary information requirement is for understanding and assessing the health status of a population and its changes over time. In recent years, practitioners have emphasized the importance of making evidence-based decisions in health care. There is little reason to doubt that evidence is better than intuition, but realizing its full benefits depends upon recognizing and acting upon the evidence. This chapter examines evidence—the facts of health and disease—and demonstrates how to assemble this evidence so that it can assist in better decision making concerning health and welfare.

A well-documented example of the relationship between decision making and data can be seen in a classic health systems project in Tanzania (**EXHIBIT 1-1**). This

EXHIBIT 1-1 Using Evidence to Improve a Health System: An Example from Africa

The **Tanzania Essential Health Interventions Project** (TEHIP), a joint venture of the Tanzanian Health Ministry, the International Development Research Centre (IDRC), and the Canadian International Development Agency, starting in 1996 was conducted in two rural districts—Morogoro and Rufiji—with a combined population of approximately 700,000. The annual health spending in Tanzania was about $8 per capita. In Morogoro and Rufiji, TEHIP added resources on the condition that they be spent rationally; in other words, the amount of money spent on interventions should reflect the burden of disease. TEHIP conducted burden of disease analysis for the two districts and established a demographic surveillance system (DSS). The routine data from the DSS provided information for the district teams to support resource allocation based on disease burden. The organization found that the amount that the local health authorities spent on addressing each disease bore little relation to the actual burden of disease. Although childhood problems (e.g., pneumonia, diarrhea, malnutrition, measles) constituted 28% of the disease burden, only 13% of the budget was devoted to addressing them. Other conditions, meanwhile, attracted more than their fair share of resources. For example, 22% of the budget was targeted to tuberculosis, even though it accounted for less than 4% of years of life lost.

TEHIP promoted the use of burden of disease analysis, district accounts, and other mapping tools for more rational decision making in the districts. It also brought management tools and community voice techniques to the district teams. The result was better ability of district-level healthcare workers and managers to control and allocate resources and processes related to healthcare provision. The district teams decided to spend more on neglected diseases for which cost-effective treatments or preventive measures were available. The extra $1 per capita was enough to allow the district health authorities to align their spending to reflect the real disease burden. For example, sexually transmitted diseases received 3% of the budget prior to TEHIP's intervention; that percentage changed to 9.5% after the realignment. Malaria accounted for 30% of the years of life lost because of death and debilitating illness; the budget for malaria prevention and treatment programs increased from 5% of total spending in 1996 to 25% in 1998.

The results of TEHIP were documented as changes in health outcomes. In Rufiji, for example, infant mortality fell by 40% in 5 years. In fact, just between 1999 and 2000, infant mortality fell from 100 deaths per 1,000 live births to 72 deaths per 1,000 live births, while the proportion of children dying before their fifth birthdays dropped by 14%, from 140 per 1,000 to 120 per 1,000. The success of TEHIP and its approach led to replication and further innovation in not only Tanzania but also many other low- and middle-income countries (LMICs), including Burkina Faso, Ghana, and Nigeria.

For additional information on the TEHIP success story, visit the websites identified in the following sources.

Data from https://www.odi.org/sites/odi.org.uk/files/odi-assets/publications-opinion-files/7814.pdf; https://www.idrc.ca/en/article/tanzanias-healthcare-breakthrough; https://www.researchgate.net/publication/268341357_Tanzania_Essential_Health_Interventions_Project_An_Overview_of_TEHIP_Interventions_Tanzania_Ministry_Of_Health_TANZANIA_ESSENTIAL_HEALTH_INTERVENTIONS_PROJECT_TEHIP_Interventions_-An_Overview

case illustrates how able people with good intentions had been making decisions routinely, only to find that using established methods to collect evidence on the burden of disease changed the nature and effectiveness of their own decisions. A major reason for the effective use of the evidence was that it was collected locally and put forward in a form helpful to decision makers.

Measuring Health and Disease

The relative importance (burden) of different diseases in a population depends on their frequency (incidence or prevalence), severity (the mortality and extent of serious morbidity), consequences (health, social, economic), and the specific people affected (gender, age, social and economic position).

Counting Disease

The first task in measuring disease in a population is to count its occurrence. Counting disease frequency can be done in several ways, and it is important to understand what these different methods of counting actually mean. The most useful way depends on the nature of the disease and the purpose for which it is being counted. There are three commonly used measures of disease occurrence: cumulative incidence, incidence density, and prevalence.

Cumulative incidence, or *incidence proportion*, is the number or proportion of new cases of disease that occur in a population at risk for developing the disease during a specified period of time. For this measure to have meaning, three components are necessary: a definition of the onset of the event, a defined population, and a particular period of time. The critical point is *new cases* of disease—the disease must develop in a person who did not have the disease previously. The numerator is the number of new cases of disease (the event), and the denominator is the number of people at risk for developing the disease. Everyone included in the denominator must have the potential to become part of the group that is counted in the numerator. For example, to calculate the incidence of prostate cancer, the denominator must include only men, because women are not at risk for prostate cancer. The third component is the period of time. Any time unit can be used as long as all those counted in the denominator are followed for a period comparable with those who are counted as new cases in the numerator. The most commonly used time denominator is one year.

Incidence density, which is often simply called *incidence rate*, is the occurrence of new cases of disease per unit of person-time. This metric directly incorporates time into the denominator and is generally the most useful measure of disease frequency; it is often expressed as new events per person-year or per 1,000 person-years. Incidence is a measure of events (in this case, the transition from a nondiseased state to a diseased state) and can be considered a measure of risk. This risk can be looked at in any population group, defined by age, sex, place, time, sociodemographic characteristics, occupation, or exposure to a toxin or any other suspected causal factor.

Prevalence is a measure of present status rather than of newly occurring disease. It measures the proportion of people who have the defined disease at a specific point of time. Thus, it is a composite measure made up of two factors—the incidence of the disease that has occurred in the past and its continuation to the present or to some specified point in time. That is, prevalence equals the incidence rate of the disease multiplied by the average duration of the disease. For most chronic diseases, prevalence rates are more commonly available than are incidence rates.

Severity of Disease

To understand the burden of disease in a population, it is important to consider not only the frequency of the disease but also its severity, as indicated by the morbidity and premature mortality that it causes. *Premature mortality* is defined as death before the expected age of death had the disease not occurred. *Morbidity* is a statement of the extent of disability that a person suffers as a consequence of the disease over time and can be measured by a number of indicators, as discussed later in this chapter.

Mortality

Traditionally, mortality has been the most important indicator of the health status of a population. John Grant developed the first known systematic collection of data on mortality with the *Bills of Mortality* in the early 1600s in London. He described the age pattern of deaths, categorized them by cause as understood at the time, and demonstrated variations from place to place and from year to year. Mortality rates according to age, sex, place, and cause continue to be central information about a population's health status and a crucial input for understanding and measuring the burden of disease. Considerable literature exists on the use of mortality to indicate health status and its application to national and subnational levels (Murray & Chen, 1992).

The fact of death by age, sex, and place is required by law in most countries through death registration, and in many countries the cause of death through death

certification is required as well. Both provide essential information about the health status of a population. Nevertheless, in many low-income countries, the fact of death, let alone its cause, is still not reliably available.

In high-income countries, vital statistics (i.e., the registration of births and deaths by age, sex, and place) are routinely collected and highly reliable. In most middle-income countries, the reliability and completeness of these data have been steadily improving and often are fairly satisfactory. In contrast, the collection of vital statistics remains grossly incomplete in many low-income countries. An analysis of death registration in the course of the Global Burden of Disease study showed that vital registration data together with sample registration systems still do not cover 100% of global mortality. Survey data and indirect demographic techniques are needed to provide information on levels of child and adult mortality to paint a complete picture of global mortality (GBD 2015 Mortality and Causes of Death Collaborators, 2016). Nevertheless, even in low-income countries, increasing use of survey methods is delivering useful estimates of the mortality rates for the population younger than age 5 years and other populations.

Obtaining information about cause of death remains difficult even in many middle-income countries; a lot of information depends on special surveys or studies of select populations. Verbal autopsies (VAs) have been used increasingly for judging the likely cause of death, especially for children younger than age 5. This method comprises structured questions administered by trained interviewers with family members after a death; the information is then reviewed by physicians (or computers) to assign a cause of death using algorithms. VAs are useful for assessing some causes of death such as neonatal tetanus and severe diarrhea, but their sensitivity and specificity may be limited for diseases whose symptoms are variable and nonspecific, such as malaria (Anker et al., 1999; Thatte, Kalter, Baqui, Williams, & Darmstadt, 2009). Recently, automated systems for analyzing VA data have been developed and are being tested.

Age-specific mortality profiles are a prerequisite for a burden of disease analysis. Although extensive work has been done to document and analyze child mortality in low- and middle-income countries (LMICs), less has been done for adult mortality (Hill, 2003). LMICs have higher rates of age-specific adult mortality than do high-income nations (GBD 2015 Mortality and Causes of Death Collaborators, 2016; Lopez et al., 2002; Murray & Chen, 1992). Indeed, mortality rates are higher for both women and men in LMICs at every age when compared with the high-income world. In Africa, the enormous increase in deaths of young and middle-aged women and men from acquired immunoeficiency syndrome (AIDS) has had a profound impact on mortality and survival (**EXHIBIT 1-2**).

Traditional indicators of mortality have been the standard for assessing population health status. Neonatal mortality rates (NMR; deaths of live-born infants before 28 days of age per 1,000 live births), infant mortality rates (IMR; deaths of live-born infants before 12 months of age per 1,000 live births), and child mortality (deaths of children younger than 5 years of age) are considered sensitive indicators of the overall health of nations. The United Nations Children's Fund (UNICEF) publishes an annual global report that includes a ranking of nations based on these indicators (UNICEF, 2015). These indicators have the added advantage of having been studied for their relationships with other indicators of the social and economic development of nations. For example, a clear relation exists between the gross national product (GNP) per capita, which is an indicator of national wealth, and child mortality. In general, the higher the level of economic development, the lower the rate of child mortality. However, there are exceptions, and they need to be examined carefully. For example, Sri Lanka and the Indian state of Kerala are both low-income regions that have traditionally had low child mortality rates. These examples demonstrate that the relationship between mortality and poverty is complex and needs in-depth investigation.

There are major deficiencies in cause-specific mortality data in low- and most middle- income countries. In keeping with demographic and epidemiologic transitions, the pattern of cause-specific mortality changes at different levels of total mortality, with a general trend of decreasing infectious and parasitic disease cause-specific mortality with declining total mortality. Indeed, mortality from these communicable causes has been a major reason for the historical difference between high- and low-mortality populations (Murray & Chen, 1992).

The cause of death certification system based on WHO's *International Classification of Diseases* (ICD) has been used widely in many countries for many years (WHO, 2016). Despite the existence of this standardized process for categorizing deaths, variations in the reliability of these data occur because of variations in the training and expertise of the people who are coding causes of death, as well as the supervision and feedback provided. Nevertheless, there have been steady improvements in many countries, including automation of data collection and analysis, and these kinds of data provide some of the best information available on major causes of mortality.

EXHIBIT 1-2 Trends of the HIV/AIDS Epidemic

Globally, AIDS is the leading infectious cause of death among 15- to 49-year-olds (Global Burden of Disease Risk Factors Collaborators et al., 2015). Untreated disease caused by the human immunodeficiency virus (HIV) has a case fatality rate that approaches 100% (WHO, 2003). Unknown more than 30 years ago, the HIV/AIDS epidemic has killed more than 35 million people.

At the end of 2016, an estimated 36.7 million people were living with HIV/AIDS, with 69.5% of those individuals living in sub-Saharan Africa (WHO, 2017) . The prevalence of new HIV infections has increased by 60% in eastern Europe and Central Asia (**TABLE 1-1**) (UNAIDS, 2017; WHO, 2017).

HIV/AIDS is the tenth leading cause of disability-adjusted life years, accounting for 2.7% of this global burden. In terms of mortality, it is the eleventh leading cause of death among people of all ages, accounting for 2.1% of all deaths (Global Burden of Disease Risk Factors Collaborators et al., 2015). Nearly 42% of the 1 million global deaths from HIV/AIDS have occurred in East and Southern Africa (**FIGURE 1-1**) (UNAIDS, 2017).

TABLE 1-1 Global Summary of HIV and AIDS Epidemic

Number of people living with HIV	**Total**	**36.7 million**	**(30.8–42.9 million)**
	Adults	34.5 million	(28.8.4–40.2 million)
	Women	17.8 million	(15.4–20.3 million)
	Children	2.1 million	(1.7–2.6 million)
Number newly infected with HIV	**Total**	**1.8 million**	**(1.6–2.1 million)**
	Adults	1.7 million	(1.4–1.9 million)
	Children	160,000	(100,000–220,000)
AIDS deaths	**Total**	**1.0 million**	**(830,000–1.2 million)**
	Adults	890,000	(740,000– 1.1 million)
	Children	120,000	(79,000–160,000)

Mortality can be expressed in two important quantitative measures: (1) *mortality rate* (MR) and (2) *case fatality ratio* (CFR). The MR, a form of incidence rate, is expressed as the number of deaths in a defined population in a defined time period. The numerator can be total deaths, age- or sex-specific deaths, or cause-specific deaths; the denominator is the number of persons at risk of dying in the stated category as defined earlier for incidence. Demographers use the notation XqY for the probability of dying in the Y years following age X at the then prevailing age-specific mortality rates for the population. Thus, 5q0 is the probability of death of newborns by age 5 years (see Table 1-2 later in this chapter), and 30q15 is the probability of death in young adults from age 15 to 45. The CFR is the proportion of those persons with a given disease who die of that disease (at any time, unless specified). The MR is equal to the CFR multiplied by the incidence rate of the disease in the population.

The distinction between the proportion of deaths attributable to a cause (number of deaths due to the cause divided by total number of deaths in a given population in a given time period) as compared to the probability of death from the cause (disease-specific MR) is important to understand. For example, the probability of death (and disability) from noncommunicable causes (indeed, from virtually all causes) is higher in low- and middle-income regions than in the high-income world. However, the proportion of deaths and disability attributable to these chronic causes is smaller in LMICs than in wealthier countries because of the much larger toll taken by infectious and nutritional causes. With increasing economic development, the risk of death and disability from chronic disease does not increase; rather, the proportion of deaths attributable to chronic disease increases as the proportion of deaths attributable to communicable and nutritional disease declines.

Demographic and Epidemiologic Transitions

The demographic transition describes the changes in birth and death rates that historically have accompanied the shift from a traditional society to a modern society; it is detailed in other chapters. With modernization, sharp declines in mortality have been followed by a reduction in fertility, albeit one that commonly lags behind the change in the death rate by years or decades. The term *transition* refers to the shift away from a stable population in which very high birth rates are balanced by very high death rates to a stable population in which low birth rates are balanced with low death rates. In between these extremes, as a society undergoes modernization, there is a lag between falling mortality, especially in the under-5 age group, and the drop in birth rates that leads to explosive population growth. Thereafter birth rates fall and a new stage is reached in which birth and death rates are low and balance resumes. The result is a striking change in the age structure of the population, with a decreased proportion of children and an aging population. These changes in the population age distributions are reflected in the shift from a wide-based pyramid, reflecting larger numbers in the younger age groups, to a structure with a narrow base, nearly rectangular configuration, and nearly equal percentages in each age group.

In 1971, Omran described the underlying reasons for the demographic transition and used the term *epidemiologic transition* to explain the changing causal factors of disease that accounted for the dramatic drop in under-5 mortality, which was largely due to reduction in malnutrition and communicable diseases. Although high rates of maternal mortality are characteristic of the low- and middle-income world, reductions in maternal mortality occur in a different time frame from those in under-5 mortality. Reductions in maternal mortality require a better-developed infrastructure, including ready availability of surgical and blood transfusion capacity plus improved communication and transportation systems. Thus, drops in maternal mortality occur much further along the road toward economic development, and changes occur only after shifts in the child mortality have been seen.

Major changes in the patterns and causes of injury are also likely to occur with modernization. For example, road traffic injuries tend to increase as countries go through the stage of development in which there is a great increase in vehicles and in the speeds at which they are operated before improved roads, appropriate laws and regulations, and law enforcement are in place (Crooper & Kopits, 2003; WHO, 2015). There may also be important shifts in the nature of violence and the people toward whom it is directed, related to crime patterns, civil unrest, ethnic conflicts, and intrafamily tensions (WHO, 2002b). The profound impact of the HIV/AIDS epidemic was discussed earlier in Exhibit 1-2.

Other Health-Related Metrics

In addition to basic measures of mortality, morbidity, and life expectation that are central for population health status assessment, a variety of important health-related indicators are useful for specific purposes. Many are discussed more fully in other chapters of this text; they are summarized in **TABLE 1-2**. Those related to the Sustainable Development Goals (SDGs) are discussed in **EXHIBIT 1-3**.

TABLE 1-2 Health-Related Metrics

Type	Indicator	Definition/Interpretation
Demographic indicators: reproductive health	Maternal death	Death of a woman while pregnant or up to 42 days post-delivery from any cause except accident
	Maternal mortality ratio	Maternal deaths per number of pregnancies (maternal deaths per 100,000 live births)
	Maternal mortality rate	Maternal deaths per number of women of reproductive age (maternal deaths per 100,000 women aged 15–49)
	Lifetime risk of maternal mortality	Cumulative loss of human life due to maternal death over the female life course
	Total fertility rate	Average number of children a woman would bear if she lived to the end of her reproductive period
	Life expectation at birth	Average number of years a newborn would live if his or her life were lived under the mortality conditions for the place and year in question
Anthropometric indicators: nutrition	Weight for age	Underweight
	Height for age	Stunting
	Weight for height	Wasting
	Mid-upper arm circumference	Wasting
Mortality (death) indicators	Mortality rate	Number of deaths in a specified time period/number of persons at risk of dying during that period
	Infant mortality rate	Number of deaths of live born infants before 12 months of age per 1,000 live births
	Under-5 mortality rate	Number of deaths of children younger than age 5 per 1,000 live births averaged over the last 5 years
	5q0	Probability of death of a newborn by age 5
	Neonatal mortality rate	Number of deaths of live-born infants before 28 days of age per 1,000 live births
	Stillbirth rate	Number of babies born with no signs of life at or after 28 weeks' gestation per 1,000 births
	Perinatal mortality rate	Number of fetal deaths (28 or more weeks of gestation) + postnatal deaths (first week) per 1,000 live births
Disease frequency	Endemic	Usual occurrence of a given disease in a defined population
	Epidemic	Occurrence of a given disease in a defined population clearly in excess relative to its usual occurrence
	Pandemic	A worldwide epidemic involving large numbers

EXHIBIT 1-3 Sustainable Development Goals

On September 25, 2015, UN member states adopted 17 *Sustainable Development Goals* (SDGs) as part of the post–Millennium Development Goals (MDGs) development agenda. The SDGs build on the goals identified under MDGs and broaden the scope to include new areas of focus—for example, climate change, economic inequality, innovation, sustainable consumption, and peace and justice—to improve overall well-being and life of current and future generations through sustainable means.

The 17 SDGs were divided into 169 quantifiable targets that are measured by 230 indicators. Of these, 21 targets and 39 indicators are directly related to health. The health-related indicators include a variety of indicator types: incidence rates, prevalence "rates," mortality rates, mortality ratios, birth rates, and proportion of target populations receiving an intervention.

Appendix 1 provides examples of some of the health-related SDG indicators.

Morbidity and Disability

Measures of mortality have been the principal indicators of population health status for generations. Their relative ease of observation, availability of data, and history of use make mortality information useful for assessing and monitoring the health status of populations. However, the key limitation with mortality-based indicators is that they "note the dead and ignore the living" (Kaplan & Anderson, 1996). Measurements of morbidity, by comparison, are more problematic because there is not a clearly defined endpoint such as death provides. In addition, several components of disability need to be assessed, and there may be a substantial subjective aspect to grading the extent or severity of a condition.

The *International Classification of Impairments, Disabilities, and Handicaps* (ICIDH) was developed in the 1970s to classify nonfatal health outcomes as an extension of WHO's ICD system (WHO, 1980). It was developed to more fully describe the impact of a given disease on an individual and on society, and to account for that disease's heterogeneity of clinical expression and evolution in different individuals and societies. ICIDH categories included *impairment* (loss or abnormality of psychological, physiological, or anatomic structure or function), *disability* (restriction or lack of ability to perform an activity considered normal), and *handicap* (disadvantage from a disability or impairment for a given individual based on the inability to fulfill a normal role as defined by age, sex, or sociocultural factors). These distinctions clarified more than just processes—they helped define the contribution of medical services, rehabilitation facilities, and social welfare to the reduction of disability.

In 2002, WHO built on the ICIDH to develop the *International Classification of Functioning, Disability, and Health*, commonly known as ICF (WHO, 2002c). In this system, health-related domains are classified from the perspectives of the body, of the individual, and of society by means of two lists: a list of body functions and structures, and a list of domains of activity and participation. Because an individual's functioning and disability occur within a context, the ICF also includes a list of environmental factors that provide a description of that context. The ICF has become WHO's framework for measuring health and disability at both individual and population levels. It was officially endorsed by all 191 WHO member states in the Fifty-Fourth World Health Assembly on May 22, 2001 (resolution WHA 54.21). Unlike its predecessor, which was endorsed for field trial purposes only, the ICF was endorsed for use in member states as the international standard to describe and measure health and disability.

Using such classifications, indicators of disability—such as *impairment-free*, *disability-free*, and *handicap-free* life expectancies—have been developed. These, in turn, have been used to estimate health-adjusted life expectancies using severity and preference weights for time spent in states of less than perfect health.

Hospital inpatient discharge records—when they are based on good clinical evidence and coded by staff well trained in coding procedures—can provide high-quality data on the major causes of morbidity serious enough to require hospitalization. They also can provide good cause-of-death data for hospitalized persons, and some sense of the outcome status of those with serious conditions. Hospital data are generally improving in quality, especially in middle-income countries and in selected sentinel (usually tertiary care) teaching hospitals in low-income countries. Such information is inevitably biased because of the highly skewed distribution of those using such hospitals, but in many situations it is possible to have a good understanding of those biases and make appropriate adjustments to draw useful conclusions.

Generally, outpatient records in most of the world are highly deficient in terms of diagnosis; indeed,

they often identify only the patient's chief complaint and the treatment dispensed. The main value of most such records is limited to establishing the fact of using a facility. There are usually strong biases in terms of those patients who use outpatient facilities because of access factors (distance and cost of use), nature and severity of the disease problem, and opportunity for using alternative services.

Visits to healthcare facilities, functional disability (a measure of activity that is less than the norm), and time spent away from work (absenteeism, work days lost) have all been used to assess the magnitude of morbidity from various conditions. A commonly used approach to evaluating morbidity in a population has been the assessment of the impact on social roles or functional performance, such as days missed from work or spent in bed (Kaplan & Anderson, 1996). A considerable body of literature focuses on the wide variety of instruments used to measure such functional capacity, especially in the clinical medical literature, that are not directly useful for population-based morbidity assessment.

Data about morbidity are often based on self-perceived assessments, and are frequently gleaned from survey-based interview information. The perception of morbidity and its reporting, the observation of morbidity and its impact, and other factors are responsible for the wide variations between reported and measured prevalence of conditions (Murray & Chen, 1992). This has resulted in an underestimation of the presence and impact of morbidity in both LMICs as compared with high-income nations. This situation also underscores the variations in morbidity data, which are often interpreted as indicating that wealthy individuals and low-mortality populations report higher rates of morbidity (*Global Burden of Disease and Risk Factors*, 2006; Woolf et al., 2015).

Measurement of health-related quality of life has also been discussed in the medical literature for decades. *Health-related quality of life* refers to how well an individual functions in daily life and his or her perception of well-being. Various domains of quality have been defined, such as health perception, functional status, and opportunity, and several instruments have been developed to evaluate them. Both disease-specific and general instruments exist, with such tools abounding in fields dealing with patients having chronic disabled states, such as psychiatry, neurology, and counseling. These scales are often dependent on self-reported information, although some incorporate observational data as well. However, concerns have been raised about their reliability and validity. These measures are not discussed further in this text, because they have been primarily used in clinical assessments of individuals, rather than larger populations.

Measuring Disability

If all the various forms of disability—physical, functional, mental, and social—are to be compared with mortality, they must be measured in an equivalent manner for use in health assessments. To do so, measurement of disability must quantify the duration and severity (extent) of this complex phenomenon. A defined process is needed that rates the severity of disability as compared with mortality, measures the duration of time spent in a disabled state, and converts various forms of disability into a common scale. General measures of disability without regard to cause (often carried out by special household surveys) are useful to determine the proportion of the population that is "disabled" and unable to carry out normal activities, but are not much help for quantifying the extent of disability.

In general, three components of disability need to be assessed. The first component is the *case disability ratio* (CDR)—the proportion of those diagnosed with the disease who have disability. For most diseases that are diagnosed clinically, the CDR will be 1.00 because, by the definition of disease given earlier, patients will have signs or symptoms. In contrast, when the diagnosis is based on, for example, infection rather than disease (such as tuberculosis) or on a genetic marker rather than the physical manifestation (such as sickle cell trait), the CDR is likely to be less than 1.00.

The second component of disability is its *extent or severity*—how incapacitated the person is as a result of the disease. The extent of disability is expressed on a scale, such as from 0 (indicating no disability) to 1.00 (equivalent to death). The assessment of severity can be quite subjective, particularly because so many different types and dimensions of disability exist. A number of methods have been introduced in an effort to achieve comparability and obtain consistency (Murray, Salomon, Mathers, & Lopez, 2002).

Measurement of individual preferences for different health states to determine relative severity of disability has been done by a variety of methods (Kaplan & Anderson, 1996; Murray et al., 2002; Torrance, 1986). Factors that influence the assessment of such preferences include the type of respondent, the type of instrument used to measure the response, and the time from entry into the disabled state. Individuals who are in a particular state, healthy individuals, healthcare providers, caretakers, and family members have all

been interviewed in studies. Adaptation, conditioning, development of special skills, and vocational training can all change the response of individuals over time within a particular health state, thereby affecting the value of that state to the individual. As a consequence, the valuation is time dependent—for example, the value placed on a year of life by a paraplegic soon after entering that health state would be different from that obtained after several years of adjustment to that state (Murray & Lopez, 1994).

Instruments used to extract such preferences involve visual and interview techniques (*Global Burden of Disease and Risk Factors*, 2006; Torrance, 1986). Two alternative scenarios are often presented to the subject and the point of indifference sought (as in standard gamble techniques). Despite much work in this area, there is no consensus or accepted standard method for such elicitation. Severity of disability scales have been developed by group consensus using community surveys (Kaplan & Anderson, 1996), a mixture of community and expert groups (Ghana Health Assessment Team, 1981), experts only (World Bank, 1993), and population surveys (Global Burden of Disease Risk Factors Collaborators et al., 2015; Murray et al., 2002; Salomon et al., 2012). These scales usually compare perfect health states to death on a scale of 0 to 1 (**TABLE 1-3**).

In the first Global Burden of Disease 1990 study, the disability severity estimates were based on expert opinion. Twenty-two indicator conditions were selected and used to construct seven disability classes (Table 1-3). Outcomes from all other health conditions were categorized within these seven classes (with special categories

TABLE 1-3 Examples of Disability Classification Systems

Ghana Health Assessment Team, 1981		
Class	**Severity**	**Equivalent to (Maximum)**
1	0	Normal health
2	0.01–0.25	Loss of one limb's function
3	0.26–0.50	Loss of two limbs' function
4	0.51–0.75	Loss of three limbs' function
5	0.76–0.99	Loss of four limbs' function
6	1	Equivalent to death

Global Burden of Disease Study, 2013*	
Category	**Disability Weight for Unique Health States**
Infectious disease	Acute episode, mild: 0.006 (0.002–0.012) Acute episode, moderate: 0.051 (0.032–0.074) Diarrhea, mild: 0.074 (0.049–0.104) Ear pain: 0.013 (0.007–0.024)
Cancer	Diagnosis and primary treatment: 0.288 (0.193–0.399) Metastatic: 0.451 (0.307–0.600)
Cardiovascular and circulatory disease	Acute myocardial infarction (MI), days 1–2: 0.432 (0.288–0.579) Acute MI, days 3–28: 0.074 (0.049–0.105) Heart failure, mild: 0.041 (0.026–0.062)
Diabetes and digestive and genitourinary disease	Diabetic foot: 0.020 (0.010–0.034) Gastric bleeding: 0.325 (0.209–0.462) Infertility, primary: 0.008 (0.003–0.015)

Chronic respiratory disease	Asthma, controlled: 0.015 (0.007–0.026) Chronic obstructive pulmonary disease (COPD) and other chronic respiratory diseases, mild: 0.019 (0.011–0.033) COPD and other chronic respiratory diseases, severe: 0.408 (0.273–0.556)
Neurologic disorders	Dementia, mild: 0.069 (0.046–0.099) Multiple sclerosis, moderate: 0.463 (0.313–0.613) Parkinson's disease, severe: 0.575 (0.396–0.730)
Mental, behavioral, and substance use disorders	Alcohol use disorder, very mild: 0.123 (0.082–0.177) Anxiety disorders, moderate: 0.133 (0.091–0.186) Anorexia nervosa: 0.224 (0.150–0.312)
Hearing and vision loss	Hearing loss, mild: 0.010 (0.004–0.019) Hearing loss, profound, with ringing: 0.277 (0.182–0.387) Distance vision, severe impairment: 0.184 (0.125–0.258)
Musculoskeletal disorders	Low back pain, moderate: 0.054 (0.035–0.079) Neck pain, severe: 0.229 (0.153–0.317) Gout, acute: 0.295 (0.196–0.409)
Injury	Burns, lower airway, with or without treatment: 0.376 (0.240–0.524) Crush injury, short or long term, with or without treatment: 0.132 (0.089–0.189) Concussion: 0.110 (0.074–0.158)
Other	Abdominopelvic problem, mild: 0.011 (0.005–0.021) Anemia, moderate: 0.052 (0.034–0.076) Hypothyroidism: 0.019 (0.010–0.032)

* Health states included in this table are only examples. The full list of 235 unique health states and their disability weights are available in Salomon et al., 2015.
Data from Salomon, J. A., Haagsma, J. A., Davis, A., de Noordhout, C. M., Polinder, S., Havelaar, A. H., et al. (2015). Disability weights for the Global Burden of Disease 2013 study. *Lancet Global Health, 3*(11), e712-723. doi: 10.1016/S2214-109X(15)00069-8

for treated and untreated groups). This approach was revised for the 2010 iteration of the study, for which the process included empirical studies comprising simple paired questions, and survey of the general public through household surveys in countries such as Bangladesh, Indonesia, Peru, Tanzania, and the United States, as well as a web-based survey in English, Spanish, and Mandarin. The result was a categorization that included 220 health states (Salomon et al., 2012). Generally, for most conditions a reasonable degree of consensus can be reached within broad categories (e.g., 25% disabled as compared with 50%), but efforts to reach much finer distinctions have proved equivocal. The need to seek out more refined scales for purposes of health program decision making ought to be a national or local decision.

The third component of disability is its *duration*. The duration is generally counted from onset of the disability until cure, recovery, or death. Sometimes there is continuing permanent disability after the acute phase is completed; in such a scenario, the duration would be the remaining life expectation from the time of onset of disease.

Data for Decisions

In the collection and assessment of information, the level of precision required should be guided by the purpose for collecting the information and depend on the decisions to be taken. Even rough estimates may be helpful; though disconcerting to some, the time and cost of efforts to realize further precision need to be justified by the increased precision's potential impact on decision making. LMICs, with their scarce resources, need timely and appropriate information to plan and implement health interventions that maximize the health of their populations. Methods, indicators, and assessments of disease must support and contribute to this primary purpose of health systems.

Decisions concerning deployment of interventions against diseases and underlying risk factors ideally should be taken such that maximum healthy life per resource expenditure is obtained in an equitable, fair, and just fashion. The ultimate reason for obtaining health data is to have the information to guide such decision making.

Summary Measures of Population Health

This section focuses on the major approaches used for developing composite measures of population health status that summarize mortality and morbidity occurring in a population through the use of a single number. It discusses the rationale for composite measures, reviews the origins of each major approach, examines methodological differences among these approaches, and outlines the advantages and limitations of each.

Rationale for Composite Measures

Rationing of healthcare resources is a fact of life everywhere; choices about the best use of funds for health must inevitably be made (Hyder, Rotllant, & Morrow, 1998; WHO, 2000). The global scarcity of resources for health care is a challenge for every country, rich and poor (Evans, Hall, & Warford, 1981; Figgis & Walters, 2015–2017; World Bank, 1993), but the realities in LMICs paint the choices in much starker terms. It is even more important for LMICs to choose carefully how to optimize health expenditures so as to obtain the most health in the most equitable fashion from these expenditures. Important tools under development to assist in making better choices for health spending are based on measures of the effectiveness of health interventions in improving health status in relation to their cost.

In most sectors, decisions on resource allocation are based on perceived value for money. The health sector, however, has had no coherent basis for determining the comparative value of different health outcomes (from different health programs). To make decisions about whether to put money into programs that reduce mortality in children, as compared with those programs that reduce disabling conditions in adults, a common denominator is needed. In recent decades, work has been carried out to develop composite indicators combining morbidity and mortality into a single measure that may serve as a common denominator for comparing different health outcomes. A common unit of measure for these different health outcomes is *time lost from healthy life*.

The most important reason for attempting to capture the complex mix of incommensurable consequences resulting from disease within a single number is the need to weigh the benefits of health interventions against their costs. Costs of health programs are expressed in a unidimensional measure, such as U.S. dollars; therefore, the benefits to be achieved from their expenditure should be expressed in the same manner. *Healthy lifetime* is a unidimensional measure that can be used to compress health benefits and losses into a single time dimension. An explicit, objective, quantitative approach should enable better budgetary decisions and permit resource allocation in the health sector to be undertaken in a more effective and equitable fashion.

Note that a composite indicator is simply a tool to be used to assist decision makers in resource allocation. Like any tool, it can be misused. Conclusions that are reached on the basis of these indicators must be carefully examined. Not only do problems arise in trying to put so many dimensions together, which inevitably may lead to distortions, but serious issues also emerge concerning the reliability and validity of the information on which these indicators are based. Thus, all the problems associated with determining causes of death, counting the number of cases of disease, and assessing the extent of disability from a condition will lead to uncertainties when these factors are added and multiplied together. The development of a single indicator consisting of a specific number implies deceptive stability about something that may actually be composed of fragile data. Continuing vigilance in how these data are obtained, compiled, and used is critical, and those responsible for using the tool must have a clear technical understanding of what lies behind the numbers and which underlying assumptions and limitations are associated with these approaches. Despite all of these caveats, alternative approaches to improved decision making leave even more to be desired.

Uses of Composite Indicators

Measures of health status that combine mortality and morbidity facilitate comparisons both within and across populations. They can be used to estimate the quantitative health benefits from interventions and serve as tools to assist in the allocation of resources. The development of such measures entails two major processes: the measurement of healthy life, including losses of time from premature mortality and disability; and the valuing of life, which incorporates issues of duration, age, extent of future life, productivity, dependency, and equity (Morrow & Bryant, 1995). The purpose of developing such measures and the need for refining them become clear if the following objectives are to be achieved:

- The use of such methods at the country level for evaluating the impact of diseases
- Their use in the allocation of resources within the health sector
- The generation of more relevant and useful data for policy makers

Understanding Summary Measures

Precursors of composite indicators have been discussed in the literature for decades and generally were developed to assist with prioritization of health issues. Usually these metrics were based on the measurement of losses of time, losses of productive time, income forgone, or other costs incurred as a result of diseases. The earlier indicators generally focused on economic losses and estimated time loss due to disease and converted these losses into a dollar value. Thus, these measures are more economic measures than disease burden measures.

Two types of composite summary measures have been developed: *health gap measures* (healthy life lost), such as healthy life years (HeaLYs) or disability-adjusted life years (DALYs), and *health expectancies*, such as disability-free life expectancy (DFLE) or health-adjusted life expectancy (HALE). Both types use healthy lifetime lost through disability and death as a common measure of the impact of mortality and nonfatal health outcomes. These two types of measures are complementary and can be studied using survivorship curves, as discussed by Murray and Lopez (1994) (**FIGURE 1-2**).

In Figure 1-2 (Murray et al., 2002), the darker line is the survivorship curve based on a standard hypothetical life table population that demonstrates the proportion (*y*-axis) of an initial birth cohort that remains alive at any age (*x*-axis). The area A + B is the total life expectancy at birth of this cohort. A part of this life is spent in full health (area A); the lighter line is the survivor curve of those persons in full health. Thus, area A represents time lived in full health, whereas area B is time lived in suboptimal health (with disability). Area C represents time lost due to mortality. The area of the complete rectangle (A + B + C) represents the ideal survivorship curve—the theoretical maximum of healthy life for a cohort who lived in full health until a maximum age when all died.

Health expectancies are summary measures that estimate expectancy of life in a defined state of health. Examples include DFLE, active life expectancy, and HALE. These indicators extend the concept of life expectancy to expectations of various states of health, not just of life per se. Health expectancies assign lower weights to life lived in less than full health on a scale of 0 to 1, in which full health is rated 1. In Figure 1-2, health expectancy is given by the following equation:

$$\text{Health expectancy} = A + f(B)$$

where f is some function that assigns weights to years lived in suboptimal health.

Health gaps are summary measures that estimate the difference between actual population health and some specified norm or goal. In Figure 1-2, that difference is indicated by area C (loss due to mortality) plus some function of area B—that is, survivorship with disability:

$$\text{Health gap (healthy life lost)} = C + g(B)$$

where g is some function that assigns weights to health states lived during time B. Weights range between 0, meaning no disability (full health), and 1, meaning complete disability (equivalent to death). Note that this measure is equivalent to healthy life lost based on the natural history of disease in a population as discussed in the section "Healthy Life Year" later in this chapter.

Although some believe that health expectancies such as the HALE indicator are more readily understood (because they are conceptual extensions of the

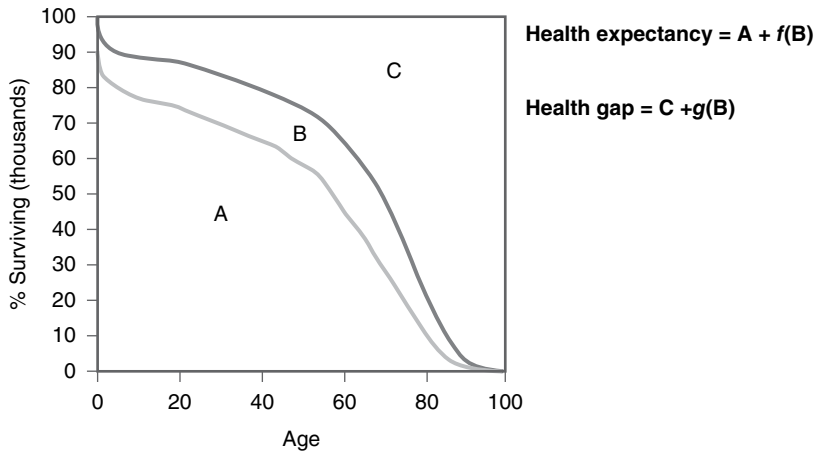

FIGURE 1-2 Survivorship curve of a hypothetical population showing health gaps and health expectancies.

Modified from Murray, C. J. L., et al. (2002). *Summary measures of population health*. Geneva, Switzerland: World Health Organization.

widely used life expectancy measure), health gap measures have important advantages for the purposes of health policy, planning, and resource allocation decisions. Both HeaLYs and DALYs are developed on the basis of disability and death attributable to a specific disease in an individual person. In their construction, great care is taken to ensure that there is *categorical attribution* using the ICD, so that each event (death or disability) is mutually exclusive and collectively exhaustive. With these measures, therefore, summing deaths and disabilities from each disease provides the total amount of death and disability for the population (a property termed *additive decomposition*). Health gap measures have this property, whereas health expectancies do not (Murray et al., 2002).

Composite Indicators

A number of composite summary indicators for burden of disease assessment have been developed. We will focus on four of these indicators: three of the health gap type (the healthy life year, the disability-adjusted life year, and the quality-adjusted life year) and one of the health expectancy type (HALE). In addition to measures of morbidity and mortality per se, these composite indicators may incorporate certain social value choices either explicitly or implicitly: the choice of life expectancy tables, valuing future life as compared with present life, valuing life lived at different ages, valuing social or economic productivity, and valuing equity in relation to cost-effectiveness. These social value choices are discussed later in this chapter (see the section "Valuing Life: Social Value Issues"), but because some social value choices are integral to the calculations of some composite indicators, they are briefly mentioned in this section.

Healthy Life Year

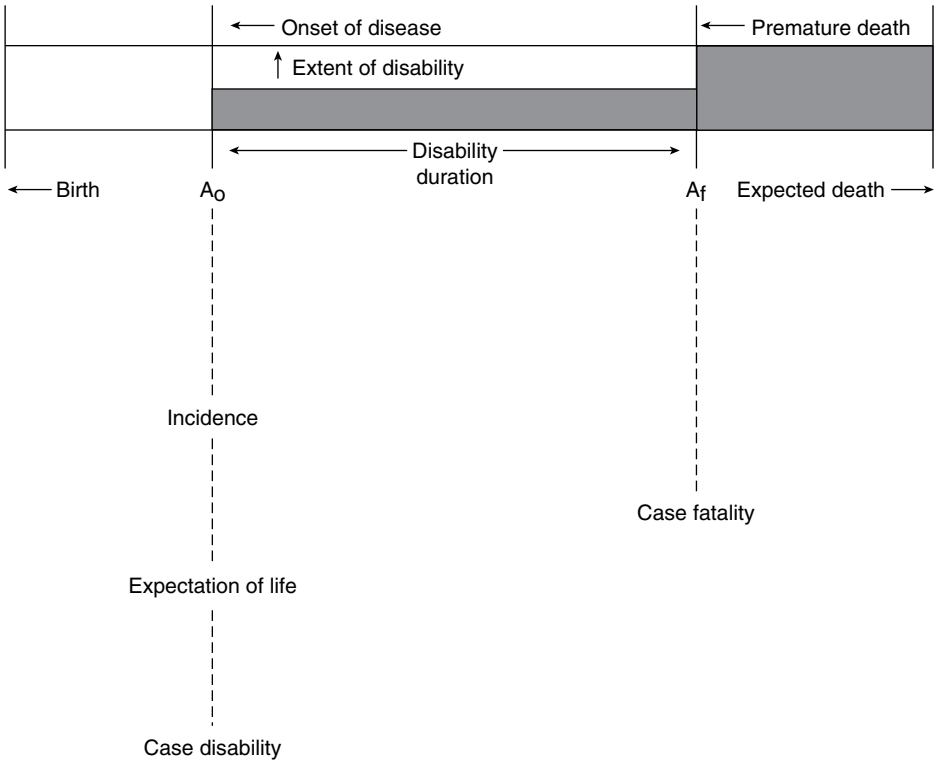
The healthy life year (HeaLY) is a composite measure that combines the amount of healthy life lost due to morbidity with that lost due to death—that is, loss of life expected had the disease not occurred (Hyder et al., 1998). We discuss the HeaLY first because it is conceptually straightforward, serves as a prototype for other health gap indicators, and was the first of the composite measures to be used as a tool in national health planning (Ghana Health Assessment Team, 1981).

Measuring the loss of healthy life from disability is more challenging than measuring the comparable loss from death, and many approaches have been used (Murray & Lopez, 1994). To incorporate loss from disability in a composite measure, such a loss must have comparable dimensions to that for life lost due to death. The HeaLY includes three components for disability: case disability ratio (comparable to the case fatality ratio), extent of disability, and duration of disability. The CDR and duration of disability can be determined objectively, but assessment of the extent of disability, which usually ranges from 0 (no disability) to 1 (equivalent to death), has a substantial subjective element (Morrow & Bryant, 1995).

The healthy life approach focuses on knowledge of the pathogenesis and natural history of disease (Last, Spasoff, & Harris, 2000) as the conceptual framework for assessing morbidity and mortality and for interpreting the effects of various interventions (**FIGURE 1-3**).

The onset of disease usually will be dated from the start of symptoms or signs, as determined by the individual afflicted, a family member, or a medical practitioner, or as the result of a lab test. Several different patterns of disease evolution are possible, of course. **FIGURE 1-4** illustrates healthy life lost from disability and premature death due to typical cases of cirrhosis, polio, and multiple sclerosis, respectively, in terms of onset, extent and duration of disability, and termination. The conclusion of the disease process depends on the natural history of the disease as modified by possible interventions. The possible outcomes include clinical recovery (the complete disappearance of clinical signs and symptoms), progression to another disease state (such as chronic hepatitis progressing to cirrhosis), and death. The last outcome includes death directly caused by the disease as well as death indirectly brought on by the disease as a result of disability.

The definitions of variables and formulas to calculate HeaLYs are provided later in this section and summarized in **TABLE 1-4**. Each disease will have a distribution of ages at which onset or death may occur, but for most diseases the average age will provide a satisfactory approximation for a population. In view of the limitations of data, this is the starting assumption for the application of the HeaLY method in LMICs. Nevertheless, as with other choices in this method, if sensitivity testing indicates that the average age is not satisfactory, then estimates may be based on age distributions. Similarly, if the natural history of a disease or response to interventions is different in different age groups, then the disease can be specifically classified by age (e.g., neonatal tetanus as compared with adult tetanus, and childhood pneumonia as compared with adult pneumonia). In recurrent diseases or diseases with multiple episodes (e.g., diarrhea), age at onset denotes the average age at first episode.



Note: A_o = average age at onset; A_f = average age at death; ■ = healthy life lost.

FIGURE 1-3 The HeaLY model: Loss of healthy life from disability and death.

The expectation of life in HeaLYs were based on normative expectations of what should occur under usual circumstances at the time of that work. Women in Japan, who had the highest global expectation of life, approximated this norm with an expectation of life at birth of 82.5 years for females (Model Life Table West, level 26) (Coale, Demeny, & Vaughan, 1983; Coale & Guo, 1989).

The definition of disease ("dis-ease") makes the value of the case disability ratio 1 by default for most disease states, because all cases are disabled (to varying degrees and duration) if those persons have been labeled as diseased. For some conditions (e.g., sickle cell trait or HIV positivity) and risk factors, however, cases may not be considered diseased by definition, but the condition nonetheless needs to be assessed.

The duration of disability can be either temporary or permanent (lifelong). If the disability is temporary, then Dt is the duration of that disability until recovery (see Table 1-4). If the disability is permanent and the disease does not affect life expectation, then Dt is the expectation of life at age of onset of disease [Dt = E(Ao)]. If the disability is permanent and the disease reduces life expectation, then Dt is the expectation of life at age of onset reduced by the difference between ages of fatality and onset [Dt = E(Ao) − (Af − Ao)]. A disability severity scale needs to be used to estimate extent (severity) of the disability (see Table 1-4).

The HeaLYs lost from death and from disability are added and expressed as the total years of life lost per 1,000 population per year. The loss is attributed to the year in which disease onset occurs and includes the stream of life lost from disability and death at any time after onset, even if these events happen many years later. This method offers a prospective view of the event (disease onset) and its natural history (or as modified by interventions) over time.

An important benefit of the HeaLY formulation is that the effects of different kinds of interventions can be readily explored to determine their expected gains in terms of healthy life. The HeaLY spreadsheet (available upon request from the authors) incorporates these concerns; it also includes options for considering the proportion of the population that will be covered by an intervention and allows for different levels of coverage for different segments of the population for each intervention.

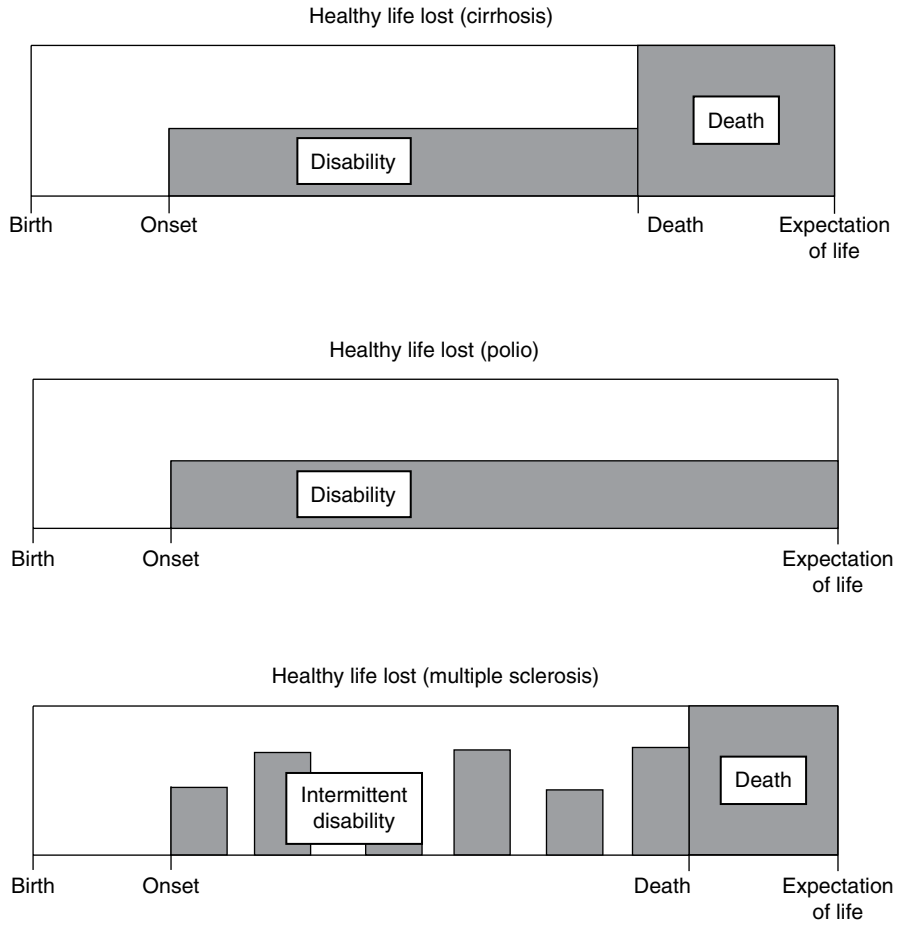


FIGURE 1-4 Different patterns of healthy life lost.

Disability-Adjusted Life Year

The disability-adjusted life year (DALY) is a health gap population summary measure that combines time lost due to disability with that lost due to death (life that would have been expected had the disease not occurred), in a manner similar to the HeaLY measure. It first appeared in the World Development Report of 1993 and has become the most widely used composite measure of population health (Global Burden of Disease Risk Factors Collaborators, 2016; Global Burden of Disease Risk Factors Collaborators et al., 2015; Jamison et al., 2006; Lim et al., 2012; Lopez et al., 2002; Murray & Lopez, 1994; Murray et al., 2002).

DALYs are calculated as two separate components for the measurement of life lost due to disease, and they may also directly include three social value choices. The two components are (1) years of life lost (YLL), referring to the loss of healthy life from death, and (2) years of life lived with disability (YLD), referring to the loss of healthy life from disability. Thus

$$\text{DALY} = \text{YLL} + \text{YLD}$$

The social value choices that may be included in DALYs are (1) life expectation values, (2) discount rates for future life, and (3) weighting for life lived at different ages, as discussed later.

Since the GBD 2010 study (Lozano et al., 2012), age weighting is no longer a default value choice for the DALY. Instead, users have the option to calculate these values with or without age weighting, as well as with or without discounting. The following three options could be applied: (1) use both age weights and discounting, (2) use either age weights or discounting, and (3) use neither age weights nor discounting.

The calculation for YLL in a population uses the age distribution of all deaths by cause in one year multiplied by life expectation at each age to estimate the loss of life for each disease that would have been expected if not for that disease. The expectation of life can be obtained either from a model life table (Coale & Guo, 1989) or based on the best achievable low levels of mortality such as those found in Japan; thus the DALY, as does the HeaLY, directly incorporates this social value choice.

TABLE 1-4 Variables for Estimating Healthy Life Years (HeaLYs)

Symbol	Explanation	Expression
I	Incidence rate per 1,000 population per year	/1,000/year
Ao	Average age at onset	years
Af	Average age at death	years
E(Ao)	Expectation of life at age of onset	years
E(Af)	Expectation of life at age of death	years
CFR	Case fatality ratio: proportion of those developing the disease who die from the disease	0.00–1.00
CDR	Case disability ratio: proportion of those developing the disease who have disability from the disease	0.00–1.00
De	Extent of disability (from none to complete disability equivalent to death)	0.00–1.00
Dt	Duration of disability in years	years
	Disability can be either permanent or temporary:	
	■ If temporary, then Dt = duration of that disability (i.e., until recovery or death)	
	■ If permanent and disease does not affect life expectation, then Dt = E(Ao)	
	■ If permanent and the disease does reduce life expectation, then Dt = Af − Ao	
HeaLY	Healthy life years lost per 1,000 population per year: $I \times \{[CFR \times \{E(Ao) - [Af - Ao]\}] + [CDR \times De \times Dt]\}$	HeaLYs per 1,000 per year

For disability, the DALY uses estimates of incidence, duration, and severity to calculate the time lived with disability (YLD) for each disease. The YLD component equals the number of incident cases in the period multiplied by the average duration of disease multiplied by a weight factor for the degree of severity (extent) of the disease. A description of the severity scale used in one version of DALY was given earlier in this chapter, in the section on measurement of disability (see Table 1-4).

The second social value choice, which was directly incorporated in the original version of DALY, is the discount rate of 3% per annum. This social time preference has been used for most estimates; recently, DALY results discounted at 0% have also become available.

The third social value choice concerns weighting life lived at different ages. Earlier DALYs were age weighted according to an arbitrary exponential curve designed to give the most value to life lived as a young adult (Hyder et al., 1998; World Bank, 1993). Weighting by age was the most controversial component of the DALYs when they appeared and caused great dissent from other health professionals (see the section "Valuing Life Lived at Different Ages" later in this chapter). Recent DALY listings from GBD studies also include results with no age weighting (all years equally valued). It has been argued that age weighting

of DALYs does not affect final results, but this depends on the purpose for making the estimates and has been challenged (Anand & Hanson, 1997; Barendregt, Bonneux, & Van der Maas, 1996; Barker & Green 1996; Hyder et al., 1998).

An important difference between the HeaLY and the DALY is the fact that the starting point for the HeaLY is the onset of disease; that is, the loss of healthy life is based on the natural history of the disease (as modified by interventions), illustrated in Figures 1-2 and 1-3. This is true for the YLD component of the DALY, but the YLL is based on mortality in the current year. In a steady state, there is no difference in these perspectives. However, when incidence is changing—such as with HIV in many parts of the globe—the DALY approach can potentially understate the true situation (Hyder & Morrow, 1999).

The calculation for DALYs can be expressed in the form of an integral that was first published in the World Bank literature (Murray & Lopez, 1994). This single equation incorporating all technical and value choices had the advantage of standardization to ensure comparability of the multiple calculations undertaken in the GBD studies, and greatly facilitated the actual computations. Nevertheless, for national and local priority setting, it may be preferable to use an indicator constructed such that the social value choices can be adjusted to suit national and local preferences (Bobadilla, 1998; Hyder et al., 1998; Morrow & Bryant, 1995). Recent DALY formulations allow for this possibility; indeed, it is useful to think of DALYs as a family of related measures using terminology specifying the following formulation: DALY (*r, K*) uses a discount rate of *r* and age weighting indexed to *K*. Other parameters can be added in a similar fashion (Jamison et al., 2006).

HeaLYs and DALYs are both "health gap" measures and can be considered part of the same family of measures. In fact, DALYS exactly equal HeaLYs when the following conditions are met: (1) the condition in question is in steady state or equilibrium (that is, the incidence, CFR, and disability variables remain constant during the time intervals under consideration); (2) age weighting is not applied ($K = 0$); and (3) the same measures of disability (weights) are used.

Quality-Adjusted Life Year

The quality-adjusted life year (QALY) was introduced in 1976 to provide a guiding principle for selecting among alternative tertiary healthcare interventions (Zeckhauser & Shepard, 1976). The idea was to develop a single measure of quality of life that would enable investigators to compare expected outcomes from different interventions—a measure that valued possible health states both for their quality of life and for their duration.

The central notion behind the QALY is that a year of life spent in one health state may be preferred to a year spent in another health state. This generic measure sums time spent in different health states using weights on a scale of 0.00 (dead) to 1.00 (perfectly healthy) for each health state; it is the arithmetic product of duration of life and a measure of quality of life (health state weight). For example, 5 years of perfect health = 5 QALYs; 2 years in a state measured as 0.5 of perfect health followed by 5 years of perfect health = 6 QALYs.

The QALY was originally developed as a differentiating indicator for individual choices among tertiary healthcare procedures, not as a measure of disease burden in a population. It was used to assess individual preferences for different health outcomes from alternative interventions (Morrow & Bryant, 1995). The QALY, too, comprises a large family of measures. Since its introduction, a wide variety of QALY measures have been developed, along with a voluminous literature on alternative methods incorporating a range of disability domains and a diversity of methods to assign weights to generate QALYs (Kaplan & Anderson, 1996; Nord, 1993). The most widely used measure is the EQ-5D (European Quality of Life with Five Domains and three levels of quality for each domain; www.euroqol.org).

Perhaps the most important use of QALYs has been as a common denominator to measure utility in cost-utility analysis (and effectiveness in cost-effectiveness analysis) to assist in resource allocation among alternative health interventions by ranking interventions in terms of cost per QALY (Kaplan & Anderson, 1996; Nord, 1992; Torrance, 1986). An early and widely publicized attempt to make the best use of healthcare resources by maximizing QALYs per dollar expended was the well-intentioned but rather unfortunate effort undertaken in Oregon in the early 1990s (**EXHIBIT 1-4**).

In the United Kingdom, as part of its 1997 National Health Service (NHS) reforms, the National Institute for Clinical Excellence (NICE; www.nice.org.uk) was created to advise public health officials about the effectiveness and cost-effectiveness of various health interventions. In an explicit attempt to introduce economic considerations in addition to medical judgments for the allocation of resources, NICE has produced a large collection of studies on the cost per QALY produced by the interventions it appraises. Some of these appraisals have been the source of considerable controversy. If a treatment is considered cost-effective for a group of patients,

EXHIBIT 1-4 Oregon: Historical Application of the QALY for Allocation of Resources

An early and well-known attempt to apply the QALY approach for allocation of health resources occurred in the state of Oregon (Blumstein, 1997). In 1988, Oregon faced a budgetary shortfall for its Medicaid program, and coverage for organ transplants was denied. In an effort to prioritize its health services, Oregon undertook a bold attempt to explicitly ration health services. A coalition including consumers, healthcare providers, insurers, business, and labor representatives launched a broad and courageous healthcare reform. It began with a series of "experiments" in which the decision-making process was based on a cost-effectiveness approach using quality of well-being (QWB—essentially a QALY) for comparing the outcomes of treatment options among people.

The initial list, published in 1990, consisted of 1600 condition/treatment pairs drawn up as follows:

Cost-effectiveness ratio = cost of services / (health gain × duration)
Cost of services = charges for treatment including all services and drugs
Quality of well-being (QWB) = sum of QWB weight (W) × each QWB state × probability that symptoms of that QWB state would occur
Health gain = QWB with treatment − QWB without treatment

From the beginning, there was great opposition to the very notion of rationing; consequent denial of services to those who had conditions that did not make the list contributed to the rancor. There were also unfortunate technical blunders in the generation of the first list. For example, treatment for thumb sucking was ranked higher than hospitalization for starvation, and treatment for crooked teeth higher than early treatment for Hodgkin's disease. Such inconsistencies, together with objections raised by groups advocating for the disabled, gave rise to alternative approaches for establishing rankings.

Although enormous public effort went into the reform and much was accomplished, the explicit cost-effectiveness approach with QALYs as the outcome measure was eventually dropped (Blumstein, 1997; Eddy, 1991; Morrow & Bryant, 1995; Nord, 1993).

NICE will recommend its use throughout the NHS; if not, it will recommend against its use in the NHS. The use of these cost-effectiveness studies as an aid to decision making is intended to increase the total healthcare benefits gained from the money spent by the NHS.

The QALY as originally used is essentially equivalent to the YLD of the DALY; in fact, it would be exactly the same as the YLD when the following conditions are met: (1) there is no discounting ($r = 0$); (2) there is no age weighting ($K = 0$); and (3) the same disability weights are used. More recently (as used in some cost-effectiveness studies), QALYs have incorporated life expectation as well.

Health-Adjusted Life Expectancies

Several types of health expectancies exist in the literature. During the 1990s, *disability-free life expectancy* (DFLE) and related measures were calculated for many countries (Robine, 1994; Mathers et al., 2001). However, these measures incorporate a dichotomous weighting scheme in which time spent in any health state categorized as disabled is assigned, arbitrarily, a weight of zero (equivalent to death). Thus, DFLE is not sensitive to differences in the severity distribution of disability in populations. In contrast, *disability-adjusted life expectancy* (DALE) adds up expectation of life for different health states with adjustment for severity weights. In 2001, WHO replaced the DALE terminology with *health-adjusted life expectancy* (HALE); the latter term will be used throughout the remainder of this text.

The HALE is a composite summary measure of population health status that belongs to the family of health expectancies; it summarizes the expected number of years to be lived in what might be termed the equivalent of "full health." WHO has used it as the measure of the average level of health of the populations of member states for annual reporting on population health for a few years (WHO, 2000).

Health expectancy indices combine the mortality experience of a population with the disability experience. The HALE is calculated using the prevalence of disability at each age so as to divide the years of life expected at each age (according to a life table cohort) into years with and without disability. Mortality is captured by using a life table method, while the disability component is expressed by additions of prevalence of various disabilities within the life table. This indicator allows an assessment of the proportion of life spent in disabled states. When compared with the total expectation of life, it translates into a measure of the total disability burden in a population.

Comparison of the various methods and specific indicators is available in the literature (Robine, 1994). Alternative methods are given in WHO's *National Burden of Disease Studies* manual (Mathers et al., 2001a). As originally designed, the HALE does not relate to

TABLE 1-5 Comparisons of Original Versions of Composite Summary Measures of Population Health

	Quality-Adjusted Life Years	Healthy Life Years	Disability-Adjusted Life Years	Health-Adjusted Life Expectancy
Origin	North America, 1976	Ghana Ministry of Health, 1981	World Bank development report, 1993	World Health Organization report, 2000
Purpose	Assess individual preferences for various outcomes from complex interventions	Assist in resource allocation decisions	Compare disease burdens in many different populations	Compare national disease burdens
Level of use	Personal decisions	National- and district-level decisions	Broad policy decisions	Global comparisons
Data	Tertiary hospital data and personal interviews	National and local data from multiple sources; expert review	Global data and expert opinion	Global data and expert opinion
Original discipline base	Economists, clinicians	Epidemiologists, clinicians, national planners	Economists, statisticians	Demographers, economists, statisticians
Social values that may be incorporated	Generally not included	Future life discounted	Age weighting (not mandatory), future life discounted	Not relevant

Reproduced from North America, 1976; Ghana Ministry of Health, 1981; World Bank Development Report, 1993; World Health Organization Report, 2000.

specific diseases, but rather to the average extent of disability among that proportion of each age group that is disabled. The lack of correlation between a condition or disease entity and the measure made it less valuable for resource allocation and cost-effectiveness calculations.

Summary

TABLE 1-5 summarizes these summary measures (original versions) in terms of origins, purposes, level of use, sources of data, and disciplinary background of originators.

Valuing Life: Social Value Issues

The very idea of valuing some lives more than others is jarring, yet these notions are regularly reflected in our actions. The value of life is often implicit in the way resource allocation decisions are made; therefore, as much as possible such decisions should be explicit, open, and transparent. Many thoughtful people have serious reservations about assigning a single number to such a complex multidimensional phenomenon as health. But what is the alternative for use as a measure of utility or effectiveness in economic analyses? Outcome measures must be expressed as a unidimensional measure to be comparable to unidimensional monetary expenditure units for costs. (However, decisions about allocation should not be made on a mechanical basis; other factors, including the effect on equity, may need to be considered in decisions in addition to the goal of maximizing healthy life per unit expenditure.)

To construct composite measures of population health, important social value choices must be made. Choices about which expectation for life should be used and about valuing life lived at different ages, valuing future life as compared with the present, valuing life in terms of economic and social productivity, and valuing equity in relation to efficiency—all raise major ethical concerns.

Expectation of Life

Years of life lost due to death and to chronic disability are based on life expected had the disease not occurred. To estimate the expectation of life in a population, a choice must be made between using a local, national, or model life table. This choice should be determined by the purpose of the study. For example, for assisting in national and local decision making, it may be more suitable to use national life tables based on the mortality and fertility of the population in question than to use model life tables. Conversely, a model life table might be selected to reflect the best health state possible in the world, as this selection may allow a fair comparison with other countries. For example, from a global perspective it would be unfair to use national life tables to compare gains that could be achieved from a particular intervention in Ghana with those in the United Kingdom, even if both costs and lives saved were the same in each country. The reason is that those lives saved in Ghana would have a lower life expectancy than those in the United Kingdom, resulting in less healthy life saved for the same expenditure. From the global viewpoint in this example, the priority would be to fund the intervention in the United Kingdom because it would produce more healthy life per expenditure than for Ghana.

Valuing Life Lived at Different Ages

Age weighting refers to the valuing of a year of life according to the age at which it is lived. This practice immediately raises questions about the basis for valuing human life. Does a day of one person's life have the same value as a day of anyone else's life? Does the value vary with age, economic productivity, or social status? Should life itself be valued separately from what is done with that life?

The Ghana Health Assessment Team (1981) judged that all human life was intrinsically valuable and that a given duration of any life was equal in value to that of any other life. The valuing of a year of life equally, irrespective of age, has been considered egalitarian (Busschbach, Hesing, & de Charro, 1993; Morrow & Bryant, 1995). This choice was incorporated into the development of the HeaLY approach: A year of life lived at any age is equally valued.

The original 1990 DALY formulation assigned an exponential function to provide a value chosen so that life lived as a dependent (e.g., infants, children, the elderly) was given less value than life lived during the productive years. With this approach, the intrinsic value of life increased from zero at birth to a maximum at age 25 and declined thereafter, so that a day of life of a 50-year-old was worth about 25% less than that of a 25-year-old. Paradoxically, the age weighting used in the original DALY formulation led to higher valuation of life lived before age 15 than did the HeaLY formulation, in which life lived at all ages has equal value (Barendregt et al., 1996; Hyder et al., 1998). Current formulations of the DALY leave age weighting as an option, and such weighting is not used with the HALE.

Age-related valuing has been justified by studies showing that individuals value their own life lived at different ages differently. Such values have been reported in the literature, and classic studies have reported that they are consistent across respondents of different ages (Busschbach et al., 1993). In addition, studies from many countries reveal a preference for saving younger lives as compared with older ones (Murray & Lopez, 1994). Nevertheless, it was not clear how much of the differential valuing of life at different ages is related to an underlying appreciation that economic and social productivity varies at different ages. If it is decided at the local or national level that healthy life should be valued according to economic and social productivity, then an alternative to age weighting might be to explicitly add a productivity factor or subtract for the societal costs of dependents, such as education (see the section "Valuing Life for Its Economic and Social Productivity").

Valuing Future Life Compared with Present Life: Discounting

Discounting is the process for determining the present value of future events. *Social time preference* takes into account the phenomenon that people value events at present more highly than those in the future (independent of inflation and of uncertainty). For investments in other sectors, time preference is normally taken into account by discounting future returns and costs by some appropriate discount rate. Thus, the discount rate can be considered the inverse of an interest rate. The main issue concerning discounting in relation to summary measures is whether discounting life itself is appropriate. There seems to be little question about the usefulness of discounting the future value of what is produced by healthy life, but should the life itself be discounted (Morrow & Bryant, 1995)?

Discounting has been applied in the health sector because both the losses from a disease and the benefits from a health intervention often occur in the future. An intervention today may not produce immediate benefits (such as in immunization), or it may result in benefits being sustained over a long time (such as in supplementary nutrition). The costs for these activities must be borne now, but the benefits are realized in the future and are less valuable than if they could

occur now. This is equivalent to investing money now so as to obtain more in the future. Thus, a HeaLY now has greater intrinsic value to an individual or community than one in the future (Gold, 1996; Weinstein, Siegel, Gold, Kamlet, & Russell, 1996).

The rate at which society is supposed to discount benefits, termed the social discount rate (SDR), is a numeric reflection of societal values regarding intertemporal allocation of current resources. There is no consensus about the most appropriate choice of a discount rate in health, but most agree that it should be lower than that used in the private commercial sector. Historically, the 1993 World Development Report and the first GBD studies used a discount rate of 3% per year (more recent iterations of the GBD studies do not use discounting in the default calculations, but instead have it as an optional parameter that can be set by the user); in lieu of other information, this rate has been adopted in many international public health cost-effectiveness studies. Nevertheless, the impact of using a range of discount rates, including zero, should be explored with each study.

Valuing Life for Its Economic and Social Productivity

Whether and how to value economic and social productivity for purposes of healthcare decision making is highly contentious; to a large extent, the age weighting incorporated in the original DALY formulation was considered by many to be a proxy for productivity. Such valuations should be considered separately, made explicit, and very much dependent on the purpose of the valuations. In general, productivity may be attributed to adults aged 15 to 64, and persons in these age groups could be given a higher value. Persons younger than age 15 and older than age 65 may be considered as dependents and given a lower value. Many variations for differential valuing are possible, including type of employment. People at different socioeconomic levels in a society are expected to have different capacities for productivity—yet, to value life according to income levels or social class would not seem fair and generally would not be acceptable. In LMICs, the value of marginal wages for subsistence agriculture is negligible, but the value of the workers' lives certainly is not.

A fundamental question is whether to consider adding a productivity component to the summary measures. Health issues do not readily conform to the requirements of market economics; information is inadequate, and misinformation is rife on the part of the providers as well as the public. Externalities from good health are generally large; demand for costly services is largely determined by the healthcare providers rather than by the consumers, and competitive market forces have not worked well for those in greatest need. In the private sector, demand for services is clearly related to productivity and willingness (and ability) to pay. However, if left to market forces alone, inequitable distribution would be inevitable.

Economic arguments have been put forward for valuing life according to productivity, but counter-claims have been made that human life cannot and should not be expressed in economic terms for decision-making purposes. Nevertheless, efforts to avoid such expression result in implicit valuation of life. More than 30 years ago, Barnum (1987) argued for adding productivity to the valuing of human life, stating that it has been ignored in health policy, is readily quantifiable, and does not ignore the welfare of children because the whole population is dependent on adult productivity for quality and sustenance. Such an economic appraisal of human life is often based on the net transfer of resources from the "producers" to the "consumers" and the consequent interdependence of people. In relation to this issue, in the *Report of the Commission on Macroeconomics and Health* (WHO, 2001), a DALY was stated to be worth at least an average annual income per head, although the basis for such a valuation was not adequately justified. More work on explicit valuations of human life and what that life produces is needed, and will certainly affect health-related cost-effectiveness decisions.

Valuing Equity in Relation to Efficiency

A child born in Malawi or Uganda will likely live only half (approximately) as long as one born in Sweden or Singapore; many babies born in Niger or Sierra Leone will not live to see their fifth birthday. These inequalities are unfair and harmful and, therefore, qualify as inequities. In terms of social justice, equity has to do with a fair distribution of benefits from social and economic development. However, the term *equity* is used in different conceptual senses: equal access to health services for all (opportunity equality), equal resources expended for each individual (supply equality), equal resources expended on each case of a particular condition (equality of resource use to meet biological need), equal healthy life gained per dollar expended (cost-effectiveness), care according to willingness to pay (economic-demand equality), care according to biological or socioeconomic need, and equal health states for all.

Decisions based on cost-effectiveness (e.g., cost per HeaLY), therefore, may not accord well with concerns about equity. These calculations are generally indifferent to equity; they are designed to steer interventions to what is efficient, whatever the differential need may be. To meet the requirements of equity,

health system planners need to go beyond ensuring equality of access to health care and require a balance so that health system responses are in accord with equity as well as efficiency.

Provided that health information is available according to socioeconomic and vulnerable groups, use of these summary indicators as tools for determining equity by calculating healthy life per dollar to be gained by all socioeconomic and vulnerable groups could readily be undertaken. It would be important to assess the impact of specific health decisions to ensure that they enhance equity. Summary measures such as HeaLYs and DALYs can be used to guide allocation of resources to ensure equitable distribution of those resources to reach those most in need. Cost-effectiveness by itself does not provide adequate guidance; equity should also be an associated criterion to govern the distribution of societal benefits.

Data for Composite Measures

Types of Data

The data needs for estimating the burden of disease in a region or country are extensive, and obtaining even reasonable estimates in LMICs has been a source of concern (Anand & Hanson, 1997; Barker & Green, 1996; Bobadilla, 1998; Murray et al., 2002). Brief descriptions of the types of data required follow. Note that any available data need to be carefully reviewed and optimally utilized.

Demographic Data. Population data are integral to burden of disease estimations and are needed both as denominators and for consistency checks. In a national setting, a recent census is useful for providing population counts by age, sex, and geographic location. Particularly helpful, when there is inadequate death registration, is to have a one-year post-census follow-up on a sample of enumeration areas to obtain robust age, sex, and place mortality. The age and sex distribution of the population is critical, and often is a major factor that determines the nature of the disease burden. A good vital registration system is a key asset that will provide both birth and death numbers. Underreporting, age misreporting, and other biases in data may have to be addressed (using standard demographic methods) prior to use of these data in burden of disease estimation.

Mortality. Mortality data are required for any burden of disease analysis. Specifically, age, sex, and place mortality rates greatly assist the analysis by defining the contribution of mortality to the pattern of disease burden. They also serve as an essential framework that constrains estimates obtained from a variety of special studies that fill important information gaps but may be incomplete or biased in the populations covered. Reporting errors, such as underreporting of deaths and failure to report age at death, need to be carefully examined. In particular, information must be evaluated for deficiencies in the under-5 group and older age groups. For the youngest ages, the probabilities of deaths in the first year (1q0) and in the next four years (4q1) provide better estimates of the risk of death than do overall mortality rates. Methods such as the Brass method for indirect estimates of mortality provide useful ways to assess age-specific mortality data for potential errors (Hill, 2001).

For burden of disease studies, cause of death data are required for all ages (except stillbirths, which are not included—a limitation of composite measures), but reliable cause of death records are often not available in LMICs, especially for deaths that do not occur in healthcare facilities. Even if available, the classification system used may be outdated and not based on the ICD, and the reliability of coding may vary by the type and location of the hospital. Young-adult deaths may be better recorded than deaths of infants and the elderly. Especially in low-income countries, it can be helpful to cross-check death records with other information, using postmortem interviews and hospital registers to assist in defining causes of death or to extrapolate from other data or other regions to assist in making estimates.

Morbidity. Meaningful data on disability are even more difficult to find and interpret than mortality data. Often morbidity information is institution-based or restricted to one or two sources, such as hospital inpatient and clinic outpatient records. The representativeness of small studies and the range and types of morbidity covered in any survey need careful evaluation. National disability surveys or regional studies conducted for the evaluation of disabled people may be available; such research is useful in providing some estimate of the prevalence of serious disabilities and their age and sex distribution. However, linkage between disability and disease is often not available, and attributing one type of disability to specific causes is difficult. For example, because many conditions can lead to blindness—for example, diabetes, hypertension, injuries, trachoma, and cataracts—the attribution of proportions of blindness in a population to its cause can be problematic. Information on the duration of disability may be found in specialized studies and the experience of institutions. The severity of disability will have to be rated on a scale; the various methods used in the literature were described earlier in this chapter.

Variables

The types of data just described need to be processed in the form of specific disease-based estimates. The key variables are defined in Table 1-4. The *incidence* rate (usually expressed per 1,000 general population per year) is central to the natural history of disease concept. Although incidence is a basic epidemiologic indicator, it is usually not found in routine data collection systems. Special studies, prospective surveys, or calculations based on the prevalence (which is more commonly available than the incidence) and knowledge of the average duration of the disease can be helpful in developing this measure.

The case fatality rate is the proportion of those developing the disease who die from it at any time. It is expressed as a decimal value between 0 (for nonfatal conditions) and 1 (for universally lethal conditions). The *case disability ratio* (analogous to the CFR) is the proportion of those diagnosed with a disease who have signs or symptoms, and is usually 1 (as discussed earlier). *Age* is required in various formats. Age at onset is when disease onset occurs in a population; age at fatality denotes the age at death as a result of the disease. The *expectation of life* at age of onset is the years of life expected at that age had the disease not occurred. Similarly, expectation of life at fatality is the years of life expected at that age had the death not occurred.

Checking Data

Data used for generation of indicators need to be evaluated for validity, reliability, and consistency, using defined qualitative and quantitative criteria. Large population-based studies may be given preference over smaller sample-based work if both are available and the quality of their data is comparable. Better conclusions may be possible by cross-checking different sources of data. Community-based studies, which may be representative of the population but have limited diagnostic validity, may be compared with hospital-based work, in which diagnosis may be valid but would come from a biased population sample. The following subsections profile simple types of checks for data quality.

Comparison of Total Numbers. Cross-checks should be done to compare total numbers. It is essential to check that the number of deaths in a year in a region is the same as the sum of all deaths from all causes in the same region. Similarly, program-based data can be compared with data from other sources to ensure better estimates of causes of death. The comparison of totals allows one to work within a frame of mortality and avoids double counting of one death. However, it does not assist in the distribution of deaths within that frame.

Relationship Between Variables. Checks based on the epidemiologic relationship between parameters refer to the application of simple, yet vital, relationships such as the following:

- Prevalence (point) = incidence × average duration of disease
- Cause-specific mortality rate = incidence × case fatality rate

These checks allow estimates from different sources to be compared for internal consistency. Such relationships can also be used to derive one of the estimates in the equations when the others are known.

Sensitivity Analysis. Sensitivity analysis is a useful tool to determine whether data that are more precise are required for the purposes of a particular decision. A one-way sensitivity analysis (Petiti, 1994) evaluates the effect of manipulating one variable at a time on the dependent variable. If the outcome is sensitive to one or more variables, their precision is more important in the estimation.

Disease Groups: Classification

Murray and Chen (1992) introduced a disease group system based on WHO's ICD classification system. Group I includes conditions characteristic of low-income countries: communicable diseases, maternal and prenatal conditions, and nutritional deficiencies. These conditions decline at rates faster than overall mortality rates as socioeconomic conditions improve; thus, group I contributes to a relatively small percentage of deaths in the high-income world. Group II, which consists of noncommunicable and chronic diseases, accounts for most loss of healthy life in high-income countries and proportionately increases with the epidemiologic transition in LMICs. Group III consists of injuries, both intentional and unintentional (including violence).

The distribution of the disease burden among these three groups is one indicator of the type of disease burden and the level of epidemiologic transition in a country. It is important to distinguish between the proportions of deaths attributed to these groups, as opposed to the risk of dying from the conditions in these groups. For example, the proportion of deaths attributable to group II causes increases from high- to low-mortality countries (or to an older age structure of the population); however, the risk of death from group II conditions is higher in high-mortality countries.

Implementing a Burden of Disease Study

Knowing how to conduct a burden of disease analysis is important for all countries. Generic steps for a national burden of disease study include the following:

- Assess demographic information, including a census with age, sex, geographic (urban/rural), and selected socioeconomic status information, and vital statistics with births and deaths.
- Collect cause-of-death information for all deaths in a year by age, sex, geographic location, and socioeconomic status as possible, according to the ICD system.
- Define disability by cause/disease, and develop a severity scale using expert and community input.
- Collate information by disease from all sources and assess these data's reliability and validity, using expert opinion when needed to define variables for a spreadsheet.
- Decide whether social value preferences such as age weighting, discounting, economic and social productivity, and expectation of life will be used and what their values will be.
- Estimate healthy life lost for each disease condition and by disease groups.
- Perform sensitivity analyses to check the robustness of results relative to critical variables and assumptions.
- Consider other variations, including assessment of losses by risk factors; regional, age, and sex breakdowns; and future projections.
- Review the policy implications for overall mortality and morbidity in the country and by cause; feed data into cost-effectiveness analysis and further research.
- Include other modifications as appropriate to the country setting.

To use summary measures to assist in health planning and resource allocation decisions, additional steps include the following:

- Estimate the effectiveness (gains of healthy life) of each intervention under consideration in terms of expected coverage and reductions in incidence and/or case fatality or case disability ratios.
- Work out the costs of the proposed interventions.
- Develop cost-effectiveness ratios to plan which combination of interventions targeted to which groups will provide a maximum return of healthy life per expenditure for the funds allocated to health.
- Review expected gains of healthy life according to age, sex, geographic area, and socioeconomic and vulnerable groups to ensure that all are better off (or at least none is worse off) and adjust as necessary.

Another very important consideration in this process is time. The conduct and analysis of such studies must be timely to assure its appropriate use by policy makers and useful for resource allocation decisions. The precision and comprehensive nature of the study must be balanced by the need for timely results.

The steps described previously may be carried out simultaneously or in some sequence, depending on the specific national situation. Modifications will likely be needed depending on the availability of data (**EXHIBIT 1-5**). An actual study requires careful planning on the part of those responsible for its conduct and may include many additional steps that are beyond the scope of this chapter. Even so, these generic steps summarize the essentials of applying the burden of disease methods to a country. Increasingly countries are obtaining, refining, and using these data on an ongoing fashion.

EXHIBIT 1-5 The Burden of Disease in United Arab Emirates, 2010

The United Arab Emirates (UAE) is one of the seven Gulf Cooperation Council (GCC) countries and consists of seven emirates: Abu Dhabi, Dubai, Sharjah, Ajman, Uum Al-Quwain, Fujairah, and Ras Al-Khaimah. An academic study was undertaken to estimate the burden of disease in UAE in 2010 and to develop a set of 2010 population estimates as well as a mortality and disability profile by age group and gender. This analysis was conducted for the UAE national and migrant populations. A burden of disease approach was used to calculate standard expected years of life lost (YLL). Data from the Global Burden of Disease 2010 study and vital registration data from the UAE's Ministry of Health were utilized for the study. Forty-five disease and injury conditions were included in the analysis. Disability estimates were calculated in terms of years of life lived with disability (YLD) using health data from the Emirate of Abu Dhabi; 150 conditions were included in the final analysis.

In 2010, the crude death rate per 1,000 population was 2.47 for UAE nationals and 1.00 for migrants. For all residents of the UAE, regardless of nationality, the leading causes of death were ischemic heart disease (14.5%), other circulatory system diseases (12.4%), motor vehicle crashes (11.3%), malignant neoplasm (6.5%), and other respiratory tract infections (5.5%). For UAE nationals, the crude death rate was estimated at 2.84 for males and 2.08 for females; for migrants, the crude death rate was estimated at 0.99 for males and 1.01 for females. Age-specific mortality rates (ASMRs) for most age groups were lower in migrant males compared to males who were UAE nationals, except for the age groups of 10–14 and 25–29 years.

(continues)

EXHIBIT 1-5 The Burden of Disease in United Arab Emirates, 2010 *(continued)*

The rates were also lower in migrant females compared to nationals, except for migrant females in the age groups of 30–39, 45–49, and 55–64 years.

A total of 291,834 YLL was lost in 2010 due to premature mortality; nationals accounted for 27% of this total and migrants for 73%. YLL lost for migrants (males: 48,514; females: 28,986) were greater than that for nationals (males: 169,864; females: 44,470), reflecting the population imbalance in the UAE wherein migrants vastly outnumber migrants. The leading causes of premature mortality for migrants were motor vehicle crashes, ischemic heart disease, and other circulatory system diseases. Drowning, falls, fires, and unintentional poisoning were some of the important causes of injuries among migrant children between 5 and 14 years of age. Occupational injuries were also an important cause of premature deaths among migrant males between 15 and 44 years.

Overall, the estimated YLD lost was 373,051; nationals accounted for 37% of YLD losses, and the losses were distributed equally among males and females. The top five conditions causing disability among nationals were low back and neck pain (26%), other musculoskeletal diseases (8.3%), injuries (7%), and diabetes (5.3%). Noncommunicable diseases and injuries were responsible for the top 20 causes of YLDs among both nationals and migrants.

FIGURE 1-5 shows the main causes of death in the UAE, and **TABLE 1-6** reviews the top conditions responsible for disease burden in the UAE.

TABLE 1-6 Burden of Disease, United Arab Emirates, 2010

	Premature Mortality Only	Disability (YLD) Only	Disability-Adjusted Life Years (DALY)
Rank	Disease	Disease	Disease
1	Motor vehicle crashes	Low back and neck pain	Injuries
2	Ischemic heart disease	Other musculoskeletal disorders	Diseases of the musculoskeletal
3	Other circulatory disease	Injury requiring urgent care	Diseases of the circulatory system
4	Congenital anomalies	Fracture of sternum, rib, or bone	Diseases of the respiratory system
5	Perinatal conditions	Diabetes	Endocrine, nutritional, and metabolic diseases, and immunity disorders
6	Other respiratory tract diseases	Chronic obstructive pulmonary disease	Neoplasm
7	Other malignant neoplasm	Open wounds, superficial injuries	Congenital anomalies
8	Cerebrovascular disease	Fracture of patella, tibia, fibula	Perinatal conditions
9	Suicide	Other neurologic disorders	Diseases of the nervous system
10	Diabetes mellitus	Eczema	Diseases of the digestive system

Data from Allen, K. (2010). A national burden of disease study for the United Arab Emirates (UAE): Quantifying mortality and morbidity differentials between nationals and migrants, 2010.

Comparisons and Trends in Disease Burden

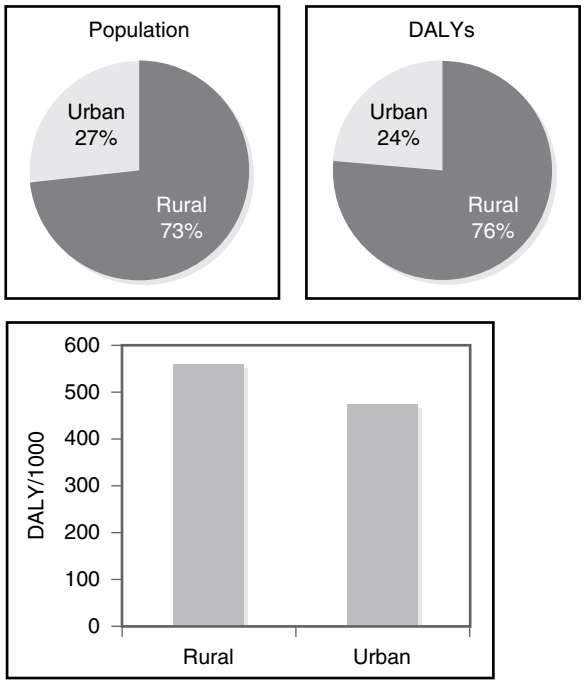
This section reviews a number of country-based and historical burden of disease studies to compare and assess trends in disease burden from place to place and over time.

National Disease Burden Assessments

Comparing the burden of disease across populations, time, and place is an important aspect of national burden of disease studies. This subsection uses examples from burden of disease studies over the past two decades to illustrate how disaggregated data can help in understanding the distribution of ill health in a country.

The Andhra Pradesh Burden of Disease Study, 2001

The regional distribution (urban/rural, state, district) of the disease burden is important to explore in a national burden of disease study. Andhra Pradesh, a state in India, was the focus of one of the most meticulous burden of disease studies, conducted between 1994 and 2001. It had a population of 76 million in 2001, 27% of whom lived in urban areas (20.8 million people); a 1:3 ratio of urban-to-rural disease burden in terms of DALYs lost was identified (Mahapatra, 2001). The burden of disease rates were 19% higher in rural areas than in urban areas, as measured by DALYs lost per 1,000 population (**FIGURE 1-6**).



Note: Total DALYs lost in Andhra Pradesh = 5 million.

FIGURE 1-6 Burden of disease in Andhra Pradesh, 2001, by region.

Data from Mahapatra, P. (2001). *Estimating national burden of disease: The burden of disease in Andhra Pradesh 1990s.* Hyderabad: Institute of Health Systems.

The Burden of Disease and Injury in New Zealand, 2013

According to the latest burden of disease estimates from New Zealand, there has been a reduction in DALYs by 1.2% per year after adjusting for population changes and age structures. The main burden of disease is due to losses from noncommunicable diseases (88%), followed by injuries (8%), and communicable diseases (4%). Approximately 52% of the DALYs are due to nonfatal outcomes. Aging of the population and longer life expectancy is an area of focus for New Zealand to develop and implement preventive and management programs. Coronary heart disease in males and back pain among females are main causes of health loss (Tobias, 2016) (**FIGURE 1-7**).

Burden of Disease Estimates for South Africa, 2000

HIV/AIDS is ravaging Africa; thus, the impact of HIV/AIDS on the burden of disease in African countries can be significant. In South Africa, 30% of the 15 million DALYs lost in 2000 were attributed to HIV/AIDS (**FIGURE 1-8**) (Bradshaw et al., 2003); for a population of 45 million, this means 0.33 DALY lost per capita. Such data are important for national decision making.

The Burden of Disease and Injury in Australia, 2003

In 2003, 2.63 million DALYs lost were attributed to the disease and injury burden in Australia, with 62% of this burden caused by noncommunicable diseases such as cancers and cardiovascular diseases and mental and neurologic disorders. Approximately 49% of the disease burden was caused by deaths from various diseases and injuries, while 51% was due to nonfatal disease and injury outcomes. The top three causes of fatal outcomes were cancers (32.0%), cardiovascular disease (29.0%), and injuries (11.0%); the leading causes of nonfatal outcomes were mental disorders (24%) and neurologic and sense disorders (19%) (Begg et al., 2007) (**FIGURE 1-9**).

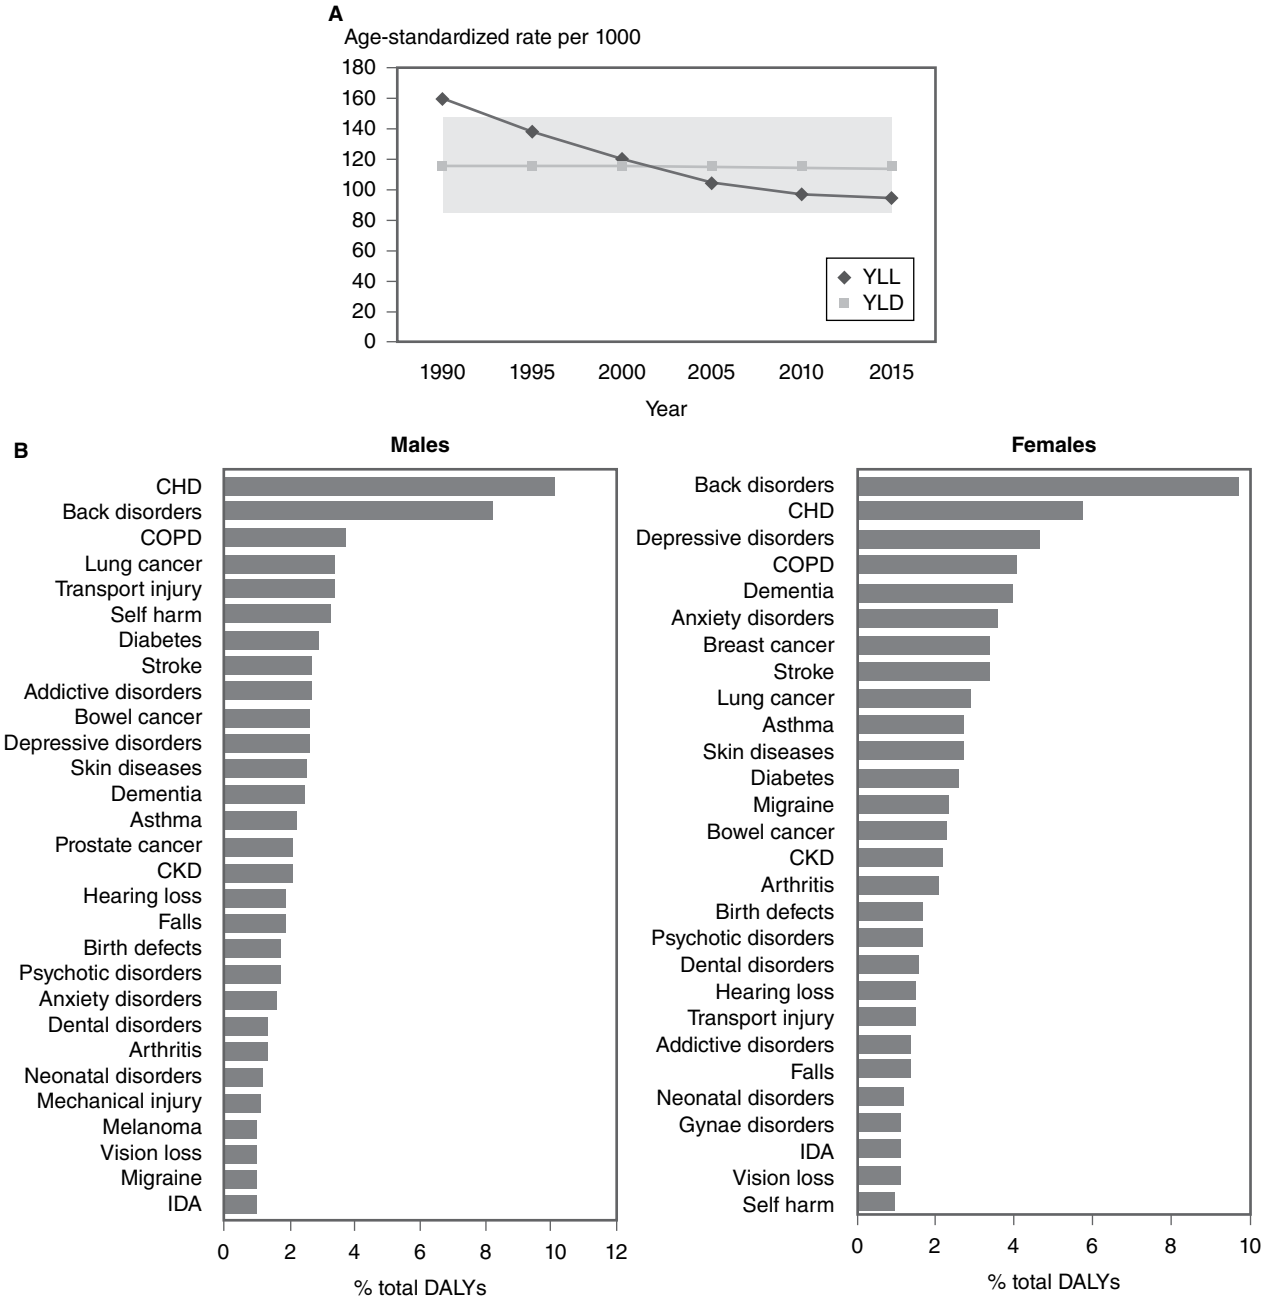


FIGURE 1-7 (a) All-cause YLL and YLD age-standardized rates per 1,000, whole population,1990–2013, in New Zealand. (b) Contribution of leading major specific conditions to health loss (% total DALYs), by gender, 2013, in New Zealand.

The Burden of Disease Attributable to 11 Risk Factors in Hubei Province, China, 2016

Health losses caused by 11 risk factors—namely, smoking, secondhand smoke, alcohol use, diet low in vegetables, diet low in fruits, diet high in sodium, low physical activity, high body mass index, high fasting plasma glucose, high total cholesterol, and high blood pressure—were estimated using multiple data sources in China. They included data related to population demographics, mortality, DALYs, and distribution of exposure to risk factors. Approximately 53% of all deaths were caused by these 11 risk factors, with the mortality rate being 330 per 100,000 people. The DALY rate for the 11 risk factors was 9624 per 100,000 people and accounted for 36% of all DALYs. The leading risk factor for death and DALYs was high blood pressure, which accounted for 15% of all deaths and 9% of total DALYs (**FIGURE 1-10**).

WHO Estimates of Global Burden of Disease

WHO has categorized its member states by income levels into high-, middle-, and low-income nations. The population of the world in 2015 totaled slightly more than 7.3 billion people, with 84% residing in LMICs (**FIGURE 1-11**). As may be expected, approximately 88% of the global burden is found in LMICs, reflecting the double challenge faced by the majority of people in the world: They are relatively poor and they are unhealthy. This relationship between ill health and poverty has long been recognized as complex and has been the object of much research and inquiry.

Burden of Disease by Disease Groups

Another way to disaggregate data is to explore the disease burden based on three disease groups: group I (communicable, infectious, maternal, and perinatal), group II (noncommunicable, chronic), and group III (injuries and violence). There is great variation in the portions allocated to these groups; for example, group I conditions may be responsible for anywhere from 12% to 70% of the burden of disease. When the countries are stratified by gross national income (GNI) per capita as a measure of development, an important trend can be seen from historical data (**TABLE 1-7**): As income rises, the proportion of the burden attributable to group I conditions decreases, while the share attributable to group II conditions increases. This effect is progressive, although countries such Turkmenistan (a middle-income country) still retain a high group I burden. This finding is consistent with the theory of epidemiologic transition, which predicts a change in a country's disease profile with economic development.

Global Assessments of Disease Burden

Information regarding health and disease for all countries of the world can be collated to provide a picture of global health status. In addition, global health assessments may be completed as a separate activity, and these data can then be disaggregated into regional

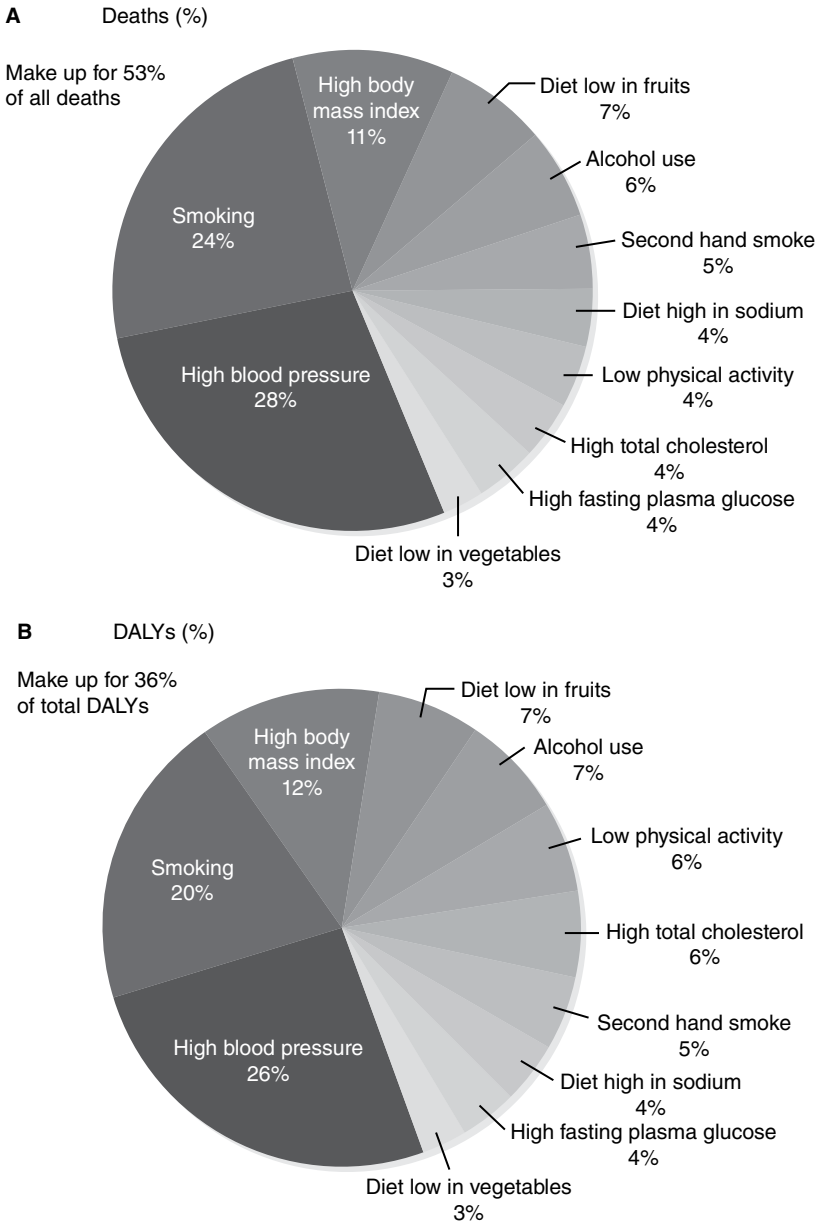

FIGURE 1-10 Burden of disease attributed to 11 risk factors in Hubei Province, China, 2013.

Data from Cui F, Zhang L, Yu C, Hu S, Zhang Y. (2016). Estimation of the disease burden attributable to 11 risk factors in Hubei Province, China: A comparative risk assessment. *International Journal of Environmental Research and Public Health*, *13*(10), 944.

information. Global assessments serve to highlight major challenges facing the world community, and trends in such assessments indicate progress, if any, in improving the health of people worldwide. Such information is critical to the work of organizations such as WHO and UNICEF in their efforts to combat ill health and disease worldwide. This section highlights results of some of these global exercises for assessment of the disease burden and projections for the future.

The Global Burden of Disease Study

The 2015 Global Burden of Disease study constructed estimates of mortality, disability, and DALYs by cause for regions of the world. Demographic estimates of deaths in 2015 by age and sex form the basis of this work. It provides all-cause and cause-specific estimates for 195 countries for 249 causes from the year 1990 to 2015. The results were based on a variety of sources, including vital registrations systems, special studies, surveys, and expert opinion. This section summarizes some of the 2015 GDB data.

Mortality. Globally, in 2015, an estimated 55.8 million deaths occurred, 55% of whom were males. Approximately 20% of global deaths in 2015 were due to group I causes (communicable, maternal, neonatal, and

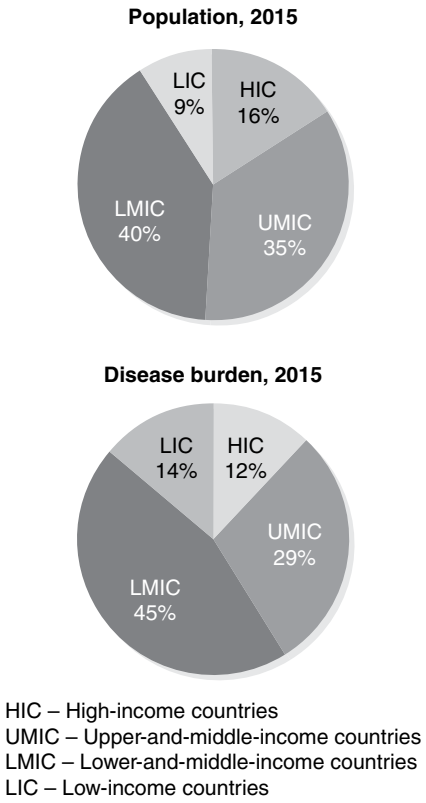

FIGURE 1-11 Global burden of disease, 2015, by income level of countries.

Data from World Health Organization. (2015). *Global burden of disease estimates*. http://www.who.int/healthinfo/global_burden_disease/en/

nutritional diseases), 71% were due to noncommunicable diseases, and 9% were due to injuries. Ischemic heart disease, cerebrovascular disease, and chronic obstructive pulmonary disease were the top three causes of death. Road traffic injuries, self-harm, falls, interpersonal violence, and drowning were the top five causes of injury-related deaths in 2015. Approximately 5.8 million deaths occurred in children younger than 5 years of age globally, with more than 80% of these fatalities being caused by group I causes. Of those under-5 deaths, 79% occurred in the African and Southeast Asia regions. An inordinate share of the mortality burden at the beginning of this century was found in LMICs, even among adults.

TABLE 1-8 shows the differences in the 10 leading causes of deaths in 2015 for high- and low-income countries. The presence of perinatal conditions, tuberculosis, HIV/AIDS, and malaria in the low-income world is indicative of the high impact of these conditions on premature mortality. These conditions are absent from the top 10 causes in the high-income countries, reflecting the success in combating these infectious conditions in the modern era. It is important to note that noncommunicable diseases such as cerebrovascular diseases and ischemic heart disease had already become prominent causes of premature deaths in the low-income world in 2015.

TABLE 1-7 Historical Distribution of Disease Burden Within Countries

Disease Burden in Disease Categories (of 100%)			
Country	**Group I**	**Group II**	**Group III**
Low-Income Nations (GNI per capita: $1,045 or less)*			
Benin	60	30	10
Guinea	65	26	9
Haiti	40	45	15
Mozambique	64	27	9
Lower Middle-Income Nations (GNI per capita: $1,046–$4,125)			
Bangladesh	32	59	9
Cambodia	33	54	13
Egypt	21	72	7
Uzbekistan	26	64	10
Upper Middle-Income Nations (GNI per capita: $4,126–$12,736)			
Colombia	13	67	20
Mauritius	9	84	7
Mexico	13	75	13
Turkmenistan	24	65	11

Note: Disease classification system: Group I: Communicable, infectious, maternal, and perinatal; Group II: Noncommunicable and chronic; Group III: Injuries and accidents.
* Gross national income (GNI) per capita calculated using the World Bank Atlas method.
Data from WHO and World Bank, 2015.

Disability. The GBD study 2015 update also provides an evaluation of the contributions made by specific conditions to disability in the world. Leading causes of disability in 2015 worldwide are shown in

TABLE 1-8 Leading Causes of Deaths in High-Income and Low-Income Countries, 2015

High-Income Countries		Low-Income Countries	
Rank	**Cause**	**Rank**	**Cause**
1	Ischemic heart disease	1	Lower respiratory infections
2	Cerebrovascular disease	2	HIV/AIDS
3	Alzheimer's and other dementias	3	Diarrheal diseases
4	Lung cancer	4	Malaria
5	Lower respiratory tract infection	5	Cerebrovascular disease
6	Chronic obstructive pulmonary disease	6	Ischemic heart disease
7	Colorectal cancers	7	Tuberculosis
8	Chronic kidney disease	8	Congenital defects
9	Diabetes	9	Neonatal preterm birth complications
10	Breast cancer	10	Neonatal encephalopathy

Data from GBD, 2015 (Based on the World Bank income categories).

TABLE 1-9. Neuropsychiatric and behavioral conditions, musculoskeletal disorders, and diabetes dominate the causes of disability, accounting for 5 of the top 10 conditions. However, a diverse spectrum of conditions, such as iron-deficiency anemia, skin diseases, and oral disorders, also appear on the list. A unique contribution of the GBD work has been its placement of nonfatal health outcomes in the center of international health policy in recent years. The important, and yet often ignored, effects of these conditions are obvious once disability is counted in these estimates of disease burden.

Disease Burden. Based on the estimation of deaths and disability presented in the preceding subsection, the global disease burden for 2015 was estimated using DALYs. Leading causes of the global burden in 2015 (**TABLE 1-10**) indicate how those conditions affect the global disease burden. The top 10 list is a mixture of communicable and perinatal conditions, noncommunicable diseases, and road traffic injuries. This situation highlights the challenge facing the global health community as it simultaneously continues to fight infectious diseases, seeks to improve the response to chronic conditions, and prepares to meet the increasing impact of injuries.

Age and Disease Distributions. **FIGURE 1-12** illustrates the distribution of the global burden in 2015 by disease groups and demonstrates the growing relative impact of chronic diseases (group II) over infectious conditions (group I). **FIGURE 1-13** provides comparable figures for loss of healthy life in seven major regions of the world. Note that communicable diseases still represent a considerable portion of the disease burden in 2015, especially in sub-Saharan Africa.

As the figures demonstrate, various subregions within middle- and low-income countries are at different stages of the epidemiologic transition. The influx of chronic diseases has added another layer of problems in some areas, while the burden of communicable diseases has not yet been eradicated. This "double burden" poses a major challenge for the health systems in these nations. In addition, the scarcity of resources in many of these countries makes the situation even more critical, and it becomes imperative to define interventions that are cost-effective and able to reduce the burden of disease.

Other Ways Burden Can Be Measured

Mortality and morbidity alone have been used for decades for international comparisons of disease

TABLE 1-9 Leading Causes of Disability Losses Globally, 2015

Rank	Cause
1	Lower back and neck pain
2	Sense organ diseases
3	Depressive disorders
4	Iron-deficiency anemia
5	Skin diseases
6	Diabetes
7	Migraine
8	Other musculoskeletal disorders
9	Anxiety disorders
10	Oral disorders

Note: Disability losses are defined by years of life lived with disability (YLD). Ranking is based on YLD rates for all age groups, both sex and level 3 cause (http://ihmeuw.org/44lj).

Data from GBD, 2015.

TABLE 1-10 Leading Cause of Global Burden of Disease, 2015

Rank	Cause
1	Ischemic heart disease
2	Cerebrovascular disease
3	Lower respiratory infections
4	Low back and neck pain
5	Neonatal preterm birth complications
6	Diarrheal diseases
7	Sense organ disease
8	Neonatal encephalopathy
9	Road traffic injuries
10	HIV/AIDS

Data from Institute for Health Metrics and Evaluation, 2015. Ranking based on DALYs rates for all age groups, both sex for 2015 and level 3 cause. Retrieved from http://ihmeuw.org/44lk.

burden. Mortality among children younger than 5 years is considered a sensitive indicator of the overall health of nations, but especially of the health of women and children. UNICEF publishes an annual *State of the World's Children* report (UNICEF, 2016) that includes a ranking of nations based on this indicator (**TABLE 1-11**).

Gross national income (GNI) per capita is an indicator of national wealth, and the relationship between these variables usually follows an expected sequence, such that the country with the lowest GNI per capita has the worst indicators of health. However, as Table 1-11 indicates, even countries that have relatively higher per capita income can have poor indicators of health service accessibility (e.g., proportion of newborns protected against tetanus). For example, the per capita GNI for Mongolia is higher than that for Nicaragua, yet both the countries rank 84th for under-5 mortality, with lower life expectancy in Mongolia compared to Nicaragua. Such examples demonstrate that the relationship between health and poverty is complex and needs in-depth investigation. When seeking to improve the health of nations, both absolute poverty and the disparities within societies serve as impediments to empowerment of the poor and needy, especially women and children.

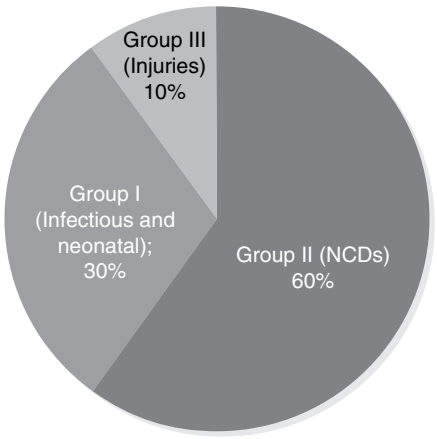

FIGURE 1-12 Global burden of disease 2015 by disease groups.
Data from GBD, 2015.

Projections

Forecasts of disease burden have been attempted with the intent of providing some basis for health planning. Making such projections is a challenging task

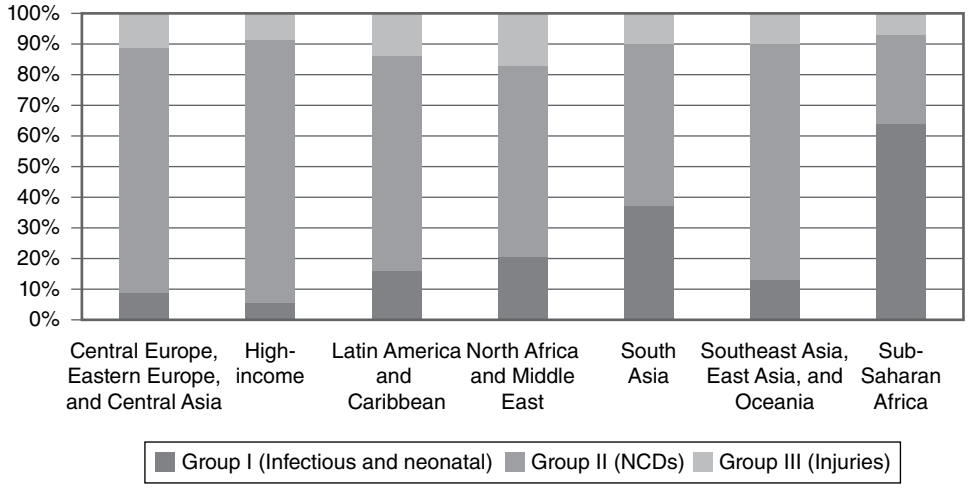

FIGURE 1-13 Proportion of disease burden by disease groups in selected regions, 2015.

Data from GBD, 2015.

TABLE 1-11 Health Status Indicators and National Income for Selected Low- and Middle-Income Countries

Country	Ranking by Child Mortality (<5 years)	Life Expectation at Birth, 2015 (years)	Stunted Children <5 Years (%)	Newborns Protected Against Tetanus *(%)	Gross National Income per Capita, 2014 (U.S. dollars)
Afghanistan	16	61	41	70	680
Angola	1	53	29	78	4,126 to 12,735
Bhutan	67	70	34	83	2,370
Guatemala	71	72	47	85	3,430
Mongolia	84	70	11	—	4,280
Nicaragua	84	75	23	81	1,870
Niger	10	62	43	81	410
Pakistan	22	66	45	75	1,400
Peru	99	75	15	85	6,360
Sierra Leone	5	51	38	85	700

* Modeling is done based on pregnant women who were given two doses or more of tetanus toxoid vaccine to calculate the percentage of births that can be considered as protected against tetanus.
Data from UNICEF, 2016.

that requires further data manipulations and the use of assumptions. These assumptions must predict changes in disease prevalence and incidence over time, the effects of interventions, and other factors. As a result, all projections are estimates with substantial variations that are highly dependent on the data used to derive them.

The GBD 2015 study was conducted to provide burden of disease estimates for more than 200 health conditions. These estimates are available based on gender, age groups, countries, and regions, allowing for comparisons across different years. Estimates are available since 1990, and the current

leading causes of disease burden are presented in Table 1-10.

The dominance of chronic diseases on this list is obvious, although respiratory conditions still appear to be important. Injuries from road traffic crashes are the ninth leading cause of the global disease burden and are expected to rise in prominence.

The growing importance of noncommunicable diseases is a global phenomenon, and these conditions' impact on low- and middle-income countries and regions needs to be assessed. However, there is a persistent burden of respiratory infections and diarrheal diseases in these regions. The situation in the low- and middle-income world is one where the "triple burden" of persistent communicable diseases, prevalent noncommunicable conditions, and increasing injuries will call for an appropriate response from public health officials.

Burden of Disease Attributed to Risk Factors

An analysis of risk factors that underlie many important disease conditions can help inform policy decisions concerning interventions directed toward health promotion and disease reduction. For example, smoking, alcohol, hypertension, and malnutrition are risk factors for a variety of diseases, and specific interventions have been developed that may reduce their prevalence. Risk factors include an array of human behaviors, nutritional deficiencies and excesses, substance abuse, and certain characteristics such as hypertension. Some factors are both an outcome and a risk factor (hypertension), some are challenging to measure (violence), and yet others (smoking and alcohol) lead to many possible disease outcomes. The linkage between an identified risk factor and the set of associated disease outcomes may be difficult to directly quantify, and the portion of specific disease prevalence attributable to any one factor may be problematic.

Relationships such as those shown in **FIGURE 1-14** require careful assessment to determine the proportion of heart disease to be attributed to hypertension in relation to other interacting causal factors. The best way to determine the portion of disease that may be ascribed to hypertension is through randomized trials with careful assessment of disease outcomes over time: Results from studies that control hypertension have shown a reduction of death and disability from not only cardiac disease, but also from cerebrovascular and renal diseases.

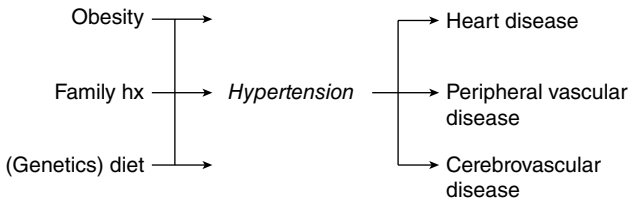

FIGURE 1-14 Flowchart of a "disease" and "risk factor" – Hypertension.

Because the most important purpose of risk factor analysis is to assist in decision making about the allocation of resources, the link between the various risk factors and potential interventions to reduce those risks should be clear. The effectiveness of interventions against risk factors ultimately should be judged by their ability to reduce the amount of healthy life lost attributed to the diseases that the risk factor affects. For the evaluation of an intervention that reduces hypertension, for example, the healthy life losses from the entire range of diseases that hypertension influences are required.

Although understanding the underlying factors that lead to disease and the complex interrelations in the web of causation has long been a major focus of epidemiology (Rothman, 2012), most analyses of the relationships of risk factors to specific diseases have been done in the context of individual risk factors in limited settings and with wide variations in the criteria for risk assessment. As a consequence, comparisons of risk factors as determinants of disease on a population health level are problematic.

The Burden of Selected Major Risk Factors

The model used in recent GBD studies for causal attribution of health outcomes is based on *counterfactual analysis* that focuses on risk factor compared to a counterfactual risk distribution (Ezzati et al., 2002). Within this analysis, the contribution of one risk factor, or a group of risk factors, to disease or mortality was estimated by comparing the current or future disease burden with the levels that would be expected under an alternative hypothetical scenario. This involves an evaluation of the effect that a risk factor has on a disease and its consequences, by setting the risk factor to its minimum while keeping all other factors constant. This method has the advantage of showing the potential gains by risk reduction from all levels of suboptimal exposure in a consistent way across risk factors (Ezzati et al., 2002).

The Comparative Risk Assessment (CRA) part of GBD 2015, for example, carried out a systematic evaluation of 79 risk factors divided into three main groups (referred to as "level 1")—behavioral, environmental

and occupational, and metabolic risks—relative to global and regional burdens of disease using a specific model for analysis (WHO, 2002a). Recently, the analysis was conducted from 1990 to 2015 for 17 level 2 risk factors (Global Burden of Disease Risk Factors Collaborators, 2016). As shown in part (a) of **FIGURE 1-15**, the five leading risks for mortality on a global level are dietary risks (19%), high systolic blood pressure (17%), tobacco smoke (11%), air pollution (10%), and high fasting plasma glucose (8%); together these account for 65% of global mortality. These five factors especially increase risks for heart disease, diabetes, and cancer and have major consequences for countries across all income groups. Part (b) of Figure 1-15

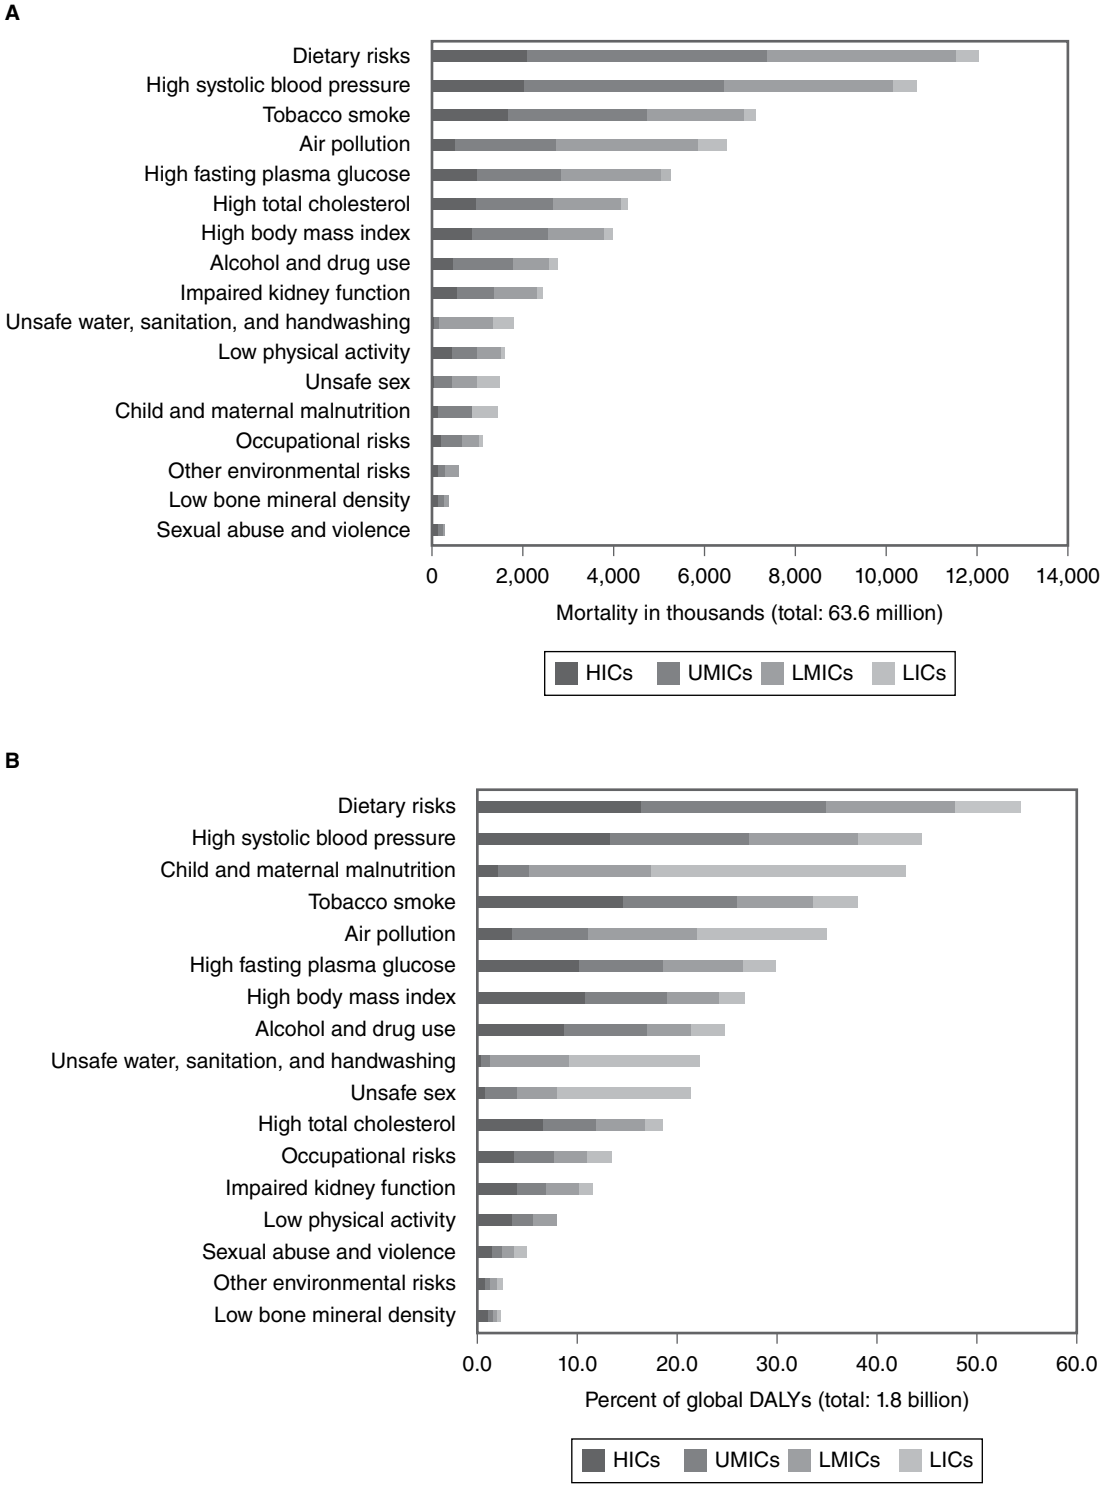

FIGURE 1-15 Mortality (a) and DALYs (b) due to 19 leading risk factors by country income level, 2015.

Data from GBD, 2015.

shows the main risks for burden of disease (DALYs) on a global level, with dietary risks (15%), high systolic blood pressure (12%), child and maternal malnutrition (9%), tobacco smoke (9%), and air pollution (9%) accounting for more than half of the global DALYs. These estimates show the contribution of behavioral and environmental risk factors toward development of group II diseases.

The recent reductions in environmental risk factors mostly stem from reductions in unsafe water, unsafe sanitation, poor hygiene, and household air pollution. In terms of behavioral risk factors, smoking is among five top risk factors contributing to DALYs at the regional level. Alcohol and drug abuse is largely a problem for men, contributing to 7% of burden of disease in 2015, but those mainly affected vary greatly by geographic region: This factor has its greatest impact on men in Southeast Asia, South Asia, and Central and Eastern European countries (Institute for Health Metrics and Evaluation, 2015).

Eight level 2 risk factors—dietary risks, high blood pressure, high total cholesterol, air pollution, tobacco, high fasting plasma glucose, high body mass index, and low physical activity—account for more than 90% of ischemic heart disease (the leading cause of death worldwide). Although these major risk factors are associated with high-income countries, more than 88% of the total global burden of disease that they cause occurs in LMICs (Institute for Health Metrics and Evaluation, 2015). Some risk factors may have few effects on the total global burden of disease, yet be very important locally within certain populations and regions. For example, iodine deficiency affects certain LMICs and results in substantial disability in those populations.

The demographic and epidemiologic transitions discussed earlier in this chapter affect shifts in these major risk factors by changing social, economic, and political trends and their complex interactions. Low-income countries continue to struggle against the high burdens of infectious diseases, malnutrition (including undernutrition and micronutrient deficiencies), and maternal and child health problems; at the same time, they must deal with the additional burdens of high levels of noncommunicable disease and injuries. WHO has estimated that if such types of risks did not exist, global life expectancy would be 10 years longer (Mathers, Stevens, & Mascarenhas, 2009).

Conclusion

The health of populations is the fundamental concern of global public health. The first step in the pursuit of population health improvement is the measurement of health and disease. Measurement is required to establish the magnitude of disease problems, define causal factors, explore potential solutions, and determine the impact of interventions. Measuring the impact of diseases on populations in terms of mortality and morbidity and their consequences is essential for planning effective ways to reduce the burden of illness and for setting priorities.

The burden of disease in populations has been gauged in many ways. Examples include measures of mortality, such as infant mortality rates; demographic measures, such as expectation of life at birth; and measures of morbidity, such as days away from work. However, for purposes of comparison among populations and for assisting in health planning and resource allocation, a common denominator combining these factors is needed. Summary measures of population health based on the amount of healthy life lost from disability and from death have been developed to serve that purpose. Composite indicators (such as HeaLYs and DALYs) use duration of time (years, weeks, days) to measure the loss of healthy life from disease and the gain from interventions. These metrics are evolving into important tools for assisting health-related decision making. Nevertheless, to avoid misuse of such indicators, it is critical for those using them to understand the underlying assumptions and limitations and to meet the rather formidable data requirements. These summary measures also could be used to examine the burden of disease among subpopulations defined by sociocultural economic attributes and especially on vulnerable groups. Thus, they could be used for ensuring that health-related decisions consider equity as well as cost-effective criteria.

Trends in disease burden provide important clues about the success of ongoing health programs and the need for development of new interventions. At the same time, they reflect non-health-related factors that are important to the production or maintenance of health in populations. Inter-country and inter-regional comparisons allow for measuring progress among nations; they can highlight inequalities in health status and examine these disparities in relation to social, economic, educational, and other factors.

Health systems across the world are greatly affected by ongoing changes in disease profiles and population dynamics. These systems must develop the capacity to respond to such changes effectively within the resources of each nation. Decisions must be based on evidence about the patterns of diseases, their risk factors, and the effectiveness of alternative interventions. Timely collection and analysis of appropriate, high-quality data to support such evidence are

a prerequisite for improving equitable global health development.

Acknowledgments

The authors would like to express their gratitude to Nukhba Zia for the editorial support provided in the preparation of this chapter. The authors would also like to acknowledge the contributions of the late Dr. Richard H. Morrow, MD, MPH, who made significant contributions to previous iterations of this chapter.

Discussion Questions

1. How can data help achieve the main purpose of a health system in any country? Give examples.
2. What are the essential elements of a burden of disease assessment, and which types of data are the most challenging to obtain in a low-income country?
3. What are the relative strengths and weaknesses of summary measures such as HeaLYs and DALYs compared to more traditional indicators of disease burden such as infant or maternal mortality?
4. In your country or city, what would be the most appropriate set of indicators to assess the impact of chronic diseases on the population? Why?

Appendix 1

Some of the Health-Related SDG Indicators

Target 2.1: By 2030, end hunger and ensure access by all people, in particular the poor and people in vulnerable situations, including infants, to safe, nutritious, and sufficient food all year round

- 2.1.1 Prevalence of undernourishment

Target 2.2: By 2030, end all forms of malnutrition, including achieving, by 2025, the internationally agreed targets on stunting and wasting in children under 5 years of age, and address the nutritional needs of adolescent girls, pregnant and lactating women, and older persons

- 2.2.1 Prevalence of stunting
- 2.2.2 Prevalence of malnutrition

Target 3.1: By 2030, reduce the global maternal mortality ratio to less than 70 per 100,000 live births

- 3.1.1 Maternal mortality ratio
- 3.1.2 Proportion of births attended by skilled health personnel

Target 3.2: By 2030, end preventable deaths of newborns and children under 5 years of age, with all countries aiming to reduce neonatal mortality to at least as low as 12 per 1,000 live births and under-5 mortality to at least as low as 25 per 1,000 live births

- 3.2.1 Under-5 mortality rate
- 3.2.2 Neonatal mortality rate

Target 3.3: By 2030, end the epidemics of AIDS, tuberculosis, malaria, and neglected tropical diseases and combat hepatitis, water-borne diseases, and other communicable diseases

- 3.3.1 Number of new HIV infections per 1,000 uninfected population, by sex, age, and key populations
- 3.3.2 Tuberculosis incidence per 1,000 population
- 3.3.3 Malaria incidence per 1,000 population
- 3.3.4 Hepatitis B incidence per 100,000 population
- 3.3.5 Number of people requiring interventions against neglected tropical diseases

Target 3.4: By 2030, reduce by one third premature mortality from noncommunicable diseases through prevention and treatment and promote mental health and well-being

- 3.4.1 Mortality rate attributed to cardiovascular disease, cancer, diabetes, or chronic respiratory disease
- 3.4.2 Suicide mortality rate

Target 3.5: Strengthen the prevention and treatment of substance abuse, including narcotic drug abuse and harmful use of alcohol

- 3.5.1 Coverage of treatment interventions (pharmacological, psychosocial, and rehabilitation and aftercare services) for substance use disorders
- 3.5.2 Harmful use of alcohol, defined according to the national context as alcohol per capita consumption (aged 15 years and older) within a calendar year in liters of pure alcohol

Target 3.6: By 2020, halve the number of global deaths and injuries from road traffic accidents

- 3.6.1 Death rate due to road traffic injuries

Target 3.7: By 2030, ensure universal access to sexual and reproductive healthcare services, including for family planning, information and education, and the integration of reproductive health into national strategies and programs

- 3.7.1 Proportion of women of reproductive age (aged 15–49 years) who have their need for family planning satisfied with modern methods
- 3.7.2 Adolescent birth rate (aged 10–14 years; aged 15–19 years) per 1,000 women in that age group

Target 3.8 Achieve universal health coverage, including financial risk protection, access to quality essential healthcare services, and access to safe, effective, quality, and affordable essential medicines and vaccines for all

- 3.8.1 Coverage of essential health services
- 3.8.2 Number of people covered by health insurance or a public health system per 1,000 population

Target 3.9: By 2030, substantially reduce the number of deaths and illnesses from hazardous chemicals and air, water, and soil pollution and contamination

- 3.9.1 Mortality rate attributed to household and ambient air pollution
- 3.9.2 Mortality rate attributed to unsafe water, unsafe sanitation and lack of hygiene (exposure to unsafe Water, Sanitation and Hygiene for All [WASH] services)
- 3.9.3 Mortality rate attributed to unintentional poisoning

Target 4.2: By 2030, ensure that all girls and boys have access to quality early childhood development, care, and pre-primary education so that they are ready for primary education

- 4.2.1 Proportion of children under 5 years of age who are developmentally on track in health, learning, and psychosocial well-being, by sex

Target 5.2: Eliminate all forms of violence against all women and girls in the public and private spheres, including trafficking and sexual and other types of exploitation

- 5.2.1 Proportion of ever-partnered women and girls aged 15 years and older subjected to physical, sexual, or psychological violence by a current or former intimate partner in the previous 12 months, by form of violence and by age
- 5.2.2 Proportion of women and girls aged 15 years and older subjected to sexual violence by persons other than an intimate partner in the previous 12 months, by age and place of occurrence

Target 5.6: Ensure universal access to sexual and reproductive health and reproductive rights

- 5.6.2 Number of countries with laws and regulations that guarantee women aged 15–49 years access to sexual and reproductive health care, information, and education

Target 6.1: By 2030, achieve universal and equitable access to safe and affordable drinking water for all

- 6.1.1 Proportion of population using safely managed drinking water services

Target 6.2: By 2030, achieve access to adequate and equitable sanitation and hygiene for all and end open defecation, paying special attention to the needs of women and girls and those in vulnerable situations

- 6.2.1 Proportion of population using safely managed sanitation services, including a hand-washing facility with soap and water

Target 8.8 Protect labor rights and promote safe and secure working environments for all workers, including migrant workers, in particular women migrants, and those in precarious employment

- 8.8.1 Frequency rates of fatal and nonfatal occupational injuries, by sex and migrant status

Target 11.5: By 2030, significantly reduce the number of deaths and the number of people affected and substantially decrease the direct economic losses relative to global gross domestic product caused by disasters, including water-related disasters, with a focus on protecting the poor and people in vulnerable situations

- 11.5.1 Number of deaths, missing persons, and persons affected by disaster per 100,000 people

Target 11.7 By 2030, provide universal access to safe, inclusive, and accessible green and public spaces, in particular for women and children, older persons, and persons with disabilities

- 11.7.2 Proportion of persons who are victims of physical or sexual harassment, by sex, age, disability status, and place of occurrence, in the previous 12 months

Target 16.1: Significantly reduce all forms of violence and related death rates everywhere

- 16.1.1 Number of victims of intentional homicide per 100,000 population, by sex and age
- 16.1.2 Conflict-related deaths per 100,000 population, by sex, age, and cause
- 16.1.3 Proportion of population subjected to physical, psychological, or sexual violence in the previous 12 months
- 16.1.4 Proportion of population that feel safe walking alone around the area they live

Target 16.2 End abuse, exploitation, trafficking, and all forms of violence against and torture of children

- 16.2.1 Proportion of children aged 1–17 years who experienced any physical punishment and/or psychological aggression by caregivers in the past month
- 16.2.3 Proportion of young women and men aged 18–29 years who experienced sexual violence by age 18

CHAPTER 2

Culture, Behavior, and Health

Susan C. Scrimshaw and Sandra D. Lane

"If you wish to help a community improve its health, you must learn to think like the people of that community. Before asking a group of people to assume new health habits, it is wise to ascertain the existing habits, how these habits are linked to one another, what functions they perform, and what they mean to those who practice them" (Paul, 1955, p. 1).

People around the world have beliefs and behaviors related to health and illness that stem from cultural forces as well as individual experiences and perceptions. A 16-country study of community perceptions of health, illness, and primary health care found that in all 42 communities studied, people used both the Western biomedical system and indigenous practices, including indigenous practitioners. Also, there were discrepancies between which services the governmental agencies said existed in the community and what was really available. Due to positive experiences with alternative healing systems and shortcomings in the Western biomedical system, people relied on both (Nichter, 2008; Scrimshaw, 1992). In recognition of the widespread use of nonbiomedical therapies, the U.S. National Institutes of Health established a center for the study of alternative and complementary medicine, which is now called the National Center for Complementary and Integrative Health (NCCIH, 2014). With a yearly budget of $124.1 million, the NCCIH's mandate is to provide research evidence of efficacy for nonbiomedical treatments, such as acupuncture, herbal preparations, meditation, and spiritual healing. The popularity of complementary and integrative approaches was demonstrated by a U.S. nationwide survey, demonstrating that 33.2% of adults used such treatments (NCCIH, 2017). The global importance of those approaches is evidenced by the World Health Organization's (WHO) major report, *WHO Traditional Medicine Strategy 2014–2023*, and the establishment of 21 regional centers for the study of traditional medicine to strengthen the evidence base and promote quality.

In the past three decades, we have moved from rejecting traditional health beliefs and practices to understanding that culturally rooted, traditional healing approaches are valued and used, often in combination with biomedicine. At this time there is increasing recognition that such approaches can and should be rigorously evaluated. Nevertheless, appreciation for cultural knowledge and behaviors in the planning and execution of health programs often falls short of the mark. Experience has shown that when health programs fail to recognize and work with indigenous beliefs and practices, they also fail to reach their goals. Similarly, research to plan and evaluate health programs must take cultural beliefs and behaviors into account if researchers expect to understand why programs are not working and determine what to do about it.

This chapter draws on the social sciences—particularly, anthropology, psychology, and sociology—to examine the cultural and behavioral parameters that are essential to understanding global health efforts. It complements the *Understanding and Acting on Social Determinants of Health and Health Equity*

chapter, which covers social, political, and economic forces that affect health, but does not go deeply into the cultural components of health. This chapter begins with some key concepts from the field of anthropology and the subfield of medical anthropology. It continues with brief descriptions of the various types of health belief systems and healers around the world. Next, some key theories of health behavior and behavioral and cultural change are described and discussed. Issues of health literacy and health communication are then addressed, along with the myriad health promotion strategies available. Methodological issues are presented, followed by a case study of acquired immunodeficiency syndrome (AIDS) and a commentary on the international efforts to curb the Ebola virus pandemic in West Africa. Another case study examines the use of rapid assessment methods to guide the introduction of an improved nutritional cereal for infants and children in Ghana. The chapter concludes by summarizing how all of these areas need to be considered in global health efforts.

Basic Concepts from Medical Anthropology

Health and illness are defined, labeled, evaluated, and acted upon in the context of culture. In the nineteenth century, anthropologist Edmund Tyler (1871) defined culture as "that complex whole which includes knowledge, belief, art, morals, law, custom, and any other capabilities acquired by man as a member of society." Since those early days of anthropology, there have been literally hundreds of definitions of culture, but most have the following concepts in common (Board on Neuroscience and Behavioral Health, 2002):

- Shared ideas meanings and values
- Socially learned, not genetically transmitted
- Patterns of behavior that are guided by these shared ideas, meanings, and values
- Often exists at an unconscious level
- Constantly modified through "lived experiences"

The last of these concepts—*lived experiences*—comprises the experiences that people (and sometimes groups of people) go through as they live their lives. These experiences modify their culturally influenced beliefs and behaviors (Garro, 2000; Mattingly & Garro, 2000). As a consequence, culture is not static on either the group or the individual level; rather, people are constantly changing. This concept allows for cultural change as people migrate to a new setting (community, region, or country), as people acquire additional education and experiences, and as conditions change around them (e.g., armed conflicts, economic changes in a country or region, political changes). This is a helpful viewpoint when looking at cultural change on both individual and group levels.

Medical anthropologists observe different cultures and their perspectives on disease and illness. For example, they look at the biological and the ecological aspects of disease, the cultural perspectives, and the ways in which cultures approach prevention and treatment.

Insider Versus Outsider Perspectives

To understand the cultural context of health, it is essential to work with several key concepts. First, the concepts of insider and outsider perspectives are useful for examining when we are seeing things from our point of view and when we are trying to understand someone else's view of things. The insider perspective (*emic,* in anthropological terminology) shows the culture as viewed from within. It refers to the meaning that people attach to things from their cultural perspective. For example, the view that worms (*Ascaris*) in children are normal and are caused by eating sweets is a perspective found within some cultures. The outsider perspective (*etic,* in anthropological terminology) refers to the same thing as seen from the outside. Rather than meaning, it conveys a structural approach, or something as seen without understanding its meaning for a given culture. The outsider perspective can also convey an outsider's meaning attached to the same phenomenon. For example, this view might hold that *Ascaris* infection is contracted through eggs in contaminated soil or foods contaminated by contact with that soil; the eggs get into the soil through fecal wastes from infected individuals. The concepts of insider and outsider perspectives allow us to look at health, illness, and prevention and treatment systems from several vantage points; to analyze the differences between these perspectives; and to develop approaches that will work within a cultural context (Scrimshaw & Hurtado, 1987).

To continue the example, in Guatemalan villages where the previously mentioned insider beliefs about *Ascaris* prevailed, researchers learned that some mothers believed that worms are normal and are not a problem unless they become agitated. In their view, worms live in a bag or sac in the stomach and are fine while so confined. Agitated worms get out and appear in the feces or may be coughed up. Mothers also believed that worms are more likely to become agitated during the rainy season, because the thunder and lightning frighten them. From an outsider perspective, this relationship makes sense: Sanitation is

more likely to break down in the rainy season, so there is more chance of infection and more diarrheal disease, which will reveal the worms.

The dilemma for the health workers, in the Guatemalan worms example, was to get the mothers to accept deworming medication for their children, because most of the time worms were perceived as normal. If the health workers tried to tell the mothers that their beliefs were wrong, the mothers would reason that the health workers did not understand illness in a Guatemalan village and would reject their proposal. The compromise was to suggest that the children be dewormed just before the rainy season, so as to avoid the problem of agitated worms. It worked.*

The insider–outsider approach leads to another set of concepts. According to the Western biomedical definition, disease is the outsider perspective—that is, disease is an undesirable deviation from a measurable norm. Deviations in temperature, white blood cell count, red blood cell count, bone density, and many others are, therefore, seen as indicators of disease. Illness, in contrast, means "not feeling well." Thus, it is a subjective, insider view. This sets up some immediate dissonances between the two views. It is possible to have an undesirable deviation from a Western biomedical norm and to feel fine. Hypertension, early stages of cancer, human immunodeficiency virus (HIV) infection, and early stages of diabetes are all instances where people may feel well, yet have a disease. Thus, healthcare providers must communicate the need for behaviors to "fix" something that people may not realize is wrong.

This potential conflict becomes even more critical when we think about the role of risk factors and prevention in contemporary biomedical practice. Laboratory tests can reveal the potential risk of future disease—for example, elevated low-density lipoprotein cholesterol (LDL) level, which may be predictive of an increased possibility of future cardiac or arterial disease. To reduce the possibility of such future disease, the patient might be labeled as "high risk" and prescribed medication to take daily for years. Even among those persons with substantial education, it is difficult to understand how to interpret risk and probability when one feels well and does not have a disease. The widespread rejection of vaccines by some well-educated parents represents another example of the power of insider (*emic*) understandings. The failure of public health advocacy for vaccines to convince such parents of the outsider (*etic*) view of the safety and value of vaccines demonstrates the power of cultural beliefs even in the face of scientific evidence.

It is also possible for someone to feel ill and for the Western biomedical system not to identify a disease. When this occurs, there is a tendency for Western-trained healthcare providers to say that nothing is wrong or that the person has a "psychosomatic" problem. Although both of these statements can be correct, there are several other explanations for this occurrence. One possibility is that Western biomedical science has not yet figured out how to measure a disease or disorder. Recent examples of this phenomenon include chronic fatigue syndrome and fibromyalgia: These conditions were labeled "psychosomatic" at one time, and remain incompletely understood by biomedicine, but now are defined by measurable deviations from a biological norm. Similarly, painful menstruation was labeled "subconscious rejection of femininity" in the past, but is now associated with elevated prostaglandin levels and can be helped by administration of a prostaglandin inhibitor.

A more intriguing set of conditions are what anthropologists have called "culture-bound syndromes" (Hughes, 1990; Simons, 2001; Simons & Hughes, 1985), but that might be better described as "culturally defined syndromes." *Culturally defined syndromes* are an insider way of describing and attributing a set of symptoms. They often refer to symptoms of a mental or psychological problem, but a physiological disease may also exist, posing a challenge to the health practitioner. For example, Rubel, O'Nell, and Collado-Ardon (1984) found that an illness called *susto* ("fright") in Mexico corresponded with symptoms of tuberculosis in adults. If people were told there was no such thing as *susto* and that they had tuberculosis, they rejected the diagnosis and the treatment on the grounds that the doctors obviously knew nothing about *susto*. This situation was complicated by the fact that tuberculosis was viewed as serious and stigmatizing. The solution was to discuss the symptoms with people and mention that Western biomedicine has a treatment for those symptoms (Rubel et al., 1984). *Susto* may also be used to describe other sets of symptoms—for example, those of diarrheal disease in children (Scrimshaw & Hurtado, 1988). Other examples of culture-bound syndromes include evil eye (Latin America, the Mediterranean), zar (the Middle East and North Africa), brain fag or brain fog (West Africa), amok (running amok) or *mata elap* (Indonesia, Malaysia, and the Philippines), *latah* (Malaysia and Indonesia), *p'a leng* (China), and *ataque de nervios* (Puerto Rico) (Guarnaccia et al., 2010; Simons & Hughes, 1985).

* We are indebted to Elena Hurtado of Guatemala for this example.

A recent example of what appears to be a new culture-bound syndrome has emerged among refugee children in Sweden whose families faced deportation (Aviv, 2017). *Uppgivenhetssyndrom*, or resignation syndrome, afflicting hundreds of children on the eve of their families' deportation, involves loss of speech and voluntary movement. The children exhibit no neurologic pathology in clinical tests, yet they must be fed, washed, and turned in bed by caregivers, as if they are comatose.

Not all individuals within a group will necessarily have the same beliefs and behaviors. With culturally defined syndromes, it is essential for an outsider to ask about the symptoms associated with the illness and to proceed with diagnosis and treatment on the basis of those symptoms. This is good practice in any event, because people often make a distinction between the cause of a disease or illness and its symptoms. Even if the perceived cause is inconsistent with the Western biomedical system, a disease can be diagnosed and treated based on the symptoms without challenging people's beliefs about the cause. When people's beliefs about the cause are denied, they may reject prevention or treatment measures entirely (Nichter, 2008).

The term *Western biomedicine* is used throughout this chapter because a term like *modern medicine* would deny the fact that there are other medical systems, such as Chinese and Ayurvedic medicine, that have modern forms. *Indigenous medical system* is used to refer to an insider—"within the culture"—system. Thus, Western biomedicine is an indigenous medical system in some countries, such as the United States and Canada, but it may exist side by side with other indigenous systems, even in the United States and Western Europe. In most of the world, Western biomedicine now coexists with, and often dominates, local or indigenous systems. Because of this multiplicity of systems, and because of class differences, physicians and policy makers in a country may not accept or even be aware of the extent to which indigenous systems exist or recognize their importance (Cameron, 2010). Also, many countries are home to peoples with multiple cultures and multiple languages. The cross-cultural principles discussed in this chapter may be just as important to work within a country as it is to work in multiple countries or cultures.

Ethnocentrism

Another key concept from medical anthropology is that of ethnocentrism. *Ethnocentric* refers to seeing your own culture as "best." Ethnocentrism is a natural tendency, because the survival and perpetuation of a culture depend on its teaching its children to accept the culture and on its members feeling that it is a good thing. In the context of cross-cultural understanding, ethnocentrism poses a barrier if people approach a culture with the attitude that it is inferior to their own culture. One of anthropology's key contributions to how we view the world is *cultural relativism*, which refers to the idea that the beliefs, behaviors, and values of each culture make sense within that culture. From this perspective, each culture has developed its own ways of solving the problems of how to live together; how to obtain the essentials of life, such as food and shelter; how to explain phenomena; and so on. Cultural relativism has been misunderstood in contemporary discourse as implying that we should not hold beliefs about "right" and "wrong," especially about culturally patterned practices that may cause harm. For example, in parts of Africa and the Middle East, female infants or young girls may have their genitals partially or completely amputated, which is sometimes called "female genital mutilation" by Western activists seeking to end the practice. Lane and Rubinstein (1996), in their analysis of the practice, advocated that cultural relativism means that we should try to understand the cultural explanations driving the practice and the context in which it occurs. At the same time, they emphasize that understanding why and how this behavior occurs does *not* mean that we condone the practice. Indeed, familiarity with the cultural rationale of a potentially harmful practice can be the basis of effective intervention against it.

The importance of seeking to understand a cultural practice can be a major challenge when global health is considered. What if a behavior is "wrong" from an epidemiologic perspective? How does one distinguish between a "dangerous" behavior (e.g., using an HIV-contaminated needle, swimming in a river with snails known to carry schistosomiasis, ingesting a powder with lead in it as part of a healing ritual) and behaviors that are merely different and, therefore, seem odd? For example, Bolivian peasants traditionally used very fine clay in a drink believed to be good for digestion and stomach ailments. Health workers succeeded in discouraging this practice in some communities because "eating dirt" seemed like a bad thing. The health workers then found themselves faced with increased caries and other symptoms of calcium deficiency in these same communities. Analysis revealed that the clay was a key source of calcium for these communities. It turns out that biomedicine also uses clay—but we color it pink or give it a mint flavor and put it in a bottle with a fancy label (S. Scrimshaw, personal observation).

Thus, there is a delicate balance between being judgmental without good reason and seeking to introduce behavior change because there is real harm from existing behaviors. In general, it is best to leave harmless practices alone and focus on understanding and changing harmful behaviors. This task is more difficult than it might seem, because the concept of cultural relativism also applies to perceptions of quality of life. A culture in which people believe in reincarnation may approach death with more equanimity, and may not embrace drastic procedures that prolong life only briefly. In some cultures, loss of a body organ is viewed as impeding the ability to go to an afterlife or the next life, and such surgery may be refused. Thus, it is important in global health for cultural outsiders to be cautious about making statements about what is good for someone else.

Holism

The concept of holism is also useful in looking at health and disease cross-culturally. *Holism* is an approach used by anthropologists that looks at the broad context of whatever phenomenon is being studied. Holism involves staying alert for unexpected influences, because you never know what may have a bearing on the program you are trying to implement. For public health, this consideration is crucial because diverse factors may influence health and health behavior (Nichter, 2008).

A classic example of this situation is the detective work that went into discovering the etiology of the New Guinea degenerative nerve disease, kuru. Epidemiologists could not figure out how people contracted the disease, which appeared to have a long incubation period and to occur more frequently in women and children than in men. Many hypotheses were advanced, including inheritance (genetic), infection (bacterial, parasitic), and psychosomatic explanations.

By the early 1960s, the most widely accepted of the prevailing hypotheses was that kuru was genetically transmitted. Nevertheless, this proposal did not explain the sex differences in infection rates in adults but not in children, nor how such a lethal gene could persist. Working with Gadjusek of the National Institutes of Health (NIH), cultural anthropologists Glasse and Lindenbaum used in-depth ethnographic interviews to establish that kuru was relatively new to that region of New Guinea, as was the practice of cannibalism. Women and children were more likely to engage in the ritual consumption of the brains of dead relatives as a way of paying tribute to them, which was culturally less acceptable for men. Also, this tissue was cooked, but women, who did the cooking, and children, who were around during cooking, were more likely to eat it when it was partially cooked and, therefore, still infectious. Lindenbaum and Glasse suggested the disease was transmitted by cannibalism. To confirm their hypothesis, Gadjusek's team inoculated chimpanzees with brain material from women who had died of kuru; the animals subsequently developed the disease. The disease, initially thought to be a slow virus, was subsequently identified as caused by prions, which are mis-folded proteins transmitted through the ingestion of brain tissue. Since then, the practice of cannibalism has declined and the disease has now virtually disappeared (Gadjusek, Gibbs, & Alpers, 1967; Lindenbaum, 1971). The research on kuru led scientists to discover a similar pattern of disease caused by the ingestion of beef that had been fed neurologic tissue of deceased cattle, called "mad cow disease" or variant Creutzfeldt-Jakob disease (Collinge et al., 2006).

Health Literacy

In recent years, increasing attention has focused on another area that intersects with culture in people's ability to understand and access health care—the concept of health literacy. *Health literacy* is defined as "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions" (Ratzan & Parker, 2000). Health literacy has been most thoroughly explored in the United States, and until recently was seen more as a literacy issue than a cultural issue. A 2004 Institute of Medicine report notes the importance of considering cultural issues such as many of those discussed in this chapter, and of taking a more global look at the problem and needed interventions (Nielsen-Bohlman, Panzer, & Kindig, 2004). Many National Academy of Medicine (NAM) reports have followed, along with an NAM Roundtable and discussion papers on the topic (e.g., Allen, Auld, Logan, Montes, & Rosen, 2017).

In looking at culture and health literacy, several categories for misunderstandings between provider and patient emerge.

First, there is a difference between medical terminology and lay terminology, which can occur in any language or culture. What is "diastolic" or a "bronchodilator"? What are HDL and LDL? What are T cells?

Second, individual and cultural differences surround concepts. What does it mean to maintain a "moderate" weight? To an anxious teen who wants to become a model, moderate weight might mean

something clinically dangerously low (from the outsider, health practitioner perspective). To some women from Latin America or the Middle East, moderate weight will be heavier than U.S. norms, whereas a U.S. woman who fears she weighs too much might be viewed as dangerously thin in those cultures.

Third, meanings may differ. While working with prenatal care programs in Mexico, Scrimshaw's team struggled with communicating the concept of risk in pregnancy as they developed materials to help women identify symptoms that meant that they should seek care. It turned out that the direct translation of "risk" into Spanish, or *riesgo*, did not carry the same meaning. When they explained the concept to women, they said, "Oh, you mean *peligro*." *Peligro* translates directly as "danger" (Alcalay, Ghee, & Scrimshaw, 1993; Scrimshaw et al., 1990).

Finally, language issues may affect understanding. While researchers were investigating seizure disorders in adolescents from three cultures, it became clear that the word "trauma" has two different meanings. It can mean psychological shock, or it can mean physical trauma, such as a blow to the head. The exact same word *trauma* is used in Spanish, with the same two potential meanings. When neurologists talked with patients who had epilepsy and their parents from Latino cultures, the neurologists used the word "trauma" as a cause of seizures to mean a blow to the head. The Latino parents heard the psychological meaning and thought their child had been traumatized psychologically by some fright or shock (Long, Scrimshaw, & Hernandez, 1992).

Lane and her colleagues (2017) found that health literacy can be compromised at times even for well-educated individuals. It is particularly important to note that health literacy is as much a problem of the healthcare provider and health communication staff as it is of a patient or the people in a community. If medical "jargon" is used, no amount of education short of experience in medicine or nursing will help someone understand. Terms such as "oncology," "nephrology," and "gastroenterology" have meaning for the medical world, but not for patients. Healthcare providers outside the United States often have a better understanding of this issue than their U.S. counterparts.

Cultural Competence

A concept related to health literacy is that of cultural competence. *Cultural competence* in health care describes "the ability of systems to provide care to patients with diverse values, beliefs and behaviors, including tailoring delivery to meet patients' social, cultural, and linguistic needs" (Betancourt, Green, & Carrillo, 2002). The concept of cultural competence emerged, in part, from the U.S. federal government's elaboration of the *Cultural and Linguistically Appropriate Services* (CLAS) guidelines to improve the care of diverse populations (Office of Minority Health, 2016). Healthcare institutions began using the CLAS standards to design cultural competence trainings for their staff. It became clear, however, that in-service training was insufficient to make participants truly competent in cultural issues. From this critique, scholars have suggested that cultural humility is a more realistic framework, because it promotes the understanding and appreciation of health beliefs and behaviors in their cultural contexts and respectful strategies to negotiate optimal health in the context of these beliefs and behaviors (Tervalon & Murray-García, 1998). To achieve this goal, we must understand our own biases.

Cultures vary in their definitions of health and of illness. A condition that is endemic in a population may be seen as normal and may not be defined as illness. *Ascaris* infection in young children was previously mentioned as a perceived "normal" condition in many populations. Similarly, malaria is seen as normal in some parts of Africa, because everyone has it or has had it. In Egypt, where schistosomiasis was common and affected the blood vessels around the bladder, blood in the urine was referred to as "male menstruation" and was seen as normal. These definitions may also vary by age and by gender. In most cultures, symptoms such as fever in children are seen as more serious than the same symptoms in adults. Men may deny symptoms more than women in some cultures, but women may do the same in others. Often, adult denial of symptoms is due to the need to continue working.

Sociologist Talcott Parsons (1948) first discussed the concept of the sick role, wherein an individual must "agree" to be considered ill and to take actions (or allow others to take actions) to define the state of his or her health, discover a remedy, and do what is necessary to become well. Individuals who adopt the sick role neglect their usual duties, may indulge in dependent behaviors, and seek treatment to get well. By adopting the sick role, they are viewed as having "permission" to be exempted from usual obligations, but they are also under an obligation to try to restore health. The process of seeking to remain healthy or to restore health is discussed in more detail later in this chapter.

Belief Systems

EXHIBIT 2-1 depicts types of insider cultural explanations of disease causation. Based on the literature, it attempts to be as comprehensive as possible for cultures around the world. The exhibit consists of generalizations about culture-specific health beliefs and behaviors; these generalizations cannot, however, be assumed to apply

EXHIBIT 2-1 Types of Insider Cultural Explanations of Disease Causation

Body Balances

- Temperature: Hot, cold
- Energy
- Blood: Loss of blood; properties of blood reflect imbalance; pollution from menstrual blood
- Dislocation: Fallen fontanel
- Organs: Swollen stomach; heart; uterus; liver; umbilicus; others
- Incompatibility of horoscopes

Emotional

- Fright
- Sorrow
- Envy
- Stress

Weather

- Winds
- Change of weather
- Seasonal disbalance

Vectors or Organisms

- Worms
- Flies
- Parasites
- Germs

Supernatural

- Dirty foods
- Sweets
- Raw foods
- Combining the "wrong" foods (incompatible foods)
- Mud/clay

Sexual

- Sex with forbidden person
- Overindulgence in sex

Heredity

Old Age

to every individual from a given culture. We can learn about the hot/cold balance system of Latinos, Asians, and Middle Easterners, explained in the next section, but the details of the system will vary from country to country, from village to village, and from individual to individual. When someone walks in the door of a clinic, you cannot know whether he or she as an individual adheres to the beliefs described for his or her culture and what shape the individual's belief system takes. This makes the task of the culturally proficient healthcare provider both easier and harder. It means a practitioner working with a Mexican population does not have to memorize which foods are hot and which are cold in Mexico, but the practitioner does need to know that the hot/cold belief system is important in Mexican culture and be able to be understanding and responsive when people bring up the topic.

The beliefs held by cultures around the world are classified into various categories, which are discussed here. These categories are used for diagnosis and treatment and for explaining the etiology or origin of the illness. Often, multiple categories are used. For example, emotions may be seen as causing a "hot" illness.

Body Balances

Within body balances (opposites) belief systems, the concepts of "hot" and "cold" are among the most pervasive around the world. The hot/cold balance is particularly important in Asian, Latin American, and Mediterranean cultures. Hot and cold beliefs are part of what is referred to as "humoral medicine," which is thought to have derived from Greek, Arabic, and East Indian pre-Christian traditions (Foster, 1953; Logan, 1972; Weller, 1983). The concept of opposites (e.g., hot and cold, wet and dry) also may have developed independently in other cultures (Rubel & Haas, 1990). For example, in the Chinese medical tradition, hot is referred to as *yin* and cold as *yang* (Topley, 1976).

In the hot and cold belief system, a healthy body is seen as in balance between the two extremes. Illness may be brought on by violating the balance, such as washing the hair too soon after childbirth (cold may enter the body, which is still "hot" from the birth), eating hot or heavy foods at night, or breastfeeding while upset (the milk will be hot from the emotions and make the baby ill). "Hot" does not always refer to temperature, however. Often foods such as beef and pork

are classified as hot regardless of temperature, whereas fish may be seen as cold regardless of temperature.

When illness has been diagnosed, the system is used to attempt to restore balance. Thus, in Central America, some diarrheas in children are viewed as hot, and protein-rich "hot" foods such as meats are withheld, aggravating the malnutrition that may be present and may be exacerbated by the diarrheal disease (Scrimshaw & Hurtado, 1988). An extensive literature exists on the topic of hot and cold illness classifications and treatments for them advocated by many of the world's cultures.

Energy balance is particularly important in Chinese medicine, where it is referred to as *chi*. When this balance is disturbed, it creates internal problems of homeostasis. Foods (often following the hot/cold theories) and acupuncture are among the strategies used to restore balance (Topley, 1976).

Blood beliefs include the concept that blood is irreplaceable; thus loss of blood—even small amounts—is perceived as a major risk. Adams (1955) describes a nutritional research project in a Guatemalan village where this belief inhibited the researcher's ability to obtain blood samples until the phlebotomists were instructed to draw as little blood as possible. Also, villagers were told that the blood would be examined to see if it was "sick" or "well" (another belief about blood) and they would be informed and given medicines if it were sick, which in fact did occur.

Menstrual blood is regarded as dangerous, especially to men, in many cultures, and elaborate precautions are taken to avoid contamination with it (Buckley & Gottlieb, 1988). As seen in the Guatemalan example, blood may have many properties that both diagnose and explain illness. Bad blood is seen as causing scabies in South India (Beals, 1976, p. 189). Haitians have a particularly elaborate blood belief system, which includes concepts such as *mauvais sang* (literally, "bad blood," when blood rises in the body and is dirty), *saisissement* (rapid heartbeat and cool blood, due to trauma), and *faiblesses* (too little blood). Blood qualities may also be seen as "opposites," such as clean–unclean, sweet–normal, bitter–normal, high–normal, heavy–weak, clotted–thin, and quiet–turbulent (C. Scott, personal communication, 1976). It is easy to see how these concepts could be used in a current program to prevent HIV infection in a Haitian community, because the culture already has ways of describing problems with blood.

Dislocation of body parts may occur with organs, but also with a physical aspect, such as the fontanel or "soft spot" in a baby's head where the bones have not yet come together in the first year or so to allow for growth. From the outsider perspective, a depression in this spot can be indicative of dehydration, often due to diarrheal disease. From the insider perspective, it is referred to as a cause of the disease (*caida de mollera*) in Mexico and Central America.

Many cultures associate illness with problems in specific organs. Good and Good (1981) talk about the importance of the heart for both Chinese and Iranian cultures. They discuss a case in which problems with cardiac medication were wrongly diagnosed for a Chinese woman who kept complaining about pain in her heart. In fact, she was referring to her grief over the loss of her son. The Hmong people of Laos link many problems to the liver, referring to "ugly liver," "difficult liver," "broken liver," "short liver," "murmuring liver," and "rotten liver." These terms are said to refer to mental and emotional problems, and so are idiomatic rather than literal (O 'Connor, 1995, p. 92; Thao, 1986).

Topley (1976) mentions incompatibility of horoscopes between mother and child in Chinese explanations for some children's illnesses.

Emotional Illnesses

Illnesses of emotional origin are important in many cultures. Sorrow (as in the case of the Chinese woman mentioned previously), envy, fright, and stress are often seen as causing illnesses. In a Bolivian village in 1965, for example, Scrimshaw was told that a young girl's smallpox infection was attributed to her sorrow over the death of her father.

Envy can cause illness because people with envy could cast the "evil eye" on someone they envy, even unwittingly, or the envious person can become ill from the emotion (Reichel-Dolmatoff & Reichel-Dolmatoff, 1961). Fright, called *susto* in Latin America, has already been mentioned. In addition to the case of tuberculosis in adults discussed previously, *susto* is a common explanation for illness in children. It is also mentioned in Chinese culture (Topley, 1976).

Weather

Everything from the change of seasons to unusual variations within seasons (too warm, too cold, too wet, too dry) can be blamed for causing illness. Winds, such as the Santa Ana in California or the Scirocco in the North African desert, are also implicated as sources of illness in many cultures. From the outsider perspective, changes in seasons can be associated with increases in risk and incidence of disease. For example, in many areas people have a greater chance of contracting malaria, cholera, and gastrointestinal infections during the rainy season.

Vectors or Organisms

Vectors or organisms are blamed for illness in some cultures and represent a blend of Western biomedical and indigenous concepts. "Germs" is a catch-all category, as is "parasites." Worms are seen as causing diarrhea, whereas flies are seen as causing illness and, sometimes, as carrying germs.

The Supernatural

The supernatural is another frequently viewed source of illness, especially in Africa and Asia, though this belief system is certainly not confined to those regions. In fact, the evil eye is a widespread concept—someone deliberately or unwittingly brings on illness by looking at someone with envy, malice, or too hot a gaze. In cultures where most people have dark eyes, strangers with light eyes may be seen as dangerous. In Latin America, a light-eyed person who admires a child can risk bringing evil eye to that child, but can counter it by touching the child. In other cultures, touching the child can be unlucky, so it is important to learn about local customs. Frequently, amulets and other protective devices, such as small eyes of glass, red hats, and a red string around the wrist, are worn to prevent evil eye. These objects can be viewed as an opportunity to discuss preventive health measures, because they are an indication that people are thinking about prevention.

Bewitching is deliberate malice, done either by the individual who wishes someone ill (literally) or by a practitioner at someone else's request. Bewitching can be countered by another practitioner or by specific measures taken by an individual. In some regions of Africa, epidemics are blamed on "too many witches," and people disperse to get away from them, thereby reducing the critical population density that had previously sustained the epidemic (Alland, 1970).

Belief in soul loss is widespread throughout the world. Soul loss can be caused by sources such as fright, bewitching, evil eye, and demons. It can occur in adults and children. Soul loss is serious and can lead to death. It must be treated through rituals to retrieve the soul. In Bolivia, for example, a village priest complained to Scrimshaw that his attempt to visit a sick child was thwarted when the family would not allow him to enter the house. The family later reported that an indigenous healer was performing a curing ritual at the time, and the soul was flying around the house as they were trying to persuade it to reenter the child. Opening the door to the priest would have allowed the soul to escape. In the Western biomedical system, this child's symptoms would have been attributed to severe malnutrition.

Spirit possession is also a worldwide belief, and one that is found especially frequently in African and Asian cultures. One of the best-known accounts of this phenomenon is *A Spirit Catches You and You Fall Down* (Fadiman, 1997), a moving story of seizure disorders in a Hmong community and the misunderstandings between the family and physicians. In another example, from South India, Beals (1976) mentions spirit possession in a daughter-in-law whose symptoms included refusing to work and speaking insultingly to her mother-in-law. He suggests that spirit possession is a "culturally sanctioned means of psychological release for oppressed daughters-in-law" (p. 188). Freed and Freed (1967) discuss similar cases in other regions of India. In Tanzania, malaria in children is sometimes blamed on possession by a bird spirit (Kamat, 2008). In Haiti, spirit possession is seen as a mark of favor by the spirits and is actively sought out. One of the drawbacks, however, is that the possessing spirits object to the presence of foreign objects in the body; as a consequence, some women do not want to use intrauterine devices as a means of birth control.

Demons are viewed as causing illness in Chinese culture, while offending God or gods is a problem in other cultures (Topley, 1976). In South India, epidemic diseases such as chickenpox and cholera (and, formerly, smallpox) are believed to be caused by disease goddesses. These goddesses bring the diseases to punish communities that become sinful (Beals, 1976, p. 187). The concept of punishment from God is seen in a case study from Mexico, where onchocerciasis (river blindness), which is caused by a parasite transmitted by the bite of a fly that lives near streams, is often thought to be due to sins committed either by the victim or by relatives of the victim. These transgressions against God are punished by God closing the victim's eyes (Gwaltney, 1970).

Food

In many cultures, food is perceived as being able to cause illness through its role in the hot and cold belief system; through spoiled foods, dirty foods, or raw foods; and by combining the wrong foods. Sweets are implicated as a cause of worms in children, and children who eat mud or dirt may become ill. Foods may also cause problems if eaten at the wrong time of day, such as "heavy" foods at night. An extensive literature describes food beliefs and practices worldwide, which has important implications for public health practice.

Sexual Illnesses

In Ecuador in the early 1970s, children's illnesses were sometimes blamed on affairs between one of the

child's parents and a *compadre* or *comadre*—one of the child's godparents (Scrimshaw, 1974). Such a relationship was viewed as incestuous and dangerous to the child. In India, sex is sometimes viewed as weakening to the man, so overindulgence is considered a cause of weakness. To return to the concept of blood beliefs, it is thought that 30 drops of blood are needed to make one drop of semen, so blood loss weakens a man.

Heredity and Old Age

Heredity is sometimes blamed for illness, early death, or some types of death. Similarly, old age may be the simple explanation given for illness or death. Heredity as noted here is expressed as an insider view, but is also part of the Western biomedical body of evidence on the causation or risk for many diseases.

Illness in Various Forms

TABLE 2-1 illustrates the way in which some of these beliefs are used to explain a particular illness—in this case, diarrheal disease in Central America. It is typical of the way in which an illness may be seen as having different forms, or manifestations, with different etiologies. It is also typical of the way in which several different explanations may be put forth for one set of symptoms.

In this case, Table 2-1 and **FIGURE 2-1** (the diagram of treatments) were key in expanding the orientation of the Central American diarrheal disease program. The program had intended to emphasize the distribution of oral rehydration solutions (ORS) in the clinics, but the insider perception was that a child should be taken to the clinic only for the worst form of diarrhea, dysentery. Instead, the most common treatment for diarrhea consisted of fluids in the form of herbal teas or sodas with medicines added. Often, storekeepers and pharmacists were consulted. It made sense to provide the ORS at stores and pharmacies as well as at clinics, so that all diarrheas were more likely to be treated (Scrimshaw & Hurtado, 1988).

In a related situation, Kendall, Foote, and Martorell (1983) found that, when the government of Honduras did not include indigenous or "folk" terminology for diarrheal disease in its mass-media messages regarding oral rehydration, people did not use ORS for diarrheas attributed to indigenously defined causes.

Healers

EXHIBIT 2-2 lists types of healers, which range from indigenous practitioners to Western biomedical providers. Pluralistic healers are those who mix the two traditions, although some Western biomedical healers and those from other medical systems may also mix traditions in their practices.

As with explanations of disease, the types of healers listed in Exhibit 2-2 are found in different combinations in different cultures. There is always more than one type of healer available to a community, even if members have to travel to seek care. The 16-country study of health-seeking behavior described earlier found that in all communities, people used more than one healing tradition, and usually more than one type of healer (Scrimshaw, 1992). The process of diagnosing

TABLE 2-1 Taxonomy of Diarrhea

CAUSE			SYMPTOMS All types have watery and frequent stools	TREATMENT
Mother's milk	Physical activity	**Hot**		Not breastfeeding when hot
	Hot foods			Mother changes diet
	Pregnancy			Breastfeeding stops
	Anger	**Emotional**	Very dangerous	Home, drugstore, injectionist, witch, spiritualist
	Sadness			
	Fright			

Food		Bad food	Flatulence, feeling of fullness	Home, folk curer
		Excess		
		Does *not* eat on time		
	Hot	Quality		
	Cold			
Tooth Eruption			Tooth eruption	None
Fallen fontanel, fallen stomach	Fallen stomach		Green with mucus Sunken fontanel; vomiting; green in color	Folk curer
	Fallen fontanel			
Evil eye			Fever	Folk curer
Stomach Worms			Worms	Drugstore, home, folk curer
Cold enters Stomach	From feet		White in color	Folk curer
	From head			
Dysentery			Blood in stools, "urgency;" color is red or black	Home, drugstore, health post

- Ayurvedic practitioners
- Taoist priests

illness and seeking a cure has been referred to as "patterns of resort," a descriptor that is now favored over the older term "hierarchy of resort" (Scrimshaw & Hurtado, 1987). People may zigzag from one practitioner to another, crossing from one type to another type of healer, and not always starting with the simplest and cheapest, but with the one they can best afford and who they believe will be most effective, given the severity of the problem. Even middle- and upper-class individuals, who can afford Western biomedical care, may use other types of practitioners and practices.

Indigenous practitioners are usually members of the culture and follow traditional practices. Today, they often mix elements of Western biomedicine and other traditional systems. In many instances, they are "called" to their profession through dreams, omens, or an illness, which usually can be cured only by their agreement to become a practitioner. Most learn through apprenticeship to other healers, although some are taught by dreams. Often, they will take courses in Western practices in programs such as those developed to train Chinese "barefoot doctors" or community-based health promoters. In some instances, they must conceal their role as traditional healer from those running the training programs. The incorporation of some Western biomedical knowledge and skills often enhances a practitioner's prestige in the community.

Some indigenous practitioners charge for their services, but many do not, accepting gifts instead. In a few traditions (including some Chinese cultures), practitioners are paid as long as family members are well, but they are not paid for illness treatment. The duty of the practitioner in those cases is to keep people well, which argues for the acceptability of prevention programs in those cultures.

For the most part, indigenous practitioners do "good," meaning healing. Some can do both good and evil (e.g., shamans, sorcerers, and witches in many cultures). A few in these categories practice only evil or negative rituals, which aim to cause harm—for example, for revenge or to counteract the good fortune of a rival. Their work must then be countered by someone who does "good" magic. The power of belief is such that if individuals believe they have been bewitched, they may need a counteractive ritual, even if the Western biomedical system detects and treats a specific disease. In Guayaquil, Ecuador, one woman believed that she had been *maleada* (cursed) by a woman who was jealous of her, and that this curse was making her and her children ill. A *curandera* (curer) was brought in to do a *limpia* (ritual cleansing) of the house and family to remove the curse (Scrimshaw, 1974).

The importance of the power of belief is not confined only to bewitching. One anthropologist working with a Haitian population discovered that a Haitian burn patient made no progress until she went to a *Houngan* (voodoo priest) on the patient's behalf and had the appropriate healing ritual conducted (J. Halifax-Groff, personal communication, 1976).

In some cultures, healers are seen as diagnosticians, while others do the treatment (Alland, 1970). Other healers may handle both tasks, but refer some

kinds of illness to other practitioners. In Haiti, both midwives and voodoo priests refer some cases to the Western biomedical system. Healers who combine healing practices or who combine the ability to do both diagnosis and treatment are viewed as more powerful than other types. Topley (1976, pp. 259–260) discusses this issue in the setting of Hong Kong, noting that Taoist priest healers are particularly respected in that area. They are seen as both priest and doctor and "claim to combine the ethics of Confucianism, the hygiene and meditation of Taoism, and the prayers and self-cultivation of the Buddhist monk."

Pluralistic healers combine Western biomedical and indigenous practices. Injectionists will give an injection of antibiotics, vitamins, or other drugs purchased at pharmacies or stores. Sometimes these injections are suggested by the pharmacist or storekeeper; at other times they are self-prescribed. Because antibiotics proved so dramatically effective in curing infections when Western biomedicine was first introduced in many cultures, injections are often seen as conveying greater healing than the same substance taken orally. Thus, many antibiotics now available orally and vitamins are injected. In today's environment, this practice increases the risk of contracting HIV or hepatitis if sterile or new needles and syringes are not used.

Traditional chemists and herbalists, as well as storekeepers and vendors (many communities are too small to have a pharmacy), often sell Western biomedical medications, including those that require a prescription in the United States and Western Europe. While prescriptions may be "legally" required in many countries, the laws are not always rigorously enforced. This is also true for pharmacies, which are very important—sometimes the most important—sources of diagnosis and treatment in many communities around the world.

For more than 50 years, countries around the world have enlisted and trained indigenous health practitioners to function as part of the national or regional health system. These programs have ranged from China's "barefoot doctors" to the education of community members in Latin America, Africa, and Asia to provide preventive care and triage. These efforts have nearly disappeared in some areas (e.g., China) and reemerged in others. For example, in Australia, indigenous people are now involved as indigenous health outreach workers to their communities (2010, healthinfonet@ecu.edu.au). In Nepal, indigenous health workers have been enlisted in programs to address diarrheal disease and acute respiratory infections (Ghimire, Pradhan, & Mahesh, 2010), and female Ayurvedic doctors are important resources for women's health (Cameron, 2010).

Western biomedical practitioners are an important source of care, but they may also be expensive or difficult to access in remote areas. As mentioned earlier, if an individual believes that an illness is due to a cause explained by the indigenous system and a Western biomedical practitioner denies that cause, the individual may not return to that practitioner but rather seek help elsewhere (Kamat, 2008; Nichter, 2008).

As noted, there are other medical systems with long traditions, systematic ways of training practitioners, and well-established diagnostic and treatment procedures. Until recently, Western biomedical practitioners totally rejected both these and indigenous systems, often failing to recognize how many practices and medicines that Western biomedicine has "borrowed" from other systems (e.g., quinine, digitalis, many anesthetics, aspirin, and estrogen). Elements of these systems that were derided in the past, such as acupuncture, have now found their way into Western biomedical practice and are being "legitimized" by Western research (Baer, 2008).

Theories of Health Behavior and Behavior Change

The fields of sociology, psychology, and anthropology have developed many theories to explain health beliefs and behaviors and behavior change (Schumacher, Ockene, & Riekert, 2009). Some theories developed by sociologists and psychologists in the United States were developed first for U.S. populations and only later applied internationally. Others were developed with international and multicultural populations in mind from the beginning. Only a few of the many theories of health and illness beliefs and behavior are covered in this section; those included here have been quite influential in general or are applicable for international work in particular.

Health Belief Model

The health belief model suggests that decision making about health behaviors is influenced by four basic premises—perceived susceptibility to the illness, perceived severity of the illness, perceived benefits of the prevention behavior, and perceived barriers to that behavior—as well as by other variables, such as sociodemographic factors (Rosenstock, Strecher, & Becker, 1974). In general, people are seen as weighing perceived susceptibility (how likely they are to get the disease) and perceived severity (how serious the disease is) against their belief in the benefits and effectiveness of the prevention behavior they must undertake and the costs of that behavior in terms of barriers such as time, money, and aggravation. The more serious the disease is believed to be, and the more effective

the prevention, the more likely people are to incur the costs of engaging in the prevention behavior.

The health belief model has been extensively studied, critiqued, modified, and expanded to explain people's responses to symptoms and compliance with healthcare regimens for diagnosed illnesses. One concern has been that this model does not work as well for chronic problems or habitual behaviors because people learn to manage their behaviors or the healthcare system. Also, it has been accused of failing to take environmental and social forces into account, which in turn increases the potential for blaming the individual. The difficulty in quantifying the model for research and evaluation purposes is also a problem.

Work by Bandura led to the inclusion of self-efficacy in the model. *Self-efficacy* has been defined as "the conviction that one can successfully execute the behavior required to produce the desired outcome" (Bandura, 1977, 1989). The concept of *locus of control*, or belief in the ability to control one's life, also has been incorporated into this model. An example of this concept can be found in a comparison of migrant Yugoslavian and Swedish females with diabetes. The study revealed a stronger locus of control in the Swedish women and more passivity toward self-care in the Yugoslavian women, who also had a lower self-efficacy. The authors attributed these findings to the different political systems in the two countries—collectivism in Yugoslavia versus individualism in Sweden (Hjelm, Nyberg, Isacsson, & Apelqvist, 1999). A more recent example, among impoverished HIV-positive women in Kenya, found that the women preferred to use indigenous treatments to manage their symptoms, rather than taking available antiretroviral therapy. The women's shared cultural model of self-management enhanced the women's confidence in their own ability to care for themselves rather than take the Western biomedical drugs (Copeland, 2017).

The value of the four basic premises of the health belief model has held up well under scrutiny. Perceived barriers have the strongest predictive value of the four dimensions, followed by perceived susceptibility and perceived benefits. Perceived susceptibility is most frequently associated with compliance with health screening exams. Perceived severity of risk has been noted to have a weaker predictive value for protective health behaviors, but is strongly associated with sick-role behaviors.

In *Medical Choice in a Mexican Village*, Young (1981) describes a health decision-making process very similar to that found in the health belief model. In choosing between home remedies, pharmacy, or store, and between indigenous healer or doctor, the villagers weigh the perceived severity of the illness, the potential efficacy of the cure to be sought, the cost (money, time, and so on) of the cure, and their own resources to seek treatment and pay the cost as they make their decision. The simplest, least costly treatment is always the first choice, but the severity of illness and efficacy issues may force adoption of a more costly option. Other studies of health-seeking behavior have found similar patterns throughout the world (e.g., Kamat, 2008).

Theory of Reasoned Action

The theory of reasoned action was first proposed by Ajzen and Fishbein (1972) to predict an individual's intention to engage in a behavior in a specific time and place. This theory was intended to explain virtually all behaviors over which people have the ability to exert self-control. Five basic constructs precede the performance of a behavior: (1) behavioral intent, (2) attitudes and beliefs, (3) evaluations of behavioral outcomes, (4) subjective norms, and (5) normative beliefs. Behavioral intent is seen as the immediate predictor of behavior. Factors that influence behavioral choices are mediated through this variable. To maximize the predictive ability of an intention to perform a specific behavior, the measurement of the intent must closely reflect the measurement of the behavior. For example, measurement of the intention to begin to take oral contraceptives must include questions about when a woman plans to visit a clinic and which clinic she plans to attend. The failure to address action, target, context, and time in the measurement of behavioral intention will undermine the predictive value of the model.

In a test of this theory's ability to predict condom use intentions in a national sample of young people in England, measures of past behavior were found to be the best predictors of intentions and attenuated the effects of attitude and subjective norms (Sutton, McVey, & Glanz, 1999).

Diffusion of Health Innovations Model

The diffusion of health innovations model proposes that communication is essential for social change, and that diffusion is the process by which an innovation is communicated through certain channels over time among members of a social system (Rogers, 1983; Rogers & Shoemaker, 1972). An *innovation* is an idea, practice, service, or other object that is perceived as new by an individual or group. Ideally, the development of a diffusion strategy for a specific health behavior change goal will proceed through six stages:

1. Recognition of a problem or need
2. Conduct of basic and applied research to address the specific problem

3. Development of strategies and materials that will put the innovative concept into a form that will meet the needs of the target population
4. Commercialization of the innovation, which will involve production, marketing, and distribution efforts
5. Diffusion and adoption of the innovation
6. Consequences associated with adoption of the innovation

According to classic diffusion theory, a population targeted by an intervention to promote acceptance of an innovation includes six groups: Innovators, early adopters, early majority, late majority, late adopters, and laggards. The rapidity and extent to which health innovations are adopted by a target population are mediated by a number of factors, including relative advantage, compatibility, complexity, communicability, observability, trialability, cost-efficiency, time, commitment, risk and uncertainty, reversibility, modifiability, and emergence (see the *Innovation, Technology and Design* chapter for more information on scaling up health innovations).

Relative advantage refers to the extent to which a health innovation is better (faster, cheaper, more beneficial) than an existing behavior or practice. Antibiotics, for example, were quickly accepted in most of the world because they were dramatically faster and more effective than traditional practices.

Compatibility is the degree to which the innovation is congruent with the target population's existing set of practices and values. Polgar and Marshall (1976) point out that injectable contraceptives were acceptable in the village in India where Marshall worked because injections were viewed so positively due to the success of antibiotics.

The degree to which an innovation is easy to incorporate into existing health regimens may also affect rates of diffusion. Iodized salt is easier to use than taking an iodine pill, because consuming salt is already a habit. Health innovations are also more likely to be adopted quickly and by larger numbers of individuals if the innovation itself can be easily communicated.

The concept of trialability involves the ease of trying out a new behavior. For example, it is easier to try a condom than to be fitted for a diaphragm. Observability refers to role models, such as village leaders volunteering to be the first recipients in a vaccination campaign.

A health innovation is also more likely to be adopted if it is seen as cost-efficient. A famous case study of water boiling in a Peruvian town demonstrated that the cost in time and energy of gathering wood and making a fire to boil the water far outweighed any perceived benefits, so water boiling was seldom adopted (Wellin, 1955). Successful health innovations are likely to be those that do not require expenditure of much additional time, energy, or other resources.

One of the overall messages regarding communicating health education and promotion stated by Rogers (1973) is that mass media and interpersonal communication channels should both be used. Implementing both methods is of particular importance in low- and middle-income countries (LMICs), especially in rural communities. Rogers emphasizes that mass media deliver information to a large population and add knowledge to the general knowledge base, but interpersonal contacts are needed to persuade people to adopt new behaviors (thereby using the knowledge function, the persuasion function, and the innovation-decision process). In Rogers's work and other work cited by him, "family planning diffusion is almost entirely via interpersonal channels" (p. 263). Notably, Rogers presents five examples in different countries (including India, Taiwan, and Hong Kong), wherein interpersonal channels were the primary source for family planning information and were the motivating factors to seeking services.

The limitations of using mass media to disseminate health messages include the following issues:

- *Limited exposure.* In LMICs, smaller audiences have access to mass media. Radio continues to be an important mass-media tool, but social media via cell phones and other modes of Internet access are now a key way to reach people. Low literacy levels are another barrier.
- *Message irrelevancy.* The content of mass-media messages may be of no practical use for many rural and "non-elite" populations. Often instrumental information—"how to" information—is not included in the messages (e.g., where to receive services or the positive and negative consequences of adapting a particular health behavior).
- *Low credibility.* For people to accept and believe the messages being diffused, trustworthiness needs to exist between the sender and the receiver. In many LMICs, radio and TV stations are run by a government monopoly and their content may be considered to be government propaganda by the receivers. Radio and TV in Nigeria, Pakistan, and other African and Asian countries, for example, are controlled by the government (Rogers, 1973).

The diffusion of innovations model focuses solely on the processes and determinants of adoption of a new behavior and does not help to understand or

explain the maintenance of behavior change. Many health behaviors require permanent or long-term changes. Also, it is important to understand whether a new behavior is being carried out appropriately, consistently, or at all. One salient example involves condom use, which healthcare practitioners demonstrated to a population by unrolling the condom over a banana. Women who became pregnant while they reported using condoms had been faithfully putting them on bananas.

The rapid development of information technology—in particular, the use of smartphones—is revolutionizing diffusion of information and communication. For example, a smartphone innovation among men who have sex with men (MSM) consists of a computer app designed to facilitate finding sexual partners of men infected with a sexually transmitted disease. This app was used by the Monroe County Health Department in Rochester, New York, to map the spread of several sexually transmitted infections among this group, to document their sexual networks, and to advise sexual partners that they may have been exposed to an infection (Pennise et al., 2015).

Wearable devices range from sensors embedded in clothing to glasses to computerized watches and health-related wrist units. These devices have multiple applications, including fall risk assessment, quantifying sports exercise, studying people's habits, and monitoring the elderly (Hagthi, Thurow, & Stoll, 2017). Smartphone apps, in some cases, are motivating people to engage in more physical activity or eat healthier—for example, by tracking their daily steps or completing a food diary (Karpman, 2016). Others allow patients to upload their blood glucose readings, heart rates and other health data that they and their providers can monitor over time. Hagthi et al. (2017) note that "Based on consultation with expert scientists in environmental engineering and medicine, we believe that, motion trackers, gas detectors, and vital signs are the most important elements in health monitoring. . . ." Globally, smartphones and wrist or belt units are the most likely to be relevant for health-related applications in the near future.

Transtheoretical Model

Theories around the concept of stages of change have been evolving since the early 1950s. Currently, the most widely accepted stage change model is the transtheoretical model of behavior change developed by Prochaska, DiClemente, and Norcross (1992) (**FIGURE 2-2**). This model includes five core constructs: (1) stages of change, (2) decisional balance, (3) self-efficacy, (4) processes of change, and (5) maintenance. Interventions relying on this model are expected to include all four constructs in the development of strategies to communicate, promote, and maintain behavior change.

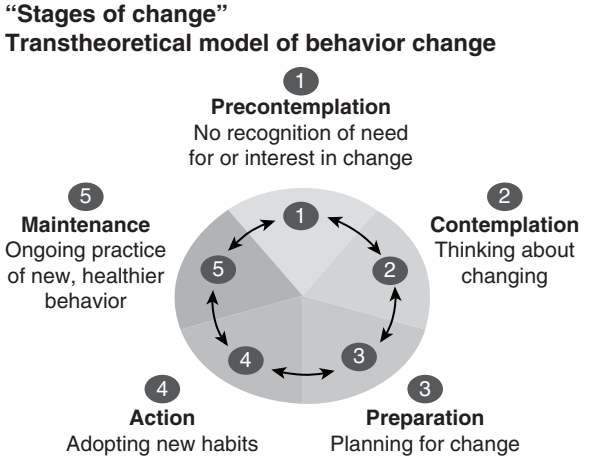

FIGURE 2-2 "Stages of change" transtheoretical model of behavior change.

Reproduced from Prochaska, J., DiClemente, C., & Norcross, J. (1992). In search of how people change: Applications to addictive behaviors. *American Psychologist, 47,* 1102–1104.

The transtheoretical model identifies five stages of change. The first is precontemplation, in which individuals have no intention to take action within the next 6 months. In the contemplation stage, individuals express an intention to take some action to change a negative health behavior or adopt a positive one within the next 6 months. The preparation stage refers to the intent to make a change within the next 30 days. The action stage involves the demonstration of an overt behavior change for an interval of less than 6 months. In the fifth stage, known as maintenance, a person will have sustained a change for at least 6 months. The model helps healthcare providers, including those working in health education and communication, to develop appropriate strategies for reaching people at the various stages of readiness for change.

Decisional balance is an assessment of the costs and benefits of changing, which will vary with the stage of change. Self-efficacy is divided into two concepts within the transtheoretical model. First, confidence exists that one can engage in the new behavior. Second, the temptation aspect of self-efficacy refers to factors that can tempt one to engage in unhealthy behaviors across different settings.

The fourth construct of the transtheoretical model deals with the process of change. It includes 10 factors that can influence the progression of individuals from the precontemplation stage to the maintenance stage.

The Harm Reduction Model

Harm reduction is a concept that emerged from chemical dependency treatment programs, in which researchers realized that expecting those persons who were addicted to substances to become abstinent in one single step, without any relapse, was not possible for the vast majority. It drew on the ideas of the transtheoretical model that changing health behavior involves several steps (contemplation, planning, action) and may also involve relapse. The important insights of the harm reduction model are that (1) relapse is not failure and (2) making even a small step in improving health behavior often leads to additional positive changes (Lane, Lurie, Bowser, Kahn, & Chen 1999). The harm reduction model has been integrated into obesity-reduction programs, smoking cessation, and teen pregnancy prevention.

Explanatory Models

Explanatory models were initially proposed by the physician-anthropologist Kleinman (1980, 1986, 1988). They differ from some of the theories described earlier in this section in that they are designed for multicultural settings. They include models such as the meaning-centered approach to staff–patient negotiation described by Good and Good (1981). Although such models focus on individual interactions between physician or other staff and patients, the concepts underlying them—such as Kleinman's negotiation model—have proved useful for research and for behavioral interventions for larger populations. An explanatory model is seen as dynamic, and can change based on individual experiences with health, with health information, or with the illness in question (McSweeney, Allan, & Mayo, 1997).

EXHIBIT 2-3 adapts and summarizes concepts from Good and Good's (1981) description of the meaning-centered approach. This approach involves mutual interpretations across systems of meaning. The interpretive goal is understanding the patient's perspective. The underlying premise is that disorders vary profoundly in their psychodynamics, cultural influences in interpretation, behavioral expression, severity, and duration. As noted earlier, it is difficult to apply "codes" to culture and symptoms due to factors such as individual variations, groups assimilating or changing, and groups adding beliefs and behaviors from other cultures. For example, belief in *espiritismo* (spiritism) was traditionally strongest among Puerto Rican groups in the United States, but this belief has now been adopted by other cultures of Latin American origin as well. Thus, instead of trying to provide "formulas" for understanding health and illness belief systems within different cultures, the focus with the meaning-centered approach is on the meaning of symptoms. The medical encounter must involve the interpretation of symptoms and other relevant information.

Other Theories

A number of other theories can be useful in looking at culture and behavior. For example, the multi-attribute utility theory predicts behavior directly from an individual's evaluation of the consequences or outcomes

EXHIBIT 2-3 Meaning-Centered Approach to Clinical Practice

Primary Principles

- Groups vary in the specificity of their medical complaints.
- Groups vary in their style of medical complaining.
- Groups vary in the nature of their anxiety about the meaning of symptoms.
- Groups vary in their focus on organ systems.
- Groups vary in their response to therapeutic strategies. Human illness is fundamentally semantic or meaningful (it may have a biological base, but is a human experience).

Actions

Practitioners must:

- Elicit patients' requests, questions, and other communications.
- Elicit and decode patients' semantic networks.
- Distinguish disease and illness and develop plans for managing problems.
- Elicit explanatory models of patients and families, analyze conflict with biomedical models, and negotiate alternatives.

Corollary

- Clinical practice is inherently interpretive.

associated with both performing and not performing a given behavior. Some models, such as social learning theory, have been criticized by anthropologists who argue against the notion that people are like a "black box" into which you can pour information and expect a specific behavior change.

Common Features of Successful Health Communication and Health Promotion Programs

When applied in practice, many of the principles discussed in this chapter can help increase the success of health communication and health promotion programs. In particular, understanding and incorporating people's insider cultural values, beliefs, and behaviors; a community-based approach with strong community participation; recognition of gender issues (Zamen & Underwood, 2003); peer group education, including use of community-based outreach workers; and multilevel intervention approaches have proved essential to program success.

The Agita Sao Paulo Program in Brazil provides a case study in using local culture to design both the content and the delivery system for a program to use physical activity to promote health (Matsudo et al., 2002). Just the word *agita* (which means to move the body—to "agitate" in the sense of "stirring," but also to change) is more culturally understood and internalized than a literal translation of "exercise." In addition to representing careful work on culturally acceptable ways of delivering the message, this project provides multiple culturally valued ways to increase physical activity, and "tailors" these options to the age, gender, and lifestyles of community members.

In a very different project, work in three townships in South Africa focused on identifying where AIDS prevention would be most effective from the culturally appropriate, insider perspective (Weir et al., 2003). Among other things, researchers learned that ideal prevention intervention sites varied depending on whether the central business district or the township was the most popular location for initiating new sexual encounters. The type of sex (commercial versus casual) as well as the availability of condoms varied with the site. The age of people engaging in risky behaviors and risk behaviors by gender also varied by site. Again, prevention programs needed to be tailored.

In another HIV/AIDS prevention project, this time in Vietnam, paying attention to culture and religion was essential to program strategies (Rekart, 2002). In Belize, understanding adolescents and making sure the program met their needs in both cultural- and age-appropriate ways was key (Martiniuk, O'Connor, & King, 2003). In Nepal, the use of indigenous workers and attention to cultural practices helped lower the incidence and severity of diarrheal and respiratory infections in the districts targeted for interventions (Ghimire et al., 2010). Evaluation of programs addressing family planning and HIV prevention shows that behavior-change communication increases knowledge and interpersonal communication among audience members and motivates positive changes in behavior (Salem, Bernstein, Sullivan, & Lande, 2008).

Another example of focusing on understanding and changing cultural values around unhealthy behaviors is found in the area of smoking cessation. Abdullah and Husten (2004) set forth a framework for public health intervention in this area that addresses multiple levels of society.

The need for the involvement of communities is also clearly demonstrated in the literature, as literally hundreds of references exist on this topic. A recent summary article outlines many of the broad principles underlying this approach, including community analysis with community participation, action plans designed with community input, and community involvement in implementation (Nguyen-Truong, Tang, & Hsiao, 2017). Community involvement may take the form of ongoing oversight and evaluation as well as the more usual modes of using community outreach workers (e.g., Thevos, Quick, & Yanduli, 2000), working through community organizations, and getting individuals involved (Bhuyan, 2004). A report from a recent project in Bolivia documents the success of involving community members in everything from mapping the villages to priority setting for the program (Perry, Shanklin, & Schroeder, 2003). The former head of the United Kingdom's National Health Service, Nigel Crisp, argues strongly that the quest for global health in the twenty-first century must involve a paradigm shift in which nations, communities, and indigenous peoples around the world have a much greater voice in the design and implementation of health services (Crisp, 2010).

Two projects in Chicago demonstrate the success of the community outreach worker approach. In one case, the project focuses on intravenous drug abusers, helping them to reduce their HIV/AIDS-related risk behaviors and to initiate drug abuse treatment programs. This work simply could not have been accomplished without the efforts of community outreach workers, all of whom are former addicts who know how and when to reach

current addicts. Also, the outreach workers come from the predominant cultural/ethnic group in each community (Booth & Wiebel, 1992; Wiebel, 1993; Wiebel et al., 1996). Similarly, the Chicago Project for Violence Prevention involves ex-gang members as outreach workers. Both programs have been adopted internationally as well as in other cities in the United States. A similar focus on peer group education in Botswana led to increased knowledge and prevention behaviors among women at risk for HIV/AIDS infection (Norr, Norr, McElmurray, Tlou, & Moeti, 2004).

Methodologies for Understanding Culture and Behavior

Many of the research methodologies developed in the United States do not translate easily, literally, or figuratively to international settings. Differences in linguistic nuances, in the meanings of words and concepts, in what people would reveal to a stranger, and in what they would reveal to someone from their community have all complicated the application of the quantitative methodologies used by sociologists, psychologists, and epidemiologists. The realization of these problems came about gradually, through failed projects and missed interpretations, and especially once AIDS appeared. As a disease whose prevention is still largely behavioral, and with which many hidden or taboo behaviors are involved, AIDS highlighted the need for qualitative research and for research conducted by individuals from the cultures being studied. More recently, the Ebola pandemic of 2013–2016 reinforced the need to understand and address behaviors and beliefs as part of health interventions.

The field of global health has now moved from an almost exclusively quantitative orientation to the recognition that a toolbox of methodologies is available. Some of these tools may be more valuable than others for some situations or questions; at other times, a mix of several methodologies may offer the best approach. These methodologies derive from epidemiology, survey research, psychology, anthropology, marketing (including social marketing), and other fields. The biggest disagreement has been over the relative value of quantitative and qualitative methods.

The debate on the scientific value of qualitative versus quantitative research is well summarized by Pelto and Pelto (1978). They define *science* as the "accumulation of systematic and reliable knowledge about an aspect of the universe, carried out by empirical observation and interpreted in terms of the interrelating of concepts referable to empirical observations" (p. 22). The Peltos add that "if the 'personal factor' in anthropology makes it automatically unscientific, then much of medical science, psychology, geography, and significant parts of all disciplines (including chemistry and physics) are unscientific" (p. 23).

In fact, scientific research is not truly objective, but rather is governed by the cultural framework and theoretical orientation of the researcher. One example of this bias can be found in the past tendency of biomedical researchers in the United States to focus on adult men for many health problems that also occur in women (such as heart disease). The earlier example of kuru also demonstrates the limitations of cultural bias.

Qualitative research techniques include the following:

- Observation: Behaviors are observed and recorded.
- Participant observation: The researcher learns by participating in cultural events and practices.
- Interviews: Both open-ended and semi-structured queries are possible, usually based on interview guides or checklists.
- Focus groups: A group of people are asked to discuss specific questions and topics.
- Document analysis: Existing documents and prior research are evaluated.
- Systematic data collection: This technique ranges widely, from photography and videotaping to asking informants to draw maps; sort cards with pictures, words, or objects; answer questions based on scales; and many more (Bernard, 2013; Pelto & Pelto, 1978; Scrimshaw & Hurtado, 1987).

A key feature of qualitative research is the use of these multiple methods to triangulate, or compare, data so as to ensure accuracy. With these approaches, the researcher does not simply rely on what is said, but can observe what is actually done. Another feature is that the researcher spends enough time in the community to be able to interview, observe, or otherwise evaluate the same individuals or behaviors multiple times, thereby further ensuring the depth and accuracy of the resulting data.

These techniques yield data that are descriptive and exploratory, and that serve to investigate little-understood phenomena, identify or discover important variables, and generate hypotheses for further research. Results are often explanatory, helping researchers to understand the social and cultural forces causing the phenomenon and to identify plausible causal networks. They also present the "voices" of the participants, and introduce context and meaning into the findings. They yield themes, patterns, concepts, and insights related to cultural phenomena. They can be particularly

valuable for behaviors that are often hidden, such as sexual risk taking and drug abuse (Dickson-Gomez, 2010; Wiebel, 1993) In evaluations, they help practitioners make judgments about a program, improve its effectiveness, and inform decisions about future programming, as illustrated in the case study on acceptability of an infant cereal found later in this chapter.

The methodological concepts of validity and reliability provide a common foundation for the integration of quantitative and qualitative techniques. *Validity* refers to the accuracy of scientific measurement—"the degree to which scientific observations measure what they purport to measure" (Pelto & Pelto, 1978, p. 33). For example, in Spanish Harlem in New York City, a study using the question "¿Sabe como evitar los hijos?" ("Do you know how to avoid [having] children?") elicited responses on contraceptive methods and was used as the first in a series of questions on family planning. By not using family planning terminology at the outset, the study was able to avoid biasing respondents (Scrimshaw & Pasquariella, 1970). The same phrase in Ecuador, however, produced reactions like "I would never take out [abort] a child!" If the New York questionnaire had been applied in Ecuador without first testing it through semi-structured ethnographic interviews, the same words would have produced answers to what was, in fact, a different question (Scrimshaw, 1974). Qualitative methods often provide greater validity than quantitative methods because they rely on multiple data sources, including direct observation of behavior and multiple contacts with people over time. Thus, they can be used to increase the validity of survey research.

Reliability refers to replicability—the extent to which scientific observations can be repeated and the same results obtained. In general, this goal is best accomplished through survey research or other quantitative means. Surveys can test hypotheses and examine questions generated through qualitative data. Qualitative methods may help us discover a behavior or learn how to ask questions about it, while quantitative data can tell us how extensive the behavior is in a population and which other variables are associated with it.

Murray (1976) describes just such a discovery during qualitative research in a Haitian community, where a simple question—"Are you pregnant?"—had two meanings. Women could be pregnant with *gros ventre* ("big belly") or could be pregnant and in *perdition*. Perdition meant a state where a woman was pregnant, but the baby was "stuck" in utero and refused to grow. Perdition was attributed to causes such as "cold," spirits, or ancestors. Women may be in perdition for years, and may be separated, divorced, or widowed, but the pregnancy is attributed to her partner when it commenced. Murray subsequently included questions about perdition in a later survey, which revealed that it was apparently a cultural way of making infertility or subfecundity socially acceptable, as many women in perdition fell into these categories.

Surveys are effective tools for collecting data from a large sample, particularly when the distribution of a variable in a population is needed (e.g., the percentage of women who obtain prenatal care) or when rarely occurring events must be assessed (e.g., neonatal deaths). Surveys are also used to record people's answers to questions about their behavior, motivations, perception of an event, and similar topics. Although surveys are carefully designed to collect data in the most objective manner possible, they often suffer inaccuracies based on respondents' perceptions of their own behavior, their differing interpretations of the meaning of the question, or their desire to please the interviewer with their answers. Surveys also can encounter difficulty in uncovering motives (i.e., why individuals behave as they do), and they are not apt to uncover behaviors that may be consciously or unconsciously concealed. In "Truths and Untruths in Village Haiti: An Experiment in Third World Survey Research," Chen and Murray (1976) describe some of these problems.

The traditional anthropological approach involves one person or a small team who remain at the research site for at least a year. This practice is intended to ensure that the findings take into account the changes in people's lifestyles with the changes in seasons, activities, available food, and so on. Also, the anthropologist often needs time to learn a language or dialect and learn enough about the culture to provide a context for questions and observations. More recently, a subset of anthropological tools (ethnographic interview, participant observation, conversation, and observation) plus the market researchers' tool of focus groups have been combined in a rapid anthropological assessment process known as the Rapid Assessment Procedure (RAP) (Scrimshaw, Carballo, Carael, Ramos, & Parker, 1992; Scrimshaw, Carballo, Ramos, & Blair, 1991; Scrimshaw & Hurtado, 1987).

RAP evolved around the same time as Rapid Rural Appraisal was developed by rural sociologists (Chambers, 1992). Both methods made listening to community voices easier for program planners and healthcare providers and became frequently used tools for program development and evaluation. RAP is designed to involve local researchers who already know the language and much of the cultural context. Such procedures have been developed for many topics, including AIDS, women's health, diarrheal disease, seizure disorders, water and health, and childhood

obesity prevention. RAP has become a generic concept, and has been modified for many uses. Modified titles include RARE, ERAP, and FES (focused ethnographic study). In the past 20 years, the RAP methodologies have been embraced by community members, researchers, and funders alike and have been broadly used in community participatory research.

The case study on the use of focused ethnographic methods to assess the feasibility of introducing a fortified infant cereal in an African country, which appears in the next section of this chapter, is a good example of the use and value of this approach. With a relatively small number of interviews, researchers were able to establish that the cereal as constituted and packaged would be unlikely to succeed. Minor modifications (i.e., a cereal that did not require cooking and was packaged in small amounts) were recommended to change the product's likely acceptability.

In community participatory research, community members become involved in the design, conduct, and interpretation of research. This approach has been used most often for health intervention and behavior change programs where community acceptance of such interventions and programs is essential for success. It also has been found to increase the validity (accuracy) of the data, as community members are invested in developing programs that work.

A final comment on methodology is that as the social sciences are increasingly combining methodologies and sharing each other's tools, it is also important to share theoretical approaches. Where methodology is concerned, this leads to using multilevel approaches to research, in which environment, biological factors, cognitive issues, societal and cultural context, and political and economic forces all can contribute to the analyses. This should take place at least to the extent that an examination is made of data one step above and one step below the phenomenon being explained (Rubenstein, Scrimshaw, & Morrissey, 2000).

An example of a logic framework using this approach can be found in the work of the Centers for Disease Control and Prevention (CDC) task force that developed and maintains the *Guide to Community Preventive Services*—a series of evidence-based recommendations for community public health practice based on a systematic and critical review of the evidence. Topics considered in the guide include major risk behaviors (e.g., tobacco use, alcohol abuse and misuse, other substance abuse, nutrition, physical activity, healthy sexual behavior), specific illnesses (e.g., cancer, diabetes), and one overarching topic, the sociocultural environment. **FIGURE 2-3** presents the logic framework for this topic. The outcomes of community health (on the right side of the figure) stem

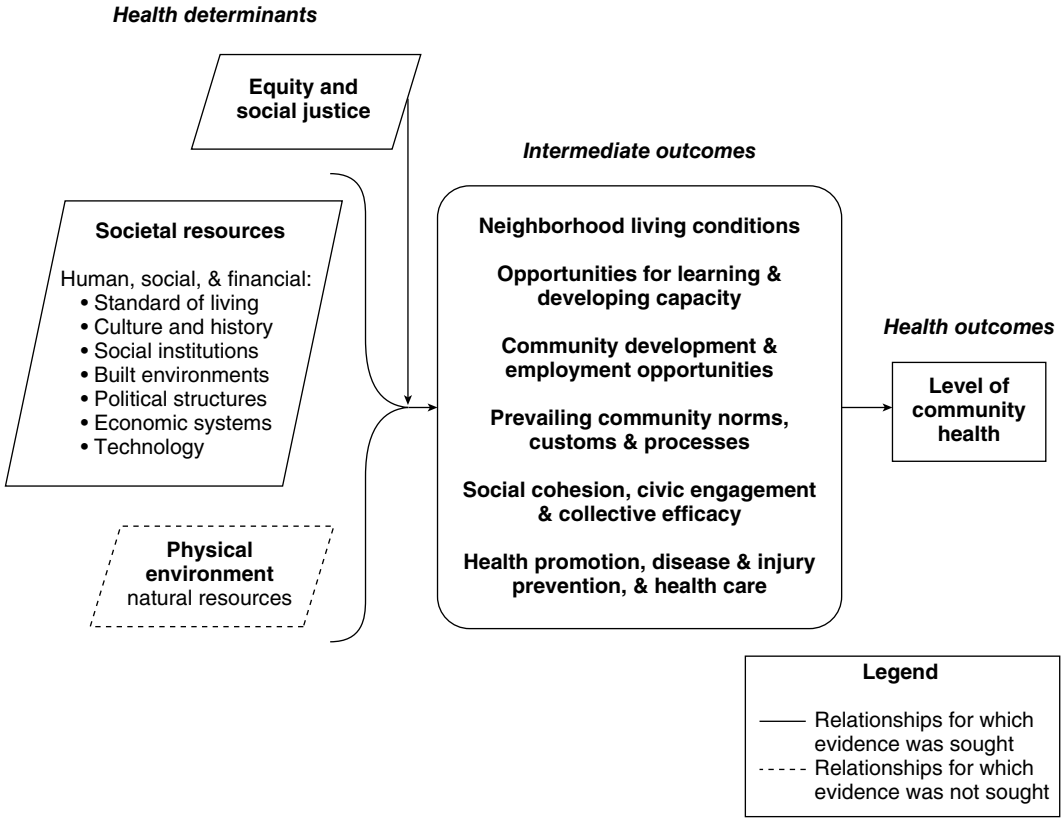

FIGURE 2-3 The *Guide to Community Preventive Services'* social environment and health model.

Reproduced from Anderson L. M., Scrimshaw S. C., Fuillilove M. T., et al. (2003). The community guide's model for linking the social environment to health. *American Journal of Preventive Medicine, 24*(35), p. 13. Reprinted with permission from Elsevier.

from factors in the physical environment and societal resources; outcomes related to equity and social justice issues derive from factors on the left side of the figure. The immediate outcomes, which are listed in the middle of the figure, range from neighborhood living conditions to prevailing community norms regarding prevention and health care (Anderson, Fielding, et al., 2003; Anderson, Scrimshaw, et al., 2003). This approach greatly broadens the context for understanding and addressing the health of individuals and of communities.

The CDC's *Community Guide* can be accessed through the following website: www.thecommunityguide.org. That website and related publications listed there provide evidence-based guidelines for improving community health, many of which have global relevance.

Case Study: Use of a Focused Ethnographic Study to Assess the Acceptability of a Fortified Infant Cereal in Africa†*

Earlier in this chapter, qualitative methods derived largely from anthropology were described as being important tools for ascertaining cultural facilitators and impediments to behavior changes that lead to improved health. As discussed then, these tools have been adapted for use in rapid assessment. This case study involves a rapid (focused) ethnographic study that was conducted before a new infant cereal was introduced to assess the potential success of this cereal by investigating household and local market behaviors.

Many infants and young children (IYC) in Africa continue to suffer from malnutrition or undernutrition. Where mothers breastfeed exclusively for at least six months, quality foods that complement the nutrients in human milk are important after six months when human milk alone is not adequate to meet nutritional needs.

In one African country, a project was devised to introduce a fortified cereal-based food that could help contribute to improved nutrition for infants and children consuming it. The aim of the focused ethnographic study was to determine whether families would purchase the food if available and, if the product was purchased, who actually consumed it. Why each of these steps did or did not occur was also important to assess. The price of the product was pegged at the amount that most urban families, even the poor, could afford to spend per day for a cereal.

It was important to the researchers to make the study framework broad enough to include key variables, so that they could avoid mistakes made by intervention projects that fail to take important cultural, economic, access, and other factors into account. A household perspective was chosen because the purchase and preparation of the cereal would be done at the household level.

Research questions included the following items:

- How much are households currently spending on food for their infants?
- Are their current expenditures providing a nutritionally adequate diet?
- Do households that are spending less than *x* amount (e.g., cents/day) have the potential to shift their expenditures?
- Which other factors determine household buying and/or preparation of foods for the infant or young child, and would these other factors interfere with making a switch, even if the family could afford it monetarily?

It was also important to take into account the possible foods for infants and young children in this environment: (1) human milk, (2) home-prepared foods that are made for family members and are also given to the infant or young child, (3) home-prepared foods that are made exclusively for the infant or young child, (4) commercial products that are marketed and purchased for household consumption, (5) commercial products that are marketed and purchased exclusively for the infant or young child, and (6) commercial products that are marketed for household consumption, but are purchased exclusively for the infant or young child.

The focused ethnographic study interviewed key informants—people who had personal knowledge and experience in an area of concern to the project. Four different techniques were used:

1. *Free listing exercises.* The respondent is asked a question or set of questions that elicit a series of items (objects, events, issues) pertaining to a particular cultural domain. For example, the interviewer can ask, "What are all the different places where a person can get food for infants or young children?"

†* This case study is based on Pelto, G. H., & Armar-Klemesu, M. (2010). *Focused ethnographic study to assess the potential of a commercial complementary food*. Report prepared for the Global Alliance for Improved Nutrition, Geneva, Switzerland.

2. *Open-ended interviewing, with guiding questions.* In open-ended questions, the interviewer writes down what the respondent says in response to a question without using precoding. Questions can be broad or narrow—for example, "How do you prepare cereal for your baby?"
3. *Rating and ranking exercises.* Respondents are asked to rate and rank items such as foods and sources of health care. Methods include handing respondents' cards with pictures of objects to be ranked and asking them to arrange these from most to least important, as well as asking them to assign the card to a slot along a continuum. (A similar technique for the latter method is the familiar scale of perceived pain.)
4. *Mapping exercises.* Respondents create visual maps on which they indicate the locations of specific features of concern for the researcher, such as places to obtain commercial foods.

In this case study, there were two main types of key informant-respondents: (1) women who gave information from the perspective of people who take care of children and (2) people who gave information from the perspective of marketing infant and young child foods. Thirty primary care givers, 10 alternate caregivers, and 12 sellers of these foods were interviewed. The sellers were divided into street venders and keepers of small shops.

The results of the study provided evidence to answer the key question about the potential acceptability of a new fortified cereal for infants and young children. They revealed that fortified cereals are, indeed, used and accepted, and that a relatively high proportion of the food budget for households with infants is spent on these items. Thus the key question about a dietary niche for a fortified cereal was answered affirmatively.

Importantly, the study uncovered the reality that a food that must be cooked, however briefly, is *unlikely* to be chosen over instant foods that do not require cooking. Busy mothers will spend more money to purchase prepared cooked cereals from street vendor or buy small packets of instant cereal that can be mixed with water rather than cooking a cereal themselves. This was extremely important guidance, as it showed that the cereal planned for introduction would need to be modified so that it would not require cooking if it was to be a success.

Because families were already spending so much for these foods, there was clearly a niche for a lower-cost fortified cereal, but it must be instant and available in small packets to be a financially viable option for families. The findings of this study were valuable in planning a program to introduce the cereal, providing the guidance that healthcare practitioners needed to proceed with an appropriately modified product, and to avoid spending time and money on something that would not work.

Case Study: The Slim Disease—HIV/AIDS in Sub-Saharan Africa‡*

AIDS changed the way in which epidemiologic and behavioral research is conducted and health interventions designed and carried out. This case study illustrates virtually all the topics covered in this chapter.

Epidemiology

As of 2016, an estimated 36.7 million adults and children were living with HIV/AIDS worldwide (UNAIDS, 2017). Nearly half (17.8 million) were women, and 2.1 million were children. Of the 36.7 million persons with HIV/AIDS, 19.4 million reside in eastern and southern Africa, among whom 59% are women and girls. In 2016, 77,000 new HIV infections in eastern and southern Africa occurred in children. Per capita rates of infection rates in the United States decreased by 18% between 2008 and 2014, as a result of a combination of aggressive use of antiretroviral therapies and prevention strategies (HIV.gov, 2017a, 2017b; WHO, 2010).

Unlike in the Western world, where AIDS was originally associated with gay men and injection-drug users, in Africa the most common route of transmission is through heterosexual sex. Men infect their partners (often wives) as a result of their involvement with other partners. A pregnant, HIV-positive woman may transmit the virus to her fetus through the placenta or to her infant through breastfeeding.

Generally, AIDS patients in Africa suffer from intestinal infections, skin disease, tuberculosis, herpes zoster, and meningitis. In the industrialized countries, AIDS is associated with Kaposi's sarcoma (a skin cancer), meningitis, and pneumonia.

‡* This case study was developed by Isabel Martinez, MPH.

Why does the same disease spread so differently from one region of the world to another? History, politics, economics, and cultural and social environments influence the course of a disease in a society. In the case of Africa, traditional family, social, and environmental structures were disrupted by European colonization, which imposed changes on the existing culture. Even after countries became independent from Europe, their political, ecological, and economic structures remained disrupted and often unstable. Many of these factors contributed to an environment in which AIDS easily took hold (Akeroyd, 1997; Bond, Kreniske, Susser, & Vincent, 1997; Hunt, 1989; Jok, 2001). These factors and their association with the AIDS pandemic are described in the following subsections. In addition to illustrating the relationship between cultural norms, prevention and healthcare access, and disease, this case study demonstrates the profound relationship between the general sociocultural, political, physical, and economic environment and health.

Risk of AIDS Associated with Migratory Labor

The integral family structure of the African culture has been broken up by the migratory labor system in eastern, central, and southern Africa. This system was historically part of the region's industrial development and colonization by European powers. These large industries, which include mining, railroad work, plantation work, and primary production facilities (e.g., oil refineries), have absorbed a massive labor influx from rural areas. Men typically leave their homes and travel outside their communities to work sites, where they remain for long periods of time. This system has not only kept families apart, but also increased the numbers of sex partners for men—in turn, giving rise to a higher prevalence of sexually transmitted infections (STIs) and later AIDS. In many African cultures, regular sex is believed essential to health. Men in the migratory labor system have sex with prostitutes close to their work sites, become infected, and eventually return home and infect their wives, whose babies may in turn become infected (Hunt, 1989; Salopek, 2000).

War

In 2017, there were 14 major armed conflicts and 29 additional armed conflicts globally. Of these 43 conflicts, 21 occurred in Africa. A country at war typically faces a weakening of its political system, and this situation in Africa has intensified the impact of the AIDS epidemic. Several populations become more vulnerable to HIV/AIDS during wartime, including those affected by food emergencies and scarcity, displaced persons, and refugees. Women are especially at risk. They are six times more likely to contract HIV in refugee camps than women in populations that reside outside such camps. In addition, women are often victims of rape as a weapon of war by the enemy side. Armed forces and the commercial sex workers with whom soldiers interact are also affected by the epidemic (Akeroyd, 1997; Carballo & Siem, 1996; Jok, 2001, 2012; UNAIDS, 1999; United Nations, 1999a; Uppsala Conflict Data Program, n.d.; Wallensteen & Harbom, 2009).

Gender Roles and Cultural Traditions

The African woman's struggle with the AIDS pandemic has been depicted often in the literature (Akeroyd, 1997; Carballo & Siem, 1996; Hunt, 1989; Messersmith, 1991; Salopek, 2000; UNAIDS, 1999; Watkins, 2004). The risk to women from husbands or partners returning from work in other areas has already been discussed. Another risk—sex work or prostitution by women as a means of survival—is now almost a death sentence in Africa, considering the great risk of contracting HIV/AIDS through such employment. There are many reasons why some African women find the need to engage in sex work, although studies have linked most of these reasons to a political economy context. Sex in exchange for favors, material goods, or money is conducted in all socioeconomic levels, from female entrepreneurs in foreign trade having to use sexual ploys to ensure business to impoverished young women needing money to support themselves and their families (Swidler & Watkins, 2007). Even if women in sex work are knowledgeable about preventing HIV infection through use of condoms, their cost and availability, combined with the resistance of some males to use them, raise barriers for the safety of these women and play a part in further transmission of the disease (Akeroyd, 1997; Messersmith, 1991).

Having multiple sexual partners has increasingly been implicated in raising the risk for HIV for both men and women (Helleringer, Kohlerb, & Kalilani-Phiric, 2009). Called "concurrency," these practices are now a major focus of intervention efforts (Shelton, 2009).

Other cultural factors that place young women at greater risk for HIV infection include a superstition in some areas that having sex with a virgin will cure an HIV-infected man. Adolescent girls and young women are placed at higher risk of exposure to HIV due to the behavioral practices of engaging in sex with older men (Tulio de Oliveira et al., 2017). The practice of female circumcision also places young girls at risk. In both of these circumstances, the risk of contracting HIV through sex or infected surgical instruments increases for adolescents (Akeroyd, 1997; Salopek, 2000).

Additional Cultural Beliefs

Secrecy regarding HIV/AIDS is common within some sub-Saharan cultures. Denying that AIDS is affecting one's community or that one is infected increases the chances that the virus will be transmitted to other people because preventive actions are not taken (Akeroyd, 1997; Salopek, 2000; UNAIDS, 1999; United Nations, 1999d). Preventive actions go beyond preventing sexual transmission, to include concerns about transmission during treatment of ill individuals and during funeral practices.

In some parts of Africa, AIDS is referred to as the "slim disease" because of the wasting away that occurs as a result of the infections. Because of this belief, men prefer sex with plump women, believing that they are not infected. AIDS is called "white man's disease" in Gabon and "that other thing" in Zimbabwe. HIV and AIDS are a source of shame and denial in these African cultures. AIDS is also considered a punishment for overindulgence of the body. One *sangoma* (faith healer), who has helped revive an ancient Zulu custom of virginity testing of young girls, supported her belief in reviving this custom by saying, "We have adopted too many Western things without thinking, and we lost respect for our bodies. This has allowed things like AIDS to come torture us" (Akeroyd, 1997; Hunt, 1989; Salopek, 2000; UNAIDS, 1999).

Barriers to Prevention or Treatment of HIV/AIDS

Barriers to prevention of HIV/AIDS include lack of financial resources and allocation of funds to projects that might be less crucial than those related to health. For example, a foreign country funded a multimillion-dollar hospital in Zambia, even though the rural clinics where the majority of the population live are often not even stocked with aspirin (Bartholet, 2000; Salopek, 2000).

Changing people's health behavior and addressing cultural beliefs has also been a tough challenge when it comes to prevention efforts. Promoting safe sex and the use of contraception, as well as abstaining from some cultural rituals, can be perceived as changing traditional gender roles for both men and women, and may go against some religious values that are part of the core for some communities. The need to hide or look away from the problem of HIV/AIDS stems from the disgrace attached to the disease, which makes it difficult for people even to discuss it, much less be tested for this infection. The stigma of HIV/AIDS needs to be removed for prevention efforts to be more widely accepted by the African people (Akeroyd, 1997; Bartholet, 2000; Salopek, 2000; UNAIDS, 1999; United Nations, 1999c).

One project in Ghana used both the health belief model and social learning theory to examine the determinants of condom use to prevent HIV infection among youth. The authors of the study found that perceived barriers significantly interacted with perceived susceptibility and self-efficacy. Youth who perceived a high level of susceptibility to HIV infection and a low level of barriers to condom use were almost six times as likely to have used condoms at last intercourse. A high level of perceived self-efficacy and a low level of perceived barriers increased the likelihood of use three times (Adih & Alexander, 1999).

Prevention Efforts by Community and Governmental Agencies and Nongovernmental Organizations

In the 1990s, Uganda and Senegal reduced their HIV infection rates through aggressive public education and condom promotion campaigns, expanded treatment programs for other STIs, mobilization of nongovernmental organizations (NGOs), and reduction of stigma for people with HIV/AIDS. Health officials believe the education efforts surrounding AIDS have contributed to women delaying the onset of sexual intercourse and increased condom use among sex workers and men and women who have casual sex (UNAIDS, 1999; United Nations, 1999a).

The theory of self-efficacy has proved useful in addressing AIDS. For example, one study in South Africa found that knowledge of risk and its prevention was important, but not sufficient to change behavior. The authors stress the need to improve personal autonomy in decision making about sexual behavior and condom use for both men and women through skills development programs that promote self-efficacy (Reddy, Meyer-Weitz, van den Borne, & Kok, 1999).

The United Nations and its specialized agencies have created major programs to assist countries and communities in prevention efforts, including joining forces to accelerate the development of experimental vaccines. Academic institutions have also teamed up with local community and church organizations to create prevention projects and help organize the communities to reach more of the public. These efforts have assisted in empowering many volunteers, mostly women, to motivate others in their communities through education and increasing women's negotiation skills for safe sex or condom use (Msiza-Makhubu, 1997; United Nations, 1999d; WHO, 1997).

There is also a growing movement in which doctors in Africa work with traditional healers to do outreach and education on AIDS. As discussed earlier, traditional healers have better access to many populations. People seek their help because of tradition and lack of adequate health care (Associated Press, 2000; Green, 1994).

Antiretroviral Therapy

Donor agencies/organizations such as the Global Fund to Fight AIDS, TB, and Malaria; the U.S. President's Plan for AIDS Relief; the World Bank; the European Commission; WHO; and the Gates Foundation have aggressively provided testing for HIV/AIDS and antiretroviral (ARV) therapy during the past eight years, and infection rates have come down (UNAIDS, 2004a; WHO, 2004). Beginning in 2003, the United States implemented the President's Emergency Plan for AIDS Relief (PEPFAR/Emergency Plan). As of 2017, this program had provided antiretroviral treatment (ART) to more than 11 million HIV-infected people and supported HIV testing and counseling (HTC) for more than 56.7 million people (PEPFAR, 2017).

Innovative prevention programs such as the introduction of male circumcision in areas where it had not been practiced are also helping to reduce infection rates. Male circumcision has been found to help protect against infection, reducing transmission rates by as much as 60% (Bailey & Mehta, 2009; Bailey et al., 2007; Tobian et al., 2009; Westercamp & Bailey, 2007).

Antiretroviral Treatment Challenges

Diminished political and economic support for antiretroviral programs could lead to the interruption of treatment of HIV/AIDS patients, which in turn would provide the HIV virus with the potential to become drug resistant. Other challenges in Africa include a shortage of health professionals, many of whom have left their home countries for better opportunities in higher-income countries. In addition, a lack of treatment literacy poses a huge challenge for effective antiretroviral treatment (UNAIDS, 2004b).

The individual behaviors that place people at risk are part of the larger root causes of the problem in Africa, including colonialism, big industry's design of mass labor migration, poverty, gender inequalities, and war. The ideal prevention and intervention strategies would address health behavior changes as well as economic and community barriers to the provision of social services and treatment options (Akeroyd, 1997; Bond et al., 1997; Tylor, 1871; United Nations, 1999c, 1999d; WHO, 1997).

Ebola

The Ebola virus shares several characteristics with HIV/AIDs. First identified in 1976, Ebola is a newly emergent infection. Beginning as a zoonotic disease that infected fruit bats, nonhuman primates, and other mammals, it "jumped species" to infect humans as a result of ecological disruption—in this case, hunting wild animals for food or what is called "bush meat." An Ebola pandemic in 2013–2016 that was centered in the West African countries of Liberia, Sierra Leone, and Guinea infected some 17,145 individuals, among whom 6,070 died. The short interval between recognition of symptoms and death of 6–16 days, the appalling fatality rate of 25% to 90%, and the lack of effective antimicrobial agents and preventive vaccines produced panic that often impeded global health strategies to reduce infection and provide supportive care to the infected.

The two hardest-hit countries—Liberia and Sierra Leone—are impoverished. Liberia ranks 182th out of 187 countries in the United Nations Human Development Index; Sierra Leone comes in at 180 (United Nations Development Programme, 2017). Cultural patterns of care for the sick and dying, as well as careful tending of the dead in preparation for burial, were found to increase Ebola transmission, because contact with body fluids—even sweat—in the context of cleaning, feeding, or moving an infected person can lead to transmission (CDC, 2015).

When American and European global health personnel first arrived to help fight the epidemic, in many cases they were greeted with fear and even violence by villagers, who, upon seeing the Westerners in hazmat suits, resisted their approach and often hid their sick family members. A new psychosocial paradigm called "fear-related behaviors" in situations of mass threat is now recognized as an expected reaction to disasters and must be planned for with clear communication, cultural understanding, and the close collaboration of foreign public health workers with local professional and community leaders (Espinola et al., 2016). Viewed from this perspective, the panicked responses of the African villagers were not irrational (Richardson et al., 2016). Beginning with the slave trade and colonialism, Western incursions into Liberia and Sierra Leone have caused immense suffering. Further complicating the cultural misunderstandings is the fact that Liberia has 31 separate languages and Sierra Leone has 25 (Rodriguez, 1997).

With Ebola deaths mounting and the evidence that the health systems of the affected West African countries were under-resourced and overwhelmed, numerous well-meaning multinational, governmental, and nongovernmental agencies rushed to the scene to help.

Grieving African family members were not allowed to touch or kiss their dead. Rather than observing time-honored funereal practices, they were instead obliged to place their deceased loved ones in plastic bags, to be buried with chloride disinfectant. Those and other measures to prevent transmission represented enormous changes in cultural practices around death and dying, but they worked to reduce transmission (Agusto, Teboh-Ewungkem, & Gumel, 2015). Analyses of the Ebola pandemic, and the behavioral changes that led to decreases in transmission, demonstrated that serious attention to clear communication and understanding of cultural patterns are critical elements of responses to outbreaks and disasters.

Conclusion

This chapter has briefly explored cultural and behavioral issues that influence global health. Anthropology, sociology, and psychology have much greater depth in terms of both methods and theories than can be described in this chapter. A rich and extensive literature exists on health beliefs and behaviors, environmental and biological contexts, health systems, and programmatic successes and failures. It is essential to take these factors into account when contemplating global health work. In addition, a program must consider structural factors, such as setting, hours, child care, and ambience, as well as factors of content, such as culturally acceptable services, which includes providers who treat patients with respect and understanding.

Research and preventive services regarding health beliefs and behaviors must accept and integrate concepts different from those held by Western biomedicine, by middle- or upper-class healthcare providers, or by healthcare providers from an ethnic or cultural group that is different from their patients. This requirement demands the ability inherent in some of the anthropological methods and approaches discussed earlier—that is, the ability to "get into someone's head" and understand things from an insider perspective. There is nothing like the experience of spending time with people, in their own homes or community, and striving to reach that insider understanding.

Acknowledgments

Susan Scrimshaw would like to thank Carolyn Cline, Rose Grignon, and Lisa Brainard for their assistance in editing and preparing the bibliography; Pamela Ippoliti for her editorial assistance; Susan Levy and John Justino for providing key examples from the intervention literature; and Isabel Martinez and Janel Heinrich for their assistance with the literature search, for helpful comments on the chapter, and, in particular, for preparing and revising the case study on AIDS. Appreciation also goes to Carole Chrvala for sharing notes on the various intervention theories. In addition, we would like to thank and acknowledge Professor Gretel Pelto and Dr. Margaret Armar-Klemesu for permission to base the case study on the introduction of a fortified infant cereal on one of their recent projects.

Discussion Questions

1. Which prevention strategies for AIDS would you develop if you were the minister of health of a sub-Saharan African country? Which strategies would you use if you were a community leader? Would the strategies used for these two perspectives differ? If so, how? How would you address some of the cultural beliefs or traditions associated with HIV/AIDS mentioned in the case study?
2. If you were entering a community to introduce a health program, who would you talk to? What would you ask? Why?
3. Discuss the concepts of validity and reliability in research as they apply to the use of quantitative and qualitative methods. Next, discuss the same concepts as they apply to community participatory research.
4. What is the hot/cold illness belief system? Why is it important? How would you incorporate it into a maternal and child health program?
5. Many people believe that healers such as midwives and shamans are called to their profession by a greater spiritual power. What significance does this belief have for official health programs around the world? How should they address this belief?
6. If an indigenous practice seems peculiar to you, but does no apparent harm, what should you do?
7. How could you learn what people in a community really believe about health and illness?
8. Based on the theories of behavior change, create your own model by taking what you think is the best content from existing theories. Explain your reasoning.
9. How would you balance the need to interrupt Ebola transmission in a situation such as the recent West African outbreak with the importance of addressing the fears and panic of the population?

CHAPTER 3

Global Health, Human Rights, and Ethics

Tonya Littlejohn, Chris Beyrer, and Nancy Kass

The recent emergence and reemergence of infectious disease epidemics, the persistent burden of non-communicable disease, the enduring impact of environmental change, and the intractable effects of social disadvantage and inequity have all contributed to the rising prominence of health challenges at a global level. The promise and process of globalization, with its increased interdependence of economic, political, and social domains, accompanied by the integration of goods, services, values, and people, translates into new and interconnected global health threats, worsening health disparities, and heightened global health insecurity.

It is in this context that the human rights and ethics implications of public health challenges and interventions must be pursued and interrogated. Human rights and ethics, encompassing the right to health as well as some degree of the right to non-interference, health equity, and the determinants of health, are central to global health. This centrality is recognized by the World Health Assembly and the World Health Organization (WHO), and is enshrined in international conventions and treaties with relevance to global health, including the Universal Declaration of Human Rights; the International Convention on Social, Cultural and Economic Rights; the Convention on the Eradication of All Forms of Discrimination Against Women; and the most widely ratified of all of these foundational agreements, the Convention on the Rights of the Child. All of these conventions agree that human rights paradigms and ethics principles are inextricably linked to health and offer a normative framework to understand and address complex health issues experienced at a global level. Analysis of emerging and persistent global health challenges through the human rights and ethics lenses can be a more effective and nuanced approach for framing and responding to global health challenges and allows for focus on both the proximal causes and the social determinants of ill health (Mann, 1997).

Defining Global Health in the Context of Human Rights and Ethics

Though many constructs of global health exist, this field is generally understood to refer to a phenomenon whereby the determinants of health or health outcomes supersede the territorial boundaries of any given state. Global health recognizes that health is determined by conditions, issues, and concerns that typically transcend national boundaries (Stapleton, Schroder-Back, Laser, Meershoek, & Popa, 2014). It highlights issues that may be universally experienced, and accepts that while some burdens and challenges are shared, many

health burdens may be profoundly inequitable and disproportionate. Global issues are often recognized as beyond the capacity of individual countries alone to address through domestic institutions (Stapleton et al., 2014). The world recently witnessed this reality during the 2013–2016 Ebola outbreak in West Africa. The "global" in global health identifies the scope of problem, not the location (Koplan et al., 2009). The U.S. Institute of Medicine (1988) describes public health as "what we, as a society, do collectively to assure the conditions for people to be healthy." This definition has equal stature in relation to global public health and has particular application to both human rights and ethics.

Human rights instruments more broadly, the right to health specifically, and ethics provide entry points for understanding and outlining underlying systemic and structural social determinants of health that, if addressed, could advance health equity at a global level. Human rights and ethics discourse highlight the conditions necessary for people to be healthy, and the means and considerations necessary to enable these conditions. With human rights paradigms, these conditions also include fundamentals of good or poor governance as well as civil and political liberties, including the right to information and the right to participate in political decision making. The ethics framework insists that issues of equity, autonomy, and benevolence be included as determinants of health programs and paradigms. Underlying the social determinants of health, and considered essential elements necessary to live a healthy life, these sociopolitical and economic forces drive both local and global health inequality and disproportionate burdens of disease and shape the health, legal, institutional, and structural contexts in which they are embedded. They concern the conditions in which individuals are born, grow, live, work, and age and that influence their health status (WHO, 2017).

Just as health threats extend globally, so must the solutions. Increasingly, it has been recognized that there is both a shared global responsibility to realize the right to health and a moral impetus to address health challenges that are universally experienced. Thus, health, ethics, and human rights efforts are, by definition, synergistic. One undertaking cannot be viewed in isolation without a considered reference and integration of the others. While public health endeavors can at times impact on individual human rights and challenge ethical principles and decision making, such as may occur in a global public health crisis, the underlying complementarity of these disciplines has greater prominence than the inherent confrontation between them (Beyrer, 2004).

Setting the Context: Human Rights and Ethical Approaches to Global Health

Both human rights and ethics offer compelling discourses and frameworks to advance global health and ameliorate health disparities and differences that have a global force or reach. At the intersection of global health, human rights, and ethics, a number of consistent themes and challenges emerge. These will be explored throughout the chapter and are briefly outlined here.

First, fundamental human rights and the right to health are interrelated and inseparable. The realization of one right (such as the right to housing) can enable fulfillment and protection of the right to health; conversely, the deprivation of a right (such as the right to participation in civic life) may increase vulnerability to ill health or impair enjoyment of other human rights (Office of the United Nations Commissioner for Human Rights, 2008). Rights abrogation or violation can have measurable impacts on health, such that if an individual or population group experiences discrimination, or a deprivation of their rights, their ability to engage with and benefit from health interventions is diminished (Beyrer, 2004). Although traditionally described as being in conflict, the pursuit of individual human rights and enhanced global health at a population level are increasingly recognized as complementary and interdependent approaches to defining and advancing human well-being. The central premise of securing health for all by targeting marginalized, discriminated-against, and vulnerable populations parallels the sentiment of human rights. Promoting and protecting human rights is inextricably linked with promoting and protecting health.

Ethics, in relation to global health, is both the application of principles and norms for moral guidance and a process for identifying, analyzing, and resolving ethical issues inherent in the practice of public health. Ethics, which has traditionally been considered to exist within the purview of individual behavior and with a bioethical focus, may be recast in the context of public health ethics with broad application to global public health and governance. In turn, global health ethics may be considered a normative project with a common set of principles or values to deal with global health threats (Stapleton et al., 2014).

Second, to stimulate a more considered analysis of health, human rights, and ethics, it is imperative to understand the disproportionate burden imposed by disease and ill health and to appreciate how these

differences influence health outcomes across a range of populations. Health disparities and the social determinants of health are significantly driven by complex structural factors that can contribute to poor health outcomes and adversely affect groups of people who have systematically experienced both a greater burden of ill health and exposure to numerous structural-level social determinants (Jürgens, Csete, Amon, Baral, & Beyrer, 2010; Sollom et al., 2011).

Third (and a related concept), discrimination is often the basis of fundamental structural inequality, such that populations who are marginalized or experience discrimination are more vulnerable to ill health. According to the Office of United Nations High Commission of Human Rights (2008), discrimination refers to any distinction, exclusion, or restriction made on the basis of various grounds that has the effect or purpose of impairing or nullifying the recognition, enjoyment, or exercise of human rights and fundamental freedoms. The implication is that some diseases or health conditions that have a global distribution, such as tuberculosis or leprosy, may singularly affect marginalized populations or be more pronounced in these populations. Marginalization, stigma, and discrimination may be both the cause and the consequence of ill health. In acknowledging the importance of discrimination and marginalization, it must also be noted that some groups—such as women, children, and prisoners, for instance—face an additional risk or vulnerability due to particular circumstance or biological, structural, and social realities (Rubenstein et al., 2016). This vulnerability may be generalized, or it may be specific to certain diseases or interventions.

Fourth, human rights frameworks relate to obligations and duties at the level of the state and, therefore, are dependent on a state-based system of governance. As a signatory to the various human rights covenants, the state has an obligation to respect, protect, and fulfill those covenants in relation to the right to health. Such conventions outline the requirement of states to refrain from interfering in rights, to protect rights from demands of nonstate actors (such as armed groups and private corporations), and to take positive measures to facilitate and enable rights such as provision of immunization, training of health professionals, access to justice, access to sanitation and clean water, and other essential functions within a national health system.

How do ethical principles and human rights obligations and duties apply to states, and are they enforceable? And if the state is the primary custodian in enacting the right to health for populations within its jurisdiction, who should be made responsible and accountable for global health issues that fall outside state boundaries? Global health issues that transcend the boundary of the state require a coherent and coordinated response through public health activities such as epidemic preparedness, surveillance, health system research, treatment access, and immunization (**EXHIBIT 3-1**). This role and function in relation to global health issues is taken up by a multitude of actors and stakeholders, including nongovernmental organizations, private agencies, and businesses, each of which has its own mandates, motivations, and scope, and each of which also engages in the provision of health at a global level (see also Gostin & Mok, 2009). It should not be assumed that all actors are acting with the similar intent or understand the right to health in the same way. Determining which health challenges should be elevated to a global level of governance is an ongoing debate. Indeed, one of the ongoing challenges to global health is the need to strengthen claims to the right to health and support universality of the right to health (Gable & Meier, 2013).

Friedman and Gostin (2015) discuss the notion that global health—in this case, referring to public health, universal health coverage, and the social determinants of health—cannot be achieved without concurrent advancement of justice and global health equity. This development would lead to gains in both the aggregate level of health and the distribution of health across populations. The World Health Organization, under the leadership of Tedros Ghebreyesus of Ethiopia, has committed to universal health coverage (UHC) as the primary means of achieving the goal of global equity in healthcare access. However, others propose that improvements in health markers, such as prevalence, mortality, and morbidity, do not necessarily translate directly into improvements in health equity and justice (see, for example, Braveman & Gottlieb, 2014). Some would argue that even though war, crime, hunger, poverty, illiteracy, homelessness, and related human rights abuses interfere with the health of individuals and populations, it does not mean that eliminating these conditions is part of the mission of public health (Rothstein, 2002).

States have a shared responsibility for supporting conditions in which their populations can be healthy, including the implementation of preventive health strategies, health equity, and universal health coverage under a mandate of health for all (see also Friedman & Gostin, 2015). Incorporating the right to health, global health governance provides the institutional, financial, and legal mandates and mechanisms necessary to meet core global health challenges and risks that transcend boundaries in their origin and impact. Global health governance is an appeal to collective

EXHIBIT 3-1 Ebola, Ethics and Human Rights

The most recent Ebola outbreak, which occurred between 2013 and 2016, exposed in a very specific way the limitations of the global effort—namely, the inequalities in global power structures, the responsiveness of global health governance (see chapter on *Global Health Governance and Diplomacy* for more on strengthening global health governance after the 2013–2016 Ebola outbreak), and the limited epidemiologic information available early on—allowed the virus to flourish uncharted and undetected for up to three months. The sociopolitical realities of containing a highly pathogenic virus were laid bare. The fragility of the region, following years of conflict and instability, was evident in the weakened and dysfunctional public health governance and infrastructure, debilitated and impoverished institutions, and diverted resources, which contributed to a lack of capacity and preparedness. Local cultural practices, which included traditional burial rituals of hand-washing the body, and a highly mobile and interconnected population moving across arbitrary state boundaries allowed unhindered transmission of the virus (Richardson, 2016). It was the perfect milieu fomenting contagion, lethality, stigma, and neglect (Donnelley, 2014; see also Farmer, 2014). That so many health workers, community members, and graveyard workers were nevertheless willing to risk their lives to care for Ebola-infected patients, the many thousands of exposed persons, and those who died of Ebola complications is a tribute to the extraordinary dedication and humanity of these persons. This example reminds us all that the greatest human rights and ethical imperative remains to care for the sick, even when doing so may put us in harm's way.

The effects of the Ebola epidemic on global health structures, public health ethics, and human rights were far-reaching. First, the outbreak raised questions about who has responsibility to protect populations from public health emergencies (see also Calain & Poncin, 2015). The state must fulfill its duties and fundamental obligations to enable its population's enjoyment of the highest attainable standard of health. Revisions made to WHO's International Health Regulations (IHR) in the wake of the severe acute respiratory syndrome (SARS) outbreak required states to institute minimum core public health standards, including public health surveillance, laboratory capacity, and epidemic preparedness. However, the Ebola outbreak exposed the world's vulnerabilities due to the impoverished health systems in a small region of West Africa, decimating and overwhelming these already fragile systems that were unable, despite significant efforts, to meet their populations' most basic health needs (Gostin & Ayala, 2017). The moral impetus to protect and respond must therefore account for the deeply disproportionate impact that an outbreak has on the most marginalized and vulnerable in the event that the national government is incapacitated and unable to ensure health security for its own population.

The Ebola response was also a teaching moment regarding the weakness of global health governance, most compellingly seen in the failure of the World Health Organization to mount an effective response (see, for example, Sands, Mundaca-Shah, & Dzau, 2016). Without the intervention of nongovernmental groups, most notably Medecins Sans Frontieres, the loss of life would have been much greater. Eventually, the international community did mobilize resources, but the prominent role assumed by military medicine practitioners, notably from the United States, again exposed the weaknesses in civilian capacity to respond. While military engagement in large-scale disasters and epidemics is often essential, the delegation of humanitarian and public health responses to military and other security forces raises additional human rights and ethical challenges, including concerns from the host countries that public health responses led by military actors can be cover for other—more specifically, military or security—objectives. The U.S. Central Intelligence Agency's use of polio immunization as a cover for investigating the whereabouts of Osama Bin Laden in Pakistan is the most unfortunate example of this kind of abuse: It continues to bedevil polio eradication efforts in Pakistan and Afghanistan, and has led to the targeted killing of many immunization staff, mostly women ("Editorial," 2014).

effort, with engagement of state actors and nonstate actors alike, in pursuit of a collective outcome (see also Dodgson, Lee, & Drager, 2002).

The final point relates to priority setting. Priority setting raises ethical concerns of fairness, justice, and equity. Moreover, when it is applied to particular global health challenges, context-specific concerns inevitably emerge regarding how finite resources may be allocated in a fair and equitable manner. Priority setting will be informed by such considerations as infrastructural capacity, urgency, social value, governance, and financing. Ethics can guide approaches when a conflict arises between competing values or needs. In the case of a global health crisis, for example, it may be more readily apparent how goods should be prioritized and who should be the primary beneficiary. Resources may be reallocated or reprioritized as a means of containment to protect the affected and the most vulnerable, and this may prevent unaffected populations from maintaining their health needs. In contrast, the best decisions may be less obvious when setting priorities in the provision of non-emergent healthcare strategies, such as obesity or smoking.

Global Health and Human Rights

> All human beings are born free and equal in dignity and rights. (Article 1, Universal Declaration of Human Rights [UDHR])

Human rights pertain to the fundamental freedoms, inherent value, and dignity of all human beings. These rights are universal, inalienable, and indivisible. They confer both freedoms and entitlements. The improvement of one right facilitates advancement of others, and similarly the deprivation of one right adversely affects the others. Human rights are independent of nationality, place of residence, gender, religion, race, or any other status (United Nations, 1948).

The founding document of the modern human rights movement, the Universal Declaration of Human Rights (1948), Article 25 (1), provides the minimum standards necessary to ensure adequate health and lays out the duties and obligations of the state for upholding the rights of individuals. The UDHR is not legally binding, but states have bestowed it with great legitimacy through their actions, including its legal and political invocation at the national and international levels. Health is mentioned once in the UDHR , within the context of an overall right to an adequate standard of living:

> Everyone has the right to a standard of living adequate for the health and well-being of himself and of his family, including food, clothing, housing and medical care and necessary social services, and the right to security in the event of unemployment, sickness, disability, widowhood, old age of other lack of livelihood in circumstances beyond his control. (United Nations, 1948)

Under international human rights, sovereign states have an obligation to recognize the rights of individuals who reside within their borders.

Subsequent treaties and covenants give further articulation of the rights related to health (**EXHIBIT 3-2**). Article 12 of the International Covenant on Economic, Social, and Cultural Rights (ICESCR) of 1966, in particular, establishes the right to health. It has a significant focus on what was then called international health and would now be called global health, in the three of its four specific provisions (a, b, and c below):

1. The States Parties to the Present Covenant recognize the right of everyone to the enjoyment of the highest attainable standard of physical and mental health.
2. The steps to be taken by the States Parties to the present Covenant to achieve the full realization of this right shall include those necessary for:
   a. The provision for the reduction of the stillbirth rate and of infant mortality and for the health development of the child
   b. The improvement of all aspects of environmental and industrial hygiene
   c. The prevention, treatment, and control of epidemic, endemic, occupational, and other diseases
   d. The creation of conditions which would assure access to all medical services and medical attention in event of sickness

Interpreting the Right to Health

In 2000, the committee on ICESR issued a guideline that provides more substantive details on Article 12, the right to health. General Comment 14 on the right to health notes that health is a fundamental human right indispensable for the exercise of other human rights (Office of the High Commissioner for Human Rights, 2000). General Comment 14 proposes

EXHIBIT 3-2 International Human Rights Instruments Recognizing the Right to Health

- The 1965 International Convention on the Elimination of All Forms of Racial Discrimination: Article 5 (e) (iv)
- The 1966 International Covenant on Economic, Social, and Cultural Rights: Article 12
- The 1979 Convention on the Elimination of All Forms of Discrimination Against Women: Articles 11(1)(f), 12, and 14(2)(b)
- The 1989 Convention on the Rights of the Child: Article 24
- The 1990 International Convention on the Protection of the Rights of All Migrant Workers and Members of Their Families: Articles 28, 43(e), and 45(c)
- The 2006 Convention on the Rights of Persons with Disabilities: Article 25

Reproduced from United Nations. Human Right to Health. 2016.

that the right to health does not equate to the right to be healthy, but rather is an inherent, inalienable right to the highest attainable right that must be progressively realized through available, accessible, and affordable health care, services, and conditions. Realization of the right to health is more than the absence of disease. Indeed, it implies consideration of the conditions necessary for the realization of the highest attainable standard of health. In addressing these issues, General Comment 14 suggests that achieving this goal must take into account the "individual's biological and socio-economic preconditions and a state's available resources" (Office of the High Commissioner for Human Rights, 2000). This provision gives focus to the relationship between the state and the individual by asserting that the state cannot, by itself, guarantee good health, just as it cannot protect against all aspects of ill health (Office of the High Commissioner for Human Rights, 2000).

Additionally, General Comment 14 states that the right to health is interpreted as an inclusive right. Specifically, it extends "not only to timely and appropriate health care but also to the underlying determinants of health, such as access to safe and potable water and adequate sanitation, an adequate supply of safe food, nutrition and housing, health occupational and environmental conditions, and access to health-related education and information, including on sexual and reproductive health" (Office of the High Commissioner for Human Rights, 2000).

The Challenge in Meeting the Right to Health

Under international human rights law, a "right" is put forward as a claim to those social arrangements—norms, institutions, laws, and enabling environment—that can best secure the enjoyment of this right (WHO, 2002). The legal integrity of human rights analysis, as much as its moral appeal, is what gives the human rights movement its authority and force. Under international treaty law, states assume obligations and duties to respect, protect, and fulfill human rights, including the right to health. Violation of this right implies that the obligation and duties have not been met or fulfilled (Cohen, Kass, & Beyrer, 2007).

The rights-based approach to health includes consideration of the underlying determinants to good health such as water, housing, education, and food. Thus, the right to health includes the minimum core services, such as maternal–child health and primary health care, that governments must provide, even in places of scarce resources. While other rights may encapsulate the essence of a right to health, the challenge remains as to how the right to health may be fulfilled and measured. It is for this reason that some proponents believe a more constrained interpretation of the right to health allows for a more meaningful and representative invocation of this right (Tasiouslas & Vayena, 2015).

As part of the application of human rights principles to global public health challenges, public health strategies, such as prevention and treatment programs, must not infringe upon the human rights of those whom they are intended to benefit (**EXHIBIT 3-3**). Similarly, rights-based approaches must ensure that all individuals, and particularly those who experience greater marginalization, stigma, and discrimination, enjoy equal access to services. All too often, however, discrimination and other human rights issues have been both a consequence of global health challenges and a societal cause of vulnerability to these conditions (Mann, 1997).

At least two misconceptions about human rights tend to complicate their application. The first is that often global health challenges are perceived as being part of the realm of "economic, social, and cultural rights" (such as the right to health care) as opposed to "civil and political rights," such as the right to free expression, association, and due process of law. In fact, many of the violations of human rights that most increase risk—imprisonment without due process, censorship of health information, and violence and discrimination against women as articulated in the International Covenant on Civil and Political Rights (United Nations, 1966) and most national constitutions—have direct public health implications (Beyrer, 2007b). The fact that these rights abuses worsen health outcomes underscores what has been called the "indivisibility" of human rights norms—the notion that civil and political rights and economic, social, and cultural rights are mutually reinforcing and derive from a single principle, the concept of fundamental human dignity.

A second, related misconception is that human rights impose undue constraints on state sovereignty and restrict the legislative branch of government in its efforts to give effect to the "will of the people" (usually the majority) and/or enact effective public health policy. In fact, human rights guarantees are almost always embodied in constitutions or international treaties that have been ratified by national legislatures, and are enforced by judges who are either elected or appointed by elected officials. Moreover, human rights guarantees can come with certain limitations, as long as these limitations can be shown to be necessary and proportionate to a legitimate policy objective. Human rights analysis involves identifying the rights infringement in question (usually by reference to a specific legal guarantee), and then balancing that infringement against

EXHIBIT 3-3 Zika, Human Rights, and Ethics

The most recent Zika virus outbreak, declared a Public Health Emergency of International Concern in February 2016, and its disproportionate concentration on women of childbearing age, is an example of systemic injustice and inequality in global health. Although many of the clinical manifestations and health sequelae of Zika infection are not all known, the recent outbreak highlights a global health problem with contemporaneous individual-, community-, and country-level dimensions and ineluctable social and ethical impacts.

Acquisition of Zika during the antenatal period has been associated with miscarriage, stillbirth, and neurologic malformations including congenital microcephaly. Infection may occur at any stage of pregnancy, raising a particular challenge for intervention and prevention. Evidence that the Zika virus may also be transmitted sexually has significant implications for women who live in a region with some of the most restrictive sexual and reproductive laws,[1] where approximately 56% of pregnancies are unplanned and gender-based violence is pervasive (Guttmacher Institute, 2017; Roa, 2016).

In the most affected region of Latin America, it is estimated that 23 million women have an unmet need for contraception and account for 75% of unintended pregnancies (Guttmacher Institute, 2017). As many as 95% of pregnancy terminations are performed in unsafe conditions, and a number of countries (including El Salvador, Chile, and Dominican Republic) criminalize abortion under any circumstance. In other countries, abortion may be allowable only in cases of rape or in the event of a significant risk to the mother's life but not in the event of fetal congenital anomalies, including those resulting from Zika infection. In these cases, some women have been legally compelled to carry a pregnancy of a possibly fatal fetal anomaly to full term.

Women living in marginalized and poor communities in Brazil and elsewhere faced the greatest disproportionate burden and deprivation of basic protections and rights and their ability to exercise reproductive autonomy (see also Rasanatham, MacCarthy, Diniz, Torreele, & Gruskin, 2017).[2] Discrimination, economic inequality, and poverty entrench both the risks and impacts of Zika (Phelan & Gostin, 2016).

In response to the outbreak, governments in the region recommended women of childbearing age postpone pregnancy, but few provisions or pathways to avoid an unintended pregnancy were made available, shifting the burden from the domain of the public to the individual. Restrictions on access to contraception, including emergency contraception, safe termination, and post-abortion care, predominated.

Questions have emerged in cases regarding whether the intrusion of the state in the life and decisions of a woman is justifiable and proportional. Is the global public health threat of Zika severe enough to limit sexual and reproductive rights and freedoms? Conversely, is the threat of Zika-associated fetal anomalies sufficient to change existing restrictive laws and policies? There is a moral imperative to create conditions that allow women to decide freely and responsibly on the number, spacing, and timing of their children. Similarly, there is an ethical obligation to ensure equitable access to contraceptive options and safe reproductive services, as well as a duty to minimize harms associated with a Zika-affected pregnancy. However, as the case of Zika succinctly illustrates, to achieve the most optimal outcome, employing ethical principles requires a balancing of interests and context.

1 International human rights documents pertaining to women's reproductive health rights include the International Covenant on Economic, Social, and Cultural Rights [right to health, Article 12; right to nondiscrimination based on sex, Articles 2(2) and 3; right to special protection for mothers and their children, Article 10] and the Convention on the Elimination of All Forms of Discrimination Against Women (women's right to nondiscrimination within law, Articles 2 and 3; right to health, Article 12; and right to reproductive self-determination, Article 16).

2 Laid out by the Committee on Economic, Social, and Cultural Rights, the right to sexual and reproductive health includes both freedoms and entitlements, including the freedom to make free and responsible decision and choices, free of violence, coercion, and discrimination, over matters concerning one's body and sexual and reproductive health (Diniz, 2016).

competing policy objectives. Most importantly, perhaps, human rights aim to give voice to minorities who may be marginalized or disenfranchised by the democratic process (Decker et al., 2015).

Rights-Based Approach to Global Health

> Social justice and the protection of human rights do not ensure good health—free people can make poor choices, and affluence carries its own burdens of morbidity and mortality. But social justice and limitations on basic rights and freedoms, on human dignity itself, can have direct and indirect effects on the health of individuals, communities, and populations. (Beyrer, 2007a)

Jonathan Mann, a public health physician, was an early proponent of the integration of medicine, public health, ethics, and human rights (Gostin, 2001). He believed that health and human rights were indistinguishable.

Human rights violations lead to adverse health events and, therefore, have measurable impacts on physical and mental well-being (Gostin, 2001). Similarly, framing health disparities as a violation of human rights facilitates a more useful interpretation and implementation of the human rights instruments. The progressive realization of the right to health at a global level gives emphasis to the shared responsibility and obligations of the global community.

Mann's legacy has grown and expanded since his tragic early death in 1998. The field of health and human rights, and of public health or global health and rights, has made critical contributions to our understanding of health inequalities, disparities, and the social and structural determinants of health that have proved so challenging to address through technological or biomedical advances alone.

Global Health and Public Health Ethics

Public health ethics uses ethics principles and norms to identify, analyze, and resolve moral challenges in public health. As described earlier, when public health ethics focuses its lens on global public health challenges, it might be examining issues that extend beyond the boundaries of the state, such as pandemics, or global issues that recur within territories' or countries' own borders.

Public health ethics has largely concentrated its attention around two main areas: (1) balancing individual liberties with the ethical duty to improve the welfare of the public and the needs of many and (2) the moral duty to improve social justice as a means of improving the public's health. As such, public health ethics is concerned with the pursuit of equity in health, which then guides the approach taken to remedy the inherently unjust health inequalities. Further, public health ethics seeks to determine how to best balance the needs of a population as a whole and the liberties and rights of the individuals who make up those populations. An oft-cited example is the case in which the state executes its agency through a public health intervention to restrict individual choice, privacy, or freedom of movement in an effort to prevent or contain disease as a means to protect others in the community or to limit suffering.

The greater the burden imposed by a public health intervention or program (e.g., limitations on individual liberties), the stronger the evidence must be to demonstrate that it will achieve its goals (Kass, 2001). Hence, a restriction of liberty must be justified and proportionate to the perceived or known threat. Public health goals of producing benefits, preventing harms, and generating utility may outweigh or override moral considerations of individual liberty and justice when certain justificatory conditions of effectiveness, necessity, least infringement, and proportionality are met (Childress, Faden, Gaare, & Gostin, 2002). In instances when the benefits and burden are uneven, the expected benefit must be even greater (Kass, 2001).

Public health ethics is somewhat distinct from medical ethics. The latter has notably deeper historical roots. Medical ethics provides a set of principles to help guide physicians through moral challenges in the practice of medicine, including those that may arise between physician and patient. Tom Beauchamp and James Childress (2013) have outlined four ethical principles to guide medicine:

1. *Principle of respect for autonomy*—that is, values and loyalties are determined freely and voluntarily without coercion (e.g., informed consent).
2. *Principle of nonmaleficence*, which implies minimization of harm or injury.
3. *Principle of beneficence*, which refers to doing good by acting with the best interest of the other in mind. It implies a duty to balance benefits and harms and ensuring that benefits outweigh harms.
4. *Principle of justice*, which concerns fairness and distribution of common goods fairly. Thus, when goods or resources are limited, a means for fair distribution must be determined such that "those persons who are equal should qualify for equal treatment."

These principles are intended as nonhierarchical, such that no one principle is superior to another and each principle is considered *prima facie*.

While many frameworks for medical ethics have been put forward, frameworks for the ethics of *public health* work are a more recent contribution. While the foundations of both public health and medical ethics are similar, they also differ in some critical ways. Most notably, while both require the provision of benefit and the minimization of harm, public health targets this requirement to communities as a whole, and measures benefit the entire society. Medical ethics, by contrast, is more likely to focus exclusively on the well-being of individuals. Furthermore, public health is afforded legal authority in many environments to ensure that the *public's* health is improved and/or not threatened and, at times, can use invasive measures, as needed,

ranging from medical isolation and quarantine to mandatory hospitalization, as seen in multiresistant tuberculosis and extensively drug-resistant tuberculosis (XDR-TB), to secure that goal. Public health ethics, then, provides a framework for balancing the important and core value of public or societal benefit with restraint to ensure that individual rights and values are neither ignored nor compromised whenever possible. Public health ethics also puts emphasis on justice and equity, both as predictors of good public health outcomes and as a moral good for their own sake.

Public health ethics shares many core values with human rights but, again, is different in some critical ways. Public health ethics, at its core, is concerned with ensuring that public health interventions provide benefits and minimize harms; that they respect individuals' dignity and rights to the greatest extent possible; and that they are implemented fairly and, to a great degree, serve to increase equity. These values are completely consistent with those of human rights covenants and paradigms. Unlike human rights, however, ethics is not founded in law. While ethical norms may contribute the rationale for many laws, ethics itself has no legal standing, and "moral rightness" is not legally enforceable.

Appealing to ethics in crafting and implementing public health interventions nonetheless is critical for three reasons. First, engaging in morally right action is important in and of itself. That interactions, including interactions related to public health, ought to be implemented consistent with the highest ethical standards is itself an important end. Civil societies, by definition, are bounded by shared moral norms and practices (as well as by more formal laws and regulations), and those who are in leadership positions should uphold them.

Second, professional ethics requires a commitment to engaging *in one's work* in ways that are consistent with high ethical standards. Most of the established health professions, including medicine and nursing, have longstanding codes of professional ethics; public health more recently adopted its own code of ethics for public health professionals. Such professional codes help to self-regulate a profession (**EXHIBIT 3-4**). Acting in accordance with moral norms and codes is important to the integrity and trustworthiness of the professionals who practice public health and doing so also serves to instill trust in the profession on the part of the public.

EXHIBIT 3-4 Global Health, Ethics, and Research

Health research in low- and middle-income countries (LMICs), in pursuit of global health outcomes, raises complex ethical challenges. Research in such countries is vital to advancing knowledge on preventable disease, infectious disease epidemics, and treatments that have a global reach. However, ethical guidelines and regulations may be vastly inconsistent across different country settings due to limitations of capacity and infrastructure. Maintaining sound ethical guidelines in these settings is considered critical to safeguard against potential exploitation of research participants.

Amon et al. (2012) highlight the challenges that arise when investigating human rights violations as determinants of, or structural barriers to, health, and in particular when engaging with marginalized, stigmatized, and criminalized populations, especially when they face a disproportionate burden of ill health as a result of their social status. Amon et al. relate the experience of agency in health-based research in more repressive countries where a research ethics committee functions as an agent of the state, protecting state interests rather than legitimately representing, or protecting, the interests of vulnerable groups and research participants. This kind of environment can prevent health researchers from investigating health outcomes associated with state actors, government laws and policies, and social and cultural norms.

Other issues relate to consent in emergency settings and access to data, interventions, and treatments for the target population when research is complete. An example of the latter arose during HIV perinatal trials in the late 1990s when more inferior interventions, compared to the standard best available treatment, were employed (IJsselmuiden, Kass, Sewankambo, & Lavery, 2010). In this case, debate arose over whether use of an inferior regimen, considered more logistically or economically feasible to distribute and contributing to overall public health gains in a resource-constrained setting, should have precedence over the gold-standard intervention even though it would reach fewer people (IJsselmuiden et al., 2010).

Further examination of this trend was undertaken in a report by the Commission on Health Research for Development, which describes the vast differential between global health needs and global health research. In what is referred to as the 10/90 gap, less than 10% of global resources targeting global health research are allocated to health in low-income countries, which account for more than 90% of the global burden of preventable deaths, included neglected diseases such as Chagas disease, leishmaniasis, and human African trypanosomiasis. Conflict and political or social instability can also have profound effects on health interventions and epidemiologic surveillance efforts through disruption of health data collection and information systems, compromising the quality and sampling of core data.

(continues)

EXHIBIT 3-4 Global Health, Ethics, and Research *(continued)*

The Nuremberg Code formalized the ethical standards and principles for the conduct of medical ethics, particularly in research involving human participants. Formulated in 1947 in Nuremberg, Germany, following revelation of the murderous and tortuous conduct of Nazi doctors in World War II concentration camps, it serves as a blueprint for the rights of subjects in medical research (Shuster, 1997). The Nuremberg Code delineates core principles critical to clinical research, which are also broadly applicable to nonresearch contexts. These principles include informed voluntary consent given freely, without coercion, duress, or force, as well as the right for withdrawal, thereby extending the ethic to "first, do no harm" and protecting the rights of the individual. Article 7 of the International Covenant on Civil and Political Rights (United Nations, 1966) articulates this requirement by stating: "No one shall be subjected to torture or to cruel, inhuman or degrading treatment or punishment. In particular, no one shall be subjected with his free consent to medical or scientific experimentation."

A second foundational document concerning ethics is the Declaration of Helsinki. Introduced in 1964 and revised in 1975 by the World Medical Association, it outlines standards and protocols of research, including the requirement that the proposed research be reviewed by an independent research ethics committee. In 1979, the U.S. Department of Health and Human Services' Belmont Report provided further moral guidance by reiterating principles of respect for persons, beneficence, and justice as part of conduct of research using human subjects. These significant contributions continue to govern approaches to medical ethics and health research in humans. Research ethics committees are considered a widely accepted and fundamental component of conducting health-based research involving systematic collection of data and analysis of data on humans.

Third, as a means to an end, good ethics makes good public health sense. Ethics asks public health to ensure programs will be beneficial before imposing them on the public. It requires that individuals and communities be treated with dignity, and it requires that *all* communities receive appropriate public health interventions, not just those with more privilege or influence. Upholding these moral norms is relevant not just for their own sake: They make obvious sense for public health. Such principles help to ensure that more people get health benefit and that the "targets" of public health programs will better trust that such programs are initiated to further their own interests rather than to further some arbitrary goal on behalf of the state's leaders. Promotion of health equity has been shown though countless studies to improve the public's health. And where public health actions *do* need to infringe on civil liberties, such as in enforcing immunization requirements for public schools, it is critically important that targeted populations perceive that these programs are fair, that they are based in sound science, and that the privileged (by resources or power) are not exempted from the programs (Beyrer, 2004).

Several approaches to considering ethics in public health proposals have been put forward. One six-step approach is offered here (Kass, 2001).

Step 1. What are the public health goals for the proposed intervention, policy, or program? These goals generally should be expressed in terms of public health improvement, such as the degree to which the program will reduce morbidity or mortality. For example, a human immunodeficiency virus (HIV) screening program should have as its ultimate goal that fewer incident cases of HIV will occur, rather than that a certain proportion of individuals will agree to be tested.

Also relevant when considering public health goals and benefits is to whom the benefit will accrue. Public health interventions often are targeted to one set of individuals so as to protect *other* citizens' health. For example, partner notification programs and directly observed therapy for tuberculosis are designed, primarily, to protect citizens from the health threats posed by others. Restricting someone's liberty to protect that person—generally framed as paternalism—poses different ethical burdens than restricting liberty to protect the interests of others.

Step 2. How effective is the intervention or proposed program at achieving its stated goals? Proposed interventions or programs are based on certain assumptions that lead us to believe the programs will achieve their stated goals. Step 2 asks us whether actual *data* exist to support these assumptions. In general, the greater the burdens posed by a program—for example, in terms of cost, constraints on liberty, or targeting particular, already vulnerable segments of the population—the stronger the evidence must be to demonstrate program effectiveness. Indeed, because many public health programs are imposed on people by governments and not sought out by those targeted by the programs, the burden of proof lies with governments or public health practitioners to prove that a program will achieve its goals. If there are no good data to demonstrate program effectiveness, the analysis can stop right here, and, ethically, the program should not be implemented. Conversely, the presence of good data alone does not justify the program; it

simply allows public health practitioners to move to the next stage of the analysis.

Step 3. What are the known or potential burdens of the program? If data suggest that a program is reasonably likely to achieve its stated goals, the potential burdens or harms that could result from the public health work must be identified. The majority of such harms will fall into four broad categories: (1) risks to privacy and confidentiality, especially in data collection activities; (2) risks to liberty and self-determination, given the power accorded public health to enact almost any measure necessary to contain disease; (3) risks to health, if public health interventions carry some risk to the individuals affected; and (4) risks to justice, if public health practitioners propose targeting public health interventions only to certain groups. Data collection may not simply be viewed as a violation of personal privacy to individuals; breach of confidentiality of such data—deliberate or incidental—can lead to significant and tangible harms. Personal health information, such as that related to HIV status or sexual orientation and/or gender identity, can be dangerous in certain settings, if obtained by authorities and/or social acquaintances; even seemingly benign data such as vital statistics can reveal patterns about ethnic groups or neighborhoods that could lead to stigma, discrimination, violence, and/or forced relocation of identifiable groups.

Health education generally is thought of as the ideal public health intervention because it is completely voluntary and seeks to empower individuals to make their own decisions regarding their health. Unfortunately, education may not be effective in all settings. When it fails to meet the state's expectations, policy makers may feel the need to resort to more restrictive measures.

Regulations and legislation, strictly speaking, are coercive, since they impose penalties for noncompliance. As such, they pose risks to liberty and self-governance. While many such measures (e.g., mandatory immunizations) have demonstrated efficacy, they nonetheless are the most intrusive approach to public health. Certain mandated interventions, such as immunization or mass deworming campaigns, are implemented only when the population benefit is considerably larger than the risk to individuals, yet ethics tensions remain when even very small risks are created for healthy individuals because of public health campaigns. Further, the law can impose threats to justice if regulations pose an undue burden on particular segments of society, and the law can be designed in ways to reduce inequalities as well.

Step 4. How can burdens be minimized? Is the least burdensome approach being implemented? Once burdens have been identified, ethics requires programs to be modified in ways that minimize burdens without greatly reducing efficacy. If disease surveillance is equally effective with unique identifiers as with names, if voluntary programs yield almost identical cooperation and effectiveness as mandatory ones, or if individuals can be informed in advance about why interventions are being introduced, then these "burden-reducing" approaches should be taken.

Step 5. Is the program implemented fairly? Consistent with the principle of distributive justice, there must be a fair distribution of benefits and burdens in public health programs. Public health benefits such as clean water cannot be limited to one community alone, and equitable treatment is similarly required when restrictive measures are proposed. Injustice is wrong not just for its own sake, but for the material harms that can follow. This does not mean that programs or resources must be allocated equally or identically to all communities; rather, allocations must be *fair*. That is, differences cannot be proposed arbitrarily or based on historical assumptions about who might be at risk or who is more responsible. Instead, targeting of programs to one community and not another must be justified with strong attention to data. Moreover, the social consequences must be considered when targeting of programs occurs, and balanced against the benefits to that community or others. Also central is the role that public health can play in righting existing injustices, especially given the strong link between social inequities and poor health outcomes (Starfield, 2005). Several conceptions of justice allow and even require unequal allocation of benefits to remedy existing inequities (Daniels, 1985; Rawls, 1971).

Step 6. How can the public health benefits and the accompanying burdens be balanced? Even to the extent that public health professionals aim to follow the previously described requirements, disagreements invariably will emerge over interpretation—which types of freedoms must prevail, which types of burdens are acceptable, and which types of targeting are unjustified? Procedural justice, then, requires fair procedures to determine which public health interventions, in the end, should go forward. This process will require communities to discuss what is gained from good public health, and why such benefits often must be organized collectively. Dissent around proposed programs or interventions deserves special attention if raised by an identified subgroup, such as an ethnic minority, particular age group, or residents of a particular region. In general, the greater the burden imposed by a program, the greater must be the expected public health benefit. Likewise, the more uneven the benefits and burdens—that is, when one group is burdened to protect the health of others—the former must be both the scientific justification and the expected benefit.

Case Studies in Global Health, Human Rights, and Ethics

Obesity and Taxation on Sugar-Sweetened Beverages

Obesity and its associated conditions represent an epidemic of global proportions that does not discriminate by gender or socioeconomic status. While the rate of obesity is increasing globally, the absolute rates of its occurrence are higher with low income and low education. Most of the world's population now lives in countries where there are more deaths attributable to being overweight than underweight (Basu, McKee, Galea, & Stuckler, 2013; see also Development Initiatives, 2017).

The etiology of obesity is complex, with this condition resulting from an interplay of genetic, biological, environmental, sociopolitical, and behavioral factors (Malik, Pan, Willet, & Hu, 2013). Yet the rapid change in obesity rates globally suggests that the primary factors are environmental and behavioral rather than due to genetics, as the human genome could not have changed so rapidly. Traditional obesity prevention strategies, which have targeted individual behavior change, have yielded limited success. In more recent years, there has been growing interest in taking more of a public health approach to obesity, by intervening in the food environments in which people make their food consumption choices. Interventions related to the food environment can include changes in the production, availability, regulation, cost, and marketing of food and beverages.

One component of diet significantly implicated in the overweight and obesity epidemic globally is the high intake of dietary free sugars and, more specifically, the consumption of sugar-sweetened beverages (SSBs) (Brownell et al., 2009; Colagiuri, 2017). In the United States, for example, SSBs are the single largest contributor to adults' and children's daily caloric intake (Bleich, Wang, Wang, & Gortmaker, 2009), and increased consumption of SSBs has been associated with increased prevalence of obesity, cardiovascular disease, and diabetes (Brownell et al., 2009; Malik et al., 2013; Schulze et al., 2004; Te Morenga, Mallard, & Mann, 2013). In the United States, consumption of energy-dense foods in the form of sugary beverages accounts for almost half of the total daily intake of added sugar (Malik et al., 2013; see also Colagiuri, 2017). It has been estimated that 8.5 million disability-adjusted life years (DALYs) are related to SSB intake. The proportional mortality due to SSBs is highest among younger adults, with this factor contributing to more than 1 in 10 of all diabetes- and obesity-related deaths in nearly every region of the world; in Mexico, 30% of deaths in those younger than age 45 years are attributed to SSB consumption (Singh et al., 2015). Restriction or elimination of sugary beverages has been associated with positive changes in body weight. Sugar-sweetened beverages are less satiating, have a high caloric load, and are nutritionally deplete.

There is also compelling recent evidence that the food industry colluded with scientists in the 1960s and 1970s, when evidence began to appear on the harmful effects of sugar consumption, to focus on the purported harmful effects of dietary fat, rather than sugar (O'Connor, 2016). In a situation strikingly reminiscent of the tobacco industry's tactics, the sugar, corn-producing, and soft drink industries sought to avoid regulation of their products even as evidence of their harms emerged (Kearns, Schmidt, & Glantz, 2016). For example, industry-supported scientists at Harvard University, in a 1965 paper in the *New England Journal of Medicine*, deliberately underplayed the role of sugar in coronary artery disease, instead focusing their attention on the harms associated with fat and cholesterol (Kearns et al., 2016).

Public health efforts targeting obesity have traditionally relied on health education about good nutrition (including, for example, requirements for food labeling and public awareness of the "food pyramid" or "food plate"); individual-oriented strategies are underscored by the fact that the diet industry is a $60 billion business in the United States (Kass, Hecht, Paul, & Birnbach, 2014). In proposing public policy related to the food environment—whether related to marketing, pricing, taxation, or other influences—one must consider the ethical ramifications of alternative approaches and then choose the strategy that will yield the desired results while simultaneously posing the fewest threats to other ethically important values (Kass et al., 2014).

An ethics analysis of alternative policy options must first start by determining what the public health *goal* of a proposed policy is—for example, to decrease population obesity, rather than to reduce SSB consumption, which might simply lead to substitution with an equally harmful beverage. Second, one must determine how much evidence there is that the proposed policy will actually result in the intended public health benefit. Third, public health programs should constrain liberties as little as possible, and minimize the risk of other important harms or burdens. The fourth requirement is a justice consideration, requiring

interventions to avoid disproportionately burdening a particular population without important justification and to aim to, at least in part, reduce disparities in the population. Fifth, the introduction of a policy must follow fair procedures and should be accompanied by accountability measures. Finally, the symbolic relevance of public institutions must be preserved.

One public health intervention that has garnered particular attention as a response to the burgeoning obesity epidemic is taxation of SSBs—an approach that has been implemented in several cities in the United States and also in Mexico. Taxation is a form of public policy that allows governments to exert mild influence over products or practices they wish to encourage or discourage. For example, some jurisdictions have chosen to allow cigarettes and alcohol to remain completely legal, but have imposed higher levels of tax than the typical sales tax to provide a disincentive for their purchase (Kass et al., 2014).

One of the main ethical critiques of the SSB tax has been a liberty-based one: This view states that taxation is government overreach, and that individuals should be able to consume what they want and make their own choices. A second critique is a justice-based one, rightly citing that sales taxes are regressive, meaning that the impact on lower-income individuals is proportionally higher if they choose to buy SSBs than it is on wealthier individuals.

An ethics analysis would go deeper than these arguments, asking whether progressive taxation is required for products where there is not a government (public health) interest in ensuring access, and then asking which types of liberties governments are required to preserve. Most central to the answer would be the fundamental human rights—rights to freedom of religion, press, whom to love, and speech are most essential for governments to preserve. Claiming that there is a "liberty interest" in being able to buy and consume unhealthy products is not entirely irrelevant—the ability to pursue pleasurable activities is certainly important—but when the liberty is so deeply distant from the fundamental rights and liberties that must be preserved, more room for compromise is absolutely allowable. Indeed, the ability to still allow free access to SSBs while simply providing a financial disincentive for their purchase, similar to that instituted in many regions for cigarettes, is increasingly being viewed as both an ethically acceptable strategy and one with public policy acceptability.

While these critiques are important, an ethics analysis must go beyond claiming that there is a liberty infringement in taxing SSBs. Although a central responsibility of government is to protect foundational liberties from unwarranted intervention, it does not necessarily follow that fundamental liberties are threatened when public policy discourages consumption of unhealthy products or prohibits government spending on them (Kass et al., 2014). Also, and less often discussed in the context of liberty and taxation, too little state intervention in improving population health can violate individuals' right, just as too much can (Wilson, 2016). Limitations on health can threaten individuals' ability to pursue their life course and independent priorities. While SSBs remain widely available on the market, the intent of a tax is to act as a disincentive, rather than to prohibit their use outright. The personal pleasure to be derived from consumption of SSBs is absolutely worthy of consideration, yet such pleasure does not rise to the level of a fundamental freedom (Kass et al., 2014).

Invoking the right to health, and the concomitant obligations laid out in human rights frameworks, brings the protective function of the state and its role in obesity prevention through taxation of SSBs into sharp focus. Under the human rights provisions, states must take steps to enable full realization of the right to achieve the highest attainable standard of health. The state violates individuals' rights if it fails to take cost-effective and proportionate measures to remove health threats from the environment. For example, the right to adequate food implies enabling food security through access to nutritionally dense foods, responsible food labeling and appropriate food regulation, and a particular emphasis on advertising and marketing of foods and beverages to children and to schools. High intake of SSBs among the food-insecure and low-income populations is an important consideration, especially given that nutrient-dense foods are often more difficult to access or cost prohibitive for these populations.

HIV/AIDS

The HIV/AIDS pandemic remains one of the greatest challenges to human health, with more than 70 million being infected with the virus, and more than 35 million deaths due to AIDS-related causes having occurred by the end of 2016 (Joint United Nations Programme on HIV/AIDS, 2017). Since its inception, the HIV pandemic has been different from the pandemics of influenza, smallpox, or polio; all of those diseases were greatly feared, yet none generated the kinds of social opprobrium against the infected individuals that the HIV pandemic has so regularly created (Cohen et al., 2007). The scale of the HIV pandemic—and the stigma, discrimination, and violence that surrounded

its sudden emergence—catalyzed a public health response that expanded human rights in principle and practice and ignited ethical debates.

While the prospect of a cure and a preventive vaccine remain elusive, comprehensive and combination treatment/preventive programs have proved to be critical interventions to mitigate the impact of HIV infection and reduce HIV incidence in many settings and populations. Despite these advances, a large majority of individuals living with HIV or at risk of HIV still do not have access to prevention, treatment, and care and are unaware of their HIV status (Joint United Nations Programme on HIV/AIDS, 2017; WHO, 2014). The vast majority of people unable to access treatment reside in low- or middle-income countries and communities. In key affected populations,[3] identified as people who have both higher likelihood of HIV infection and greater risk of being excluded form essential HIV services, HIV incidence continues to rise, even as incidence stabilizes or declines in the general population (WHO, 2014). Outside of sub-Saharan Africa, 80% of all new HIV infections among adults occur among people from key populations and their immediate sexual partners (Joint United Nations Programme on HIV/AIDS, 2017).

Key populations, collectively at the global level, are disproportionately affected as a result of the additional social and structural factors that increase their vulnerability. Stigma is recognized as a powerful social determinant of health and a key driver of health disparities in vulnerable groups (Poteat et al., 2015). In many instances, this vulnerability increases when individuals are unable to realize their rights and face stigma, exclusion, harassment, and violence as a result of both their HIV status and their membership in a key population. When stigma and discrimination in healthcare settings are both overt and hidden, they may lead to delayed HIV testing, concealment of positive serostatus, and poor uptake of HIV services (Fay et al., 2011).

In 2017, 78 countries had repressive laws criminalizing homosexuality or propaganda of homosexuality; in 13 of these countries (e.g., Sudan, Iran, Nigeria, Somalia), homosexual acts are punishable by death (Carroll, 2016). In an overwhelming number of countries that criminalize homosexuality, HIV prevalence is at the highest levels, although the absence of such laws in other countries does not necessarily mean they have lower rates of HIV. Criminalization sanctions and reinforces existing prejudices and legitimizes violence; in practical terms, it translates into increased barriers to equitable access to essential services and treatment. Enforcement of antidiscrimination and protection laws invokes core human rights standards and is a key component toward advancing the health of the most vulnerable. Protecting the human rights of the most vulnerable populations necessarily includes efforts to decriminalize sexual behaviors, recognize diverse gender expression and identity, and provide inclusive and sensitized services.

Against this background, this section will explore in detail the human rights and ethical dimensions of the global health challenge that is HIV. The focus will be on two public health approaches that have defined the response: (1) HIV prevention and (2) equity of and access to HIV treatment. The use of human rights and ethics tools applied to the HIV context highlights the integrative and complementary nature of these perspectives, as well as important differences between them.

Prevention

From early on in the pandemic, tension between individual human rights and the role of the state as duty bearer drove the response. Prominence was given to individual human rights, with a focus on risk, behavior change, and agency through campaigns on access to care, information, HIV testing and counseling, and use of condoms. However, population-based policies, such as universal access to condoms and needle syringe programs, that prioritized access to prevention tools were often selectively implemented in different countries, leaving large networks within many populations at significant risk and lacking the basics of HIV prevention services.

The emergence of newer preventive paradigms, including treatment as prevention, has reframed prevention efforts to have an increased focus on the integration of individual rights into collective public health policies. Strategies such as preventing mother-to-child transmission, harm reduction, pre-exposure prophylaxis (PrEP), post-exposure prophylaxis (PEP), prevention of violence and decriminalization, and provision of opiate substitution medication for people who inject opiates have had a profound impact by stemming the acquisition and transmission of HIV. To further explore HIV prevention and the application of human rights and ethics frameworks, the section that follows highlights two examples: Harm reduction and treatment as prevention.

3 Key affected populations are defined as people who have been identified as belonging to population groups most at risk of HIV. They include men who have sex with men (MSM), transgender people, people who inject drugs, and sex workers. Vulnerability extends to groups of people who have an increased susceptibility to HIV infection as a result of their specific circumstance or context—for example, adolescents, people in closed settings, orphans, street children, and migrant and mobile workers.

People who inject drugs are at risk of HIV and other blood-borne viral infections, including hepatitis B and C, through sharing of contaminated, nonsterile syringes and injecting equipment. Globally, 123 countries—that is, 78% of the total 158 countries that report data on injecting drug use—attribute cases of HIV to injecting drug use (WHO, 2014). In 2012, it was estimated that approximately 12.7 million (range: 8.9–22.4 million) people on a worldwide basis had recently injected drugs; of those, 1.7 million people (13.1%) were living with HIV. Data from 49 countries show that the risk of HIV infection was, on average, 22 times greater among people who inject drugs than among the general population (WHO, 2014).

Injecting-drug users endure institutionalized vulnerabilities as a result of arbitrary deprivation of rights in the form of mandatory testing, inadequately targeted services, social marginalization, and punitive measures to contain drug dependence through arrest and imprisonment. Indeed, the most elemental concerns of the human rights agenda are also the determinants of the health outcomes for injecting-drug users, who face the prospects of incarceration, violence, stigmatization, isolation, and discrimination (Wolfe & Cohen, 2010). As Wolfe and Cohen (2010) note, core principles of human rights—including liberty and security of the person, autonomy, privacy, and freedom from cruel, inhuman, or degrading treatment—are vital components of effective health programs for this population group.

In the few countries that do not criminalize drug use, political and legal barriers prevent access to prevention without discrimination, and to justice such as freedom from arbitrary arrest and detention (WHO, 2014; Wolfe & Cohen, 2010). Examples can be cited of compulsory treatment centers, ostensibly used to rehabilitate or detoxify, that hold people without charge, right of appeal, or evaluation by a health professional, addiction specialist, or psychiatric specialist. In other cases, individual liberty has been usurped by law enforcement as a means of containment, further impeding universal access and public health efforts. Interned in prisons, injecting-drug users may be exposed to infectious diseases, violence, overcrowding, and high-risk behaviors. Access to key treatments, such as antiretroviral therapy, may also be limited due to ingrained stigma and perceptions of instability that may jeopardize adherence. A more recent and pressing example is the "war on drugs" in the Philippines, which highlights the difficulty of globalizing ethical, moral, and evidence-based public health interventions in highly criminalized settings where extrajudicial killings are being actively encouraged and enjoy broad popularity in the populace. This generates a broader discussion of how human rights and ethics may be applied in these settings.

Treatment as Prevention

Results of a landmark clinical trial in 2011 demonstrated that early treatment of the HIV-infected partner in sero-discordant couples with antiretroviral therapy provides durable and reliable protection against sexual transmission to the uninfected partner. This intervention was found to 96% effective in decreasing the risk of HIV acquisition (Cohen et al., 2011). This trial, named HIV Prevention Trials Network (HPTN) 052, supported the use of medical therapy as a public health prevention strategy, thereby changing the landscape for HIV prevention.

These findings have been further supported by the landmark "Opposites Attract" study of HIV sero-discordant male same-sex couples, led by Andrew Grulich and colleagues, which showed that men living with HIV and virally suppressed had no documented HIV transmission to uninfected partners despite low use of condoms (Bavinton et al., 2014). The study findings suggest that when treatment as prevention is at its most optimal, an HIV-positive individual with an undetectable viral load has a negligible risk of transmission.

This situation changes issues of disclosure and raises questions about whether there remains a moral requirement to disclose HIV status if all reasonable attempts to reduce risk are taken. Similarly, if the viral load levels are undetectable to the extent that the risk of transmission is practically negligible, is there an obligation to disclose (Haire & Kaldor, 2015)? Indeed, the question may be whether the obligation to prevent viral transmission lies solely with the individual who is infected, or whether all parties have a collective responsibility to protect and prevent this disease (Sugarman, 2013). Is it morally wrong to situate the health of an infected person as secondary to the public health benefits of a suppressed viral load, particularly when the treatment may carry side effects or toxicities (Haire & Kaldor, 2015)?

Additional issues arise for key population groups. Despite the evidence, in a number of instances, trials and rollouts of this strategy are being hampered in countries where repressive laws exist and criminalization of homosexuality is pervasive and, in some cases, where there has been an expansion of the HIV epidemic in many MSM populations (Beyrer et al., 2016). Treatment as prevention has been demonstrated to have limited utility in other key population groups,

such as people who inject drugs, particularly in circumstances where other interventions such as oral substitution therapy are unavailable.

Treatment: Equity and Access

The emergence of treatment options was a critical turning point in the HIV response, with dramatic reductions in morbidity and mortality following in their wake. The potential benefits of earlier initiation of therapy far outweigh the potential risks of increased exposure to drug toxicity and emergence of viral resistance in the setting of suboptimal adherence.

Universal access to medicine has the promise to deliver much-needed treatment to those most at need and to extend life expectancy. Nevertheless, identifying those who are infected shortly after acquisition and initiating treatment remain a challenge to the arresting the epidemic. Treatment is reliant on individuals knowing their status and having access to noncoercive testing.

In 2016, WHO released consolidated guidelines recommending that all people living with HIV be provided with antiretroviral therapy, removing limitations on eligibility for HIV-positive individuals. Expanded access to treatment resonates with the 90-90-90 targets—that 90% of people living with HIV have knowledge of their HIV status, 90% of people who know their status have access to and receive ART, and 90% of people who receive ART have suppressed viral loads. Despite this concordance, even the most ambitious targets for expanding access to antiretroviral therapy recognize that many people in need of treatment will not receive it. Utilitarian arguments as applied to access to medicines promote an ethics of resignation and the observance that resource scarcity is accepted as inevitable, and the pressure to identify and address inequality is diminished by the dissemination of those scarce resources within a population (Smith, 2016). Populations and groups who have been systematically excluded and disenfranchised from treatment programs, such as migrants and ethnic minorities, and stigmatized groups including sex workers, injection-drug users, prisoners, and sexual and gender minorities, continue to face difficulty in obtaining treatment access. The issue of equity in treatment access is complicated by the fact that in some countries, the overwhelming majority of people in need of treatment come from politically marginalized or vulnerable groups. Perhaps the clearest example of this is injection-drug users, who are consistently under-represented in national treatment programs despite accounting for the overwhelming majority of people in need of treatment in many countries. The reason for such under-representation in treatment access may be an underlying pattern of human rights abuse that renders certain populations less able to obtain basic health care.

Under human rights law, the guiding principle for equitable access to antiretroviral treatment is that of nondiscrimination and equality under the law. This principle accepts that governments have difficult choices to make and that not every "social good" can be made universally available. Undertaking a commitment to do the greatest good for the greatest number of people may be at odds with treatment paradigms. Expanding access to medicines that are known to be less efficacious or carry a greater toxicity profile, but that are inexpensive and, therefore, can reach a greater number of people, including those who may otherwise not have access to treatment, may be more beneficial or preferable than provision of the gold-standard treatment in all settings, with the understanding that this resource may be finite and available to fewer people (Persad & Emanuel, 2016). The former option challenges the idea that refusal to offer treatment, if deemed substandard or potentially more harmful, overemphasizes nonmaleficence to the extent that it is a dereliction of duty (Persad & Emanuel, 2016). The latter position reinforces the notion that equal access to the best available treatment for all people should be the primary goal (Smith, 2016).

In international covenants, governments are generally prohibited from intentionally or unintentionally denying social benefits to individuals on the basis of, among other things, race, sex, national or ethnic origin, religion, and political viewpoint. Sometimes such denial will be justified, as when pregnant women are given preference for treatment to prevent HIV transmission from parent to child. Nevertheless, such decisions should never be based on unfounded or stereotypical assumptions about marginalized groups—such as the assumption that injection-drug users should not qualify for treatment programs because they are "noncompliant" or incapable of adhering to a treatment regimen. In the case of antiretroviral treatment, their eligibility should be based on clinically relevant criteria and, beyond that, on criteria that are justified in the circumstances and that do not offend human dignity (**EXHIBIT 3-5**).

The procedures by which these criteria for treatment access are set should likewise be subject to both human rights and ethics standards. International human rights law recognizes the "right to participate," which should include a positive obligation on governments to solicit the views of affected populations in formulating public policy (International Covenant on Civil and Political Rights, 1966). More urgently,

EXHIBIT 3-5 Test and Treat

While it has been estimated that 53% of all people diagnosed with HIV are on antiretroviral therapy (Joint United Nations Programme on HIV/AIDS, 2017), approximately 30% of people living with HIV at a global level remain undiagnosed and unaware of their seropositive status (WHO, 2017). In resource-poor settings, roughly half (19.5 million) of those individuals eligible for treatment are receiving treatment (Joint United Nations Programme on HIV/AIDS, 2017). The evidence consistently shows that stigma and discrimination in healthcare settings are both overt and hidden, leading to delayed HIV testing, concealment of positive serostatus, and poor uptake of HIV services.

"Test and treat" is a strategy that universalizes voluntary counseling and testing and offers immediate treatment to individuals who test positive, irrespective of clinical stage or CD4 count. It is premised on the notion that if individuals are made aware of their status, they will access treatment and alter high-risk behaviors.

Test and treat is a proven intervention in settings where the HIV epidemic is not widespread or generalized. Even so, some challenges remain. Despite this strategy's potential to recruit newly diagnosed persons into treatment, to preserve autonomy, and to normalize and destigmatize HIV, barriers remain in regard to linkage to care once the diagnosis is known as well as persistent issues related to viral resistance and adherence.

authoritarian governments that place restrictions on civil society, including crackdowns on AIDS activism and censorship of the press, risk adopting HIV/AIDS policies that do not reflect the needs of their population. These "first generation" human rights guarantees (freedom of speech, freedom of the press, freedom of association) are essential to treatment rollouts to the extent that they foster the political participation of the widest range of stakeholders possible. Procedural justice, as mandated by ethics in creating significant public health policy, has such rights as its cornerstone.

Conclusions

Public health, human rights, and ethics have universal and deeply shared values. It is the mission of public health to improve health, reduce morbidity, and reduce mortality wherever it does its work. Human rights and ethics, too, have basic sets of principles and rules in common that are intended to guide and/or dictate behavior in a variety of situations so as to ensure that human rights and ethics norms are not compromised in the pursuit of good public health outcomes.

While the principles and values of human rights and public health ethics generally are shared, a significant difference between them remains in terms of targets and redress. Ethicists generally have little legal power to challenge what may be viewed as unethical practices or programs, even where the targets of such ethical critiques or advocacy are governments or publicly sanctioned policies. Human rights activists, in contrast, explicitly target governments or the policies they endorse; international tribunals, war crimes trials, and the like are among the most potent tools wielded by human rights advocates. Thus, whereas human rights organizations explicitly try to challenge rights violations through existing legal systems, ethical frameworks try to shape shared societal norms for morally appropriate behavior—norms that, in turn, may be reflected in the law. In addition, human rights proponents often channel their arguments through media or advocacy, whereas in ethics this is less likely to be the primary means of communicating.

In certain contexts, the goals of public health, ethics, and human rights can be very well aligned. Public health, as a branch of government, has extraordinary power to further the public's health in ways that are beneficial, careful, and fair. But because such significant power, wherever it is given, can so easily be abused, both ethics and human rights have created their own sets of checks and balances. Ethics and human rights provide the moral and legal "brakes" to redirect public health to more constructive tactics, and to highlight to public health professionals, through advocacy, argumentation, and accountability, what are and are not justifiable uses of state power and intervention in the name of furthering public health. Ethics and human rights also advocate proactively for just structures for public health—for creating the conditions under which individuals and communities can thrive.

It has been the thesis of this chapter that the human rights context in which public health work is conducted has an extraordinary impact on which public health tools ultimately must be selected to have ethically sound public health responses. The relationship of citizens to their governments has a tremendous impact on public health status in different locales; indeed, the degree to which governments believe that they have a responsibility to care for the health of their public varies strikingly from country

to country. Similarly, when public health seeks to intervene, the human rights or political context into which it enters will influence to a great degree both the potential public health benefits of a given intervention and the ways in which a given intervention is deemed ethically acceptable, ethically unacceptable, or ethically required.

Discussion Questions

1. How might the sale of high-sugar soft drinks in public schools be framed as a human rights issue?
2. What role do states have in regulating foods known to be damaging to health but popular with citizens?
3. In country X, HIV rates are disproportionately high among sexual- and gender-minority adolescents and adults. Same-sex behavior between consenting adults is criminalized. How might decriminalization of these behaviors affect HIV programs? How might this be addressed from a human rights perspective?
4. Adults have a right to purchase and consume the foods and beverages they like and want. Yet aggressive marketing of unhealthy foods can disproportionally affect the health and well-being of the poor, the marginalized, and those with less access to quality health care. How does a public health ethics framework help address the balance of freedom and responsibility? Choice and exploitation?

CHAPTER 4

Understanding and Acting on Social Determinants of Health and Health Equity

Rene Loewenson and Sarah Simpson

Introduction

A large and growing body of evidence shows that health improves when action is taken on the underlying causes of ill health, and particularly those causes that lead to social differences in ill health. "These underlying causes are complex, often reflecting systematic social, political, historical, economic and environmental factors that accumulate across people's lifetimes and are transferred across generations" (Sadana et al., 2014, p. 8). Such underlying social, economic, political, legal, and material factors that affect health are collectively called *social determinants of health* (SDH). Beyond biological processes in the human body and the disease-causing germs that are determinants of health, health outcomes have social origins, such as in the way people live and work and their economic and political systems, known as the social determinants of health. Identifying them enables us to understand and intervene to improve health, and has been a longstanding goal of public health measures. For example, such interventions may include measures to counter the marketing of tobacco to reduce smoking, or creation of cycling paths and green spaces in urban areas to promote physical activity.

These SDH have a general impact on health outcomes. With the global understanding that everyone has the right to the highest attainable standard of health (United Nations, 1976), there is also increasing international attention on social differences in health that are avoidable and unfair (termed "health inequities"). Beyond the broad understanding of the social factors that cause disease, the persistent and sometimes growing differences in health within and between social groups and countries raises questions about how SDH are associated with avoidable differences in the opportunities for a healthy life as well as the differential benefits from interventions for improved health. When this analytic lens is applied, those factors may be termed the *social determinants of health equity* (SDHE). This chapter explores the understanding and application of SDH to improve health, and, as a matter of increasing importance globally, to improve health equity.

DEFINITIONS

Equity is the absence of unfair, avoidable, or remediable differences among groups of people, whether those groups are defined socially, economically, demographically, or geographically (Regional Network on Equity in Health in East and Southern Africa [EQUINET], 2012).

Health inequities are systematic differences in health that can be avoided or remedied and that are therefore viewed as unfair or unjust (Commission on the Social Determinants of Health [CSDH], 2008). This is particularly so for health given the global context, in which the highest attainable standard of health is one of the fundamental rights of every human being (World Health Organization [WHO], 2006).

- *Health inequality* refers simply to differences in health between different individuals, without a normative judgment about those inequalities.

In a chapter in an earlier edition of this text, Kelly and Doohan (2014) explored in some detail how the understanding of social variations in ill health and its prevention developed over time. They described the causal pathways from SDH to individual disease outcomes and population-level patterns of disease.

This chapter does not seek to repeat their well-presented explanations of the causal pathways from SDH to health outcomes. Rather, it focuses on the *application* of the concepts, with examples from a range of countries globally, particularly from low- and middle-income countries (LMICs), especially those in east and southern Africa. The conceptual frameworks, discussed later, show how SDH can be organized into different and deepening levels, each of which incorporates different elements. We do not aim to discuss all the diverse SDH in this chapter, but instead present more detail on some of these elements, given their role in improving health and health equity.

Thus, this chapter describes published work on the following topics:

- The development of conceptual frameworks for understanding SDH and SDHE, including how these frameworks relate to frameworks for human rights and gender equality
- Intersectoral action for health (IAH) and health in all policies (HiAP) as approaches used to apply the conceptual understanding of different types and levels of SDH, from immediate material determinants to deeper socioeconomic and policy determinants, to improve health and health equity
- The implications of an SDH perspective for health systems and services, understanding the health system itself as a social determinant of health and health equity
- The roles of and interventions to address social exclusion, social agency, and power as cross-cutting SDH, affecting other sociopolitical, socioeconomic, and material determinants
- The increasingly global dimensions of SDH in a globalizing world, their role in national-level SDH, and the different levels of responses to them
- How to evaluate action on SDH aimed at improving health and health equity

Conceptual Frameworks for Understanding Social Determinants of Health and Health Equity

Analysis of the relationship between disease and the social and material environment dates back to ancient medico-philosophical systems. With advancing understanding of the causes of ill health and their origin in human activity, it has become clearer that socially determined health risks can be prevented, including as a matter of social justice (Kelly & Doohan, 2014). In recent decades, as public health has shifted its focus from individual risk–health relationships to more complex, multifactorial causal networks, a range of increasingly comprehensive conceptual frameworks have emerged, drawing on evidence to support analysis of the SDH and their role in health equity. This section explores how these conceptual frameworks have developed, with increasing attention over time to the relationship between SDH and health equity.

Turrell et al. (1999) identified SDH at three discrete, yet closely interrelated stages or levels—namely, *upstream*, *midstream*, and *downstream*. The upstream (or macro-level) factors include international influences, government policies, and the fundamental social, physical, economic, and environmental determinants of health. The midstream (or intermediate-level) factors include psychosocial factors, health-related behaviors, and the role of the healthcare system. Some social factors, such as

culture, beliefs, values, and norms, are seen to influence decision making, actions, and behavior at both upstream and midstream levels. The downstream (or micro-level) factors include physiological and biological functioning. This model has been used to identify interventions targeted at entry points in all three levels, either singly or in combination. While acting upstream (such as with tax policies) may have wider population effects, demonstrating its influence is often more complex.

Dahlgren and Whitehead (2007) developed a similarly multilayered and widely used "rainbow" model of determinants, shown in **FIGURE 4-1**. This model has at its core the individual biological determinants that are not considered to be SDH—age, sex, and constitutional—as characteristics affecting health that are largely fixed. From here, the framework adds layers of determinants that are socially determined from individual lifestyle factors; farther upstream are those factors and services that impact on health at the population level and that are theoretically modifiable by policy. This model shows not only the different levels, but also the preponderance of factors that may be considered as SDH. These factors may be health promoting (e.g., provision of adequate housing) or protective, by eliminating risk of disease (e.g., pollution control). In this model, healthcare services coexist with other determinants to impact on health. Dahlgren and Whitehead (2007) propose that a comprehensive health strategy should address and link the different levels of downstream and upstream determinants of health shown in Figure 4-1.

The Dahlgren and Whitehead model suggests the determinants that may be included in the definition of what is socially determined and the relationship between these different levels of SDH on health outcomes. Nevertheless, it does not show how these different SDH relate to health equity outcomes. The authors do, however, argue that the determinants of *inequities* in health may be different from the determinants of health. For example, poor working conditions may account for a higher share of the *difference* in the burden of disease between affluent and low-income groups than in the *overall* burden of disease. Thus, they argue that actions on SDH may not automatically address equity, and that specific attention needs to be paid to the *distributional* impact of those actions for them to achieve this goal. For example, urban

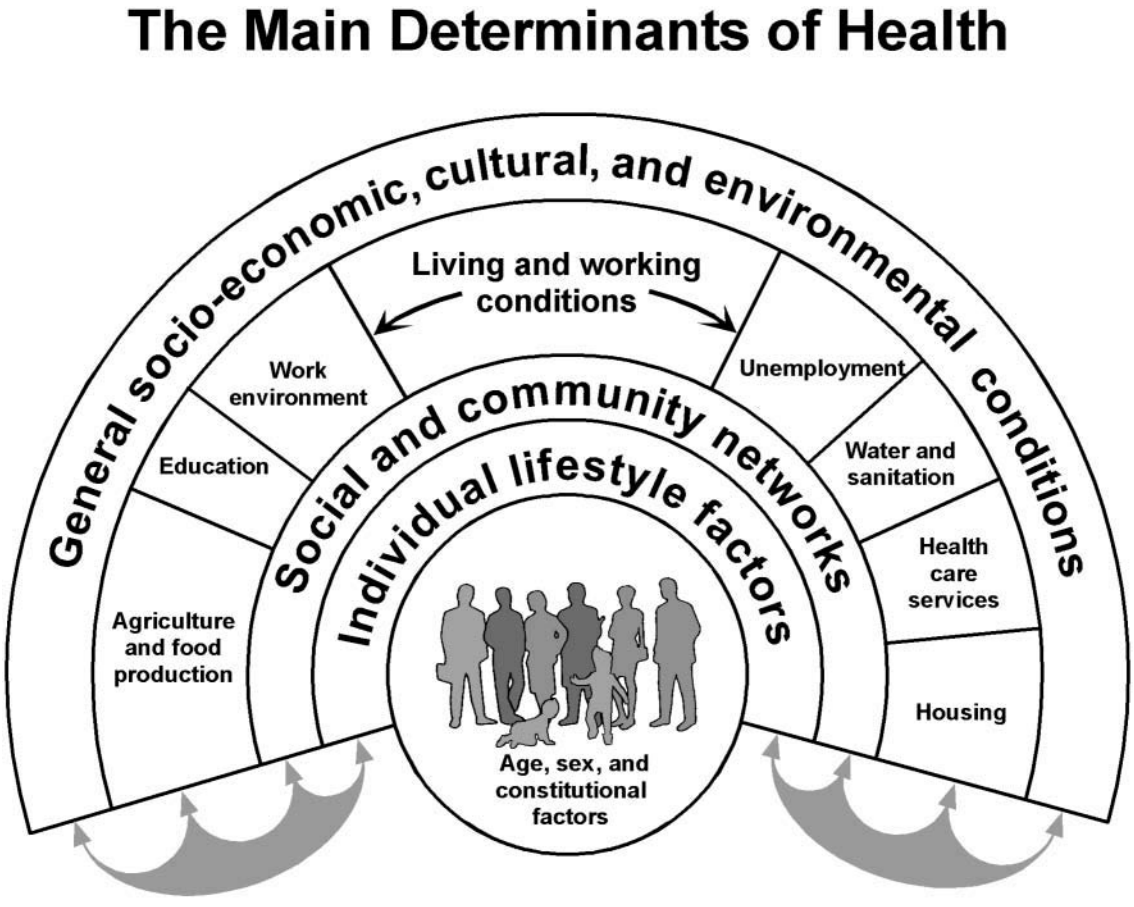

FIGURE 4-1 The "rainbow" model of determinants of health, including social determinants of health.

Reproduced from Dahlgren G., Whitehead M. (2007). *Levelling up (part 2): A discussion paper on European strategies for tackling social inequities in health*. Copenhagen, Denmark: WHO Regional Office for Europe. http://apps.who.int/iris/bitstream/10665/107791/1/E89384.pdf (accessed 22 June 2017).

developments to improve the quality of housing and green spaces are actions on SDH that may improve health, but may also raise housing costs and push local residents into more marginal urban zones, forcing them out from areas where they have been long-time residents. This trend will affect the distribution of health benefits, unless specific measures are in place to protect their tenure or well-being.

The *social gradient* in health describes the pattern that is formed by comparing health outcome measures with some measure of social position, such as occupation, education, or income (Kelly & Doohan, 2014). A population-level public health intervention that affects the whole population in the same way may shift the gradient upward by the same amount for all, without affecting the relative differences between the different social groups.

If the goal of a policy or an intervention is to improve health equity, the rate of improvement should be faster for those groups whose starting point is worse initially, making the health gradient less steep (Kelly & Doohan, 2014). If the gradient simply shifts upward at the same rate for all groups, such that all groups improve at the same rate in their absolute outcomes, then the relative differences between the groups remain unchanged—and in that sense, health inequity has not changed. Population health interventions that are applied universally to address specific SDH without taking social differentials into account may, indeed, worsen inequalities in outcomes. For example, as health technologies are introduced or health screening scales up, uptake may initially be more rapid in wealthier households, which widens (rather than narrows) the social gradient, unless specific measures are implemented to promote uptake in poorer groups (**EXHIBIT 4-1**). A more detailed discussion of absolute and relative measures of social status and their relationship to absolute and relative measures of health outcomes can be found in the chapter by Kelly and Doohan (2014).

EXHIBIT 4-1 Closing the Equity Gap: A Case Study of the Health Gradient

This example illustrates the way the health gradient does, and does not, respond to new public health interventions and the "stubborn" influence of SDH. In the state of Ceará, in a poor area of northeastern Brazil, the 1980 infant mortality rate was greater than 100 infant deaths per 1,000 live births and malnutrition was common. Based on the findings of a 1986 statewide survey of child health and nutrition, new health policies were implemented, including growth monitoring, oral rehydration, breastfeeding promotion, immunization, and vitamin A supplementation—interventions collectively known as GOBI (growth monitoring, oral rehydration, breastfeeding, and immunization). As lack of access to health services was a major problem, community health workers and traditional birth attendants were widely introduced and responsibility for health services was decentralized to rural municipalities, where health indicators were poorest. A social mobilization campaign for child health used media and small radio stations to broadcast educational messages. This work was supported by four consecutive state governors, all of whom gave high priority to improving child health, and the outcomes were reviewed through surveys in 1990 and 1994.

The surveys showed improved population coverage of the four GOBI interventions by 1994. The use of oral rehydration increased to more than 50% in children with diarrhea; nearly all children had a growth chart, and half had been weighed within the previous three months; immunization coverage rose above 90%; and the median breastfeeding duration increased from 4.0 months to 6.9 months. These improvements were noted in all income groups. The prevalence of low-weight-for-age and low-height-for-age children in the population younger than age 5 fell from 13% to 9% and from 27% to 18%, respectively, while diarrheal disease incidence in the previous two weeks was nearly halved.

While the child health interventions were applied to all families, including the poorest, the social differentials in disease and infant mortality rate between rich and poor remained largely unchanged between 1987 and 1994. In that period, family income inequalities persisted and remained largely unchanged. Diarrheal disease incidence remained approximately 60% higher among poor children, income inequalities remained largely unchanged, and the inequity ratio between rich and poor persisted.

One explanation for these findings given by the authors of the Ceará study was that wealthy families had made greater and earlier use of both public-sector and private-sector services to protect their children's health. They noted that even when public health programs are targeted at the poorest households, it is difficult to close the inequity ratio group if the richer households have not yet themselves achieved high levels of coverage with the specific services. The conclusions suggested that, even when public health programs are targeted at the poorest members of a society, the wealthiest are likely to continue to benefit from the introduction of new health technologies, and that further investments are needed to make existing and new interventions more widely accessible to the poorest populations so as to change the health gradient and close the inequity gap (Bonnefoy et al., 2007; Victora et al., 2000, cited in Kelly & Doohan, 2014).

Dahlgren and Whitehead (2007) note that understanding how SDH are linked to improving health equity calls for investigation of what is causing the social gradients in exposure to different health hazards and in access to health-promoting or health-protective factors, such as those described in Exhibit 4-1. Analysis of these SDH associated with distributional outcomes is used to identify the approaches and additional resources that may be needed to address social gradients in health, such as through "leveling-up" strategies. Once these SDH that have positive or negative influence on social gradients are identified, specific strategies can be designed to integrate them within health policies and programs. Dahlgren and Whitehead argue further that policies and programs that influence health should be assessed for their distributional impacts across different socioeconomic groups.

The SDH that have a distributional impact may arise within any of the bands of SDH in the rainbow model shown in Figure 4-1. For example, social position is an important determinant of inequities in health, as are social networks and health behaviors. Groups that are socially and economically better off typically have more power and opportunities to live a healthy life than groups that are less privileged (Australian Institute of Health and Welfare [AIHW], 2012). Legal and institutional arrangements, political and market forces can consolidate these inequalities. The relationships are not purely negative. In contrast, and as exemplified in Exhibit 4-8, shown later, education may be a positive factor in closing inequalities, as it can enhance the power and opportunity of less privileged groups to avoid unhealthy living and working conditions. The freedom and power that people have to influence their own life and society, including through greater political and economic democracy and through control of commercial markets (such as marketing of alcohol), is also a positive factor in tackling social inequities in health (EQUINET, 2012; EQUINET SC, 2007).

Given the increasing concern voiced regarding remediable inequalities in health, Solar and Irwin (2010) elaborated the conceptual framework that was used by the WHO's Commission on Social Determinants of Health (CSDH). This framework, shown in **FIGURE 4-2**, makes an explicit connection to health equity by seeking to profile how SDH relate to and address unfair, avoidable, or remediable differences in health among population groups, as an appeal to ethical norms and a matter of social justice.

The CSDH framework repeats many elements of the earlier frameworks for SDH, but applies an equity lens. It locates SDH within a hierarchy of structural and intermediary determinants that gives specific focus to the political, social, and economic contexts and institutions and the cultural and societal values (all SDH) that *generate, configure, and maintain social hierarchies and that stratify people* by income, education, occupation, gender, race/ethnicity, and other factors (also

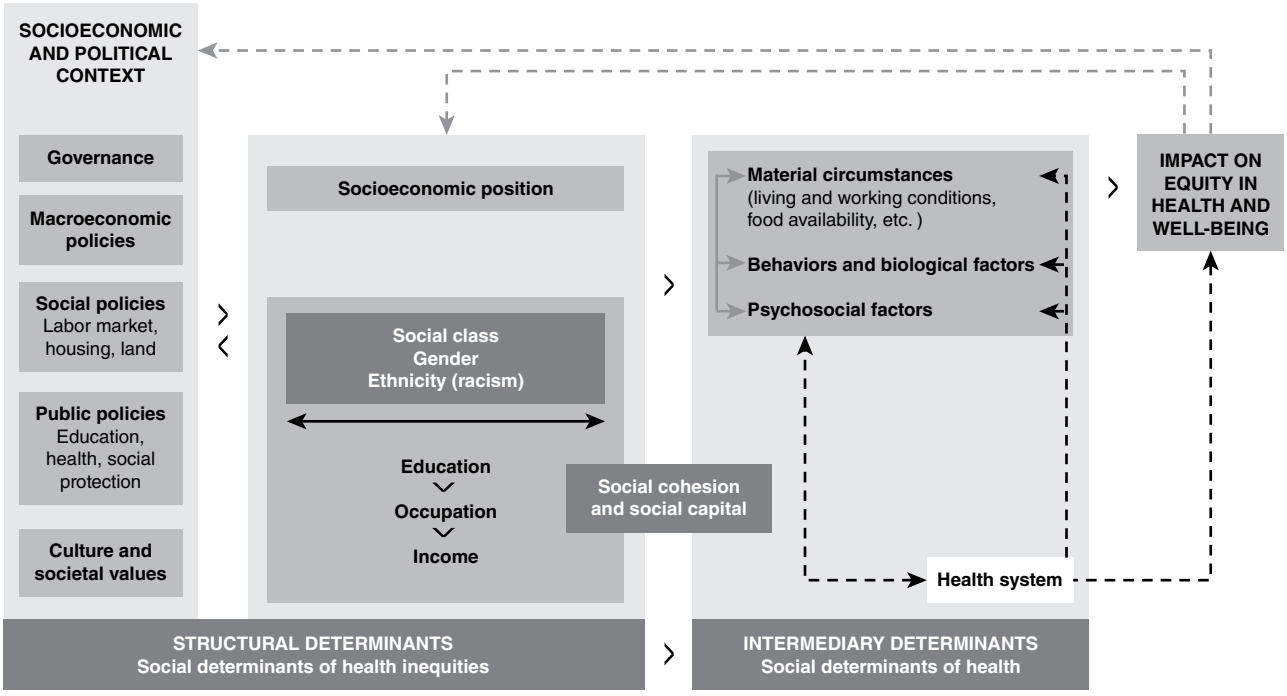

FIGURE 4-2 The Commission on Social Determinants of Health (CSDH) conceptual framework.

Reproduced from Solar, O. and Irwin, A. (2010). *A conceptual framework for action on the social determinants of health. Social Determinants of Health.* WHO Discussion Paper 2 (Policy and Practice), Geneva, Switzerland: WHO. http://www.who.int/sdhconference/resources/ConceptualframeworkforactiononSDH_eng.pdf (accessed 22 June 2017).

SDH). It includes the SDH—including state policies and programs—that *redistribute resources* and nurture relationships and systems that *close social differentials*. These structural determinants and the socioeconomic positions to which they lead, shown in the left-hand columns in Figure 4-2, thus have a central role as SDHE. They jointly shape intermediary SDH, such as material, behavioral, and psychosocial determinants. These factors largely act as SDH but may have a role in equity where they influence *differentials in exposure and vulnerability* to conditions that affect health or the social consequences of ill health, as discussed for the health system later in this chapter. The health outcomes of these conditions can themselves "feed back" on people's social position, such as by compromising employment opportunities or reducing income.

While previous models have noted the role of the health system in dealing with social determinants of health, this framework positions the health system as one of the *intermediary determinants*. It recognizes that health systems both reflect existing patterns of social inequality and provide a site from which to contest them (a topic discussed in more depth in a later section). The CSDH framework also recognizes the effect of globalization and global-level drivers on SDH at the national and local levels (also discussed later).

Policies and interventions that seek to improve equity may be targeted at SDH at both the structural and the intermediary levels: from the "micro" level of individual interactions (such as individual dietary practices), to the "meso" level of community conditions (such as neighborhood environments), to the broadest "macro" level of universal public policies (such as tax and investment policies), including in the global environment and in relation to the role and impact of private actors and corporations. Applying the framework entails assessing the distributional impact of actions and action across multiple areas of SDH. As shown in **FIGURE 4-3**, the CSDH framework identifies these distributional impacts at the level of impacts on social stratification, on differentials in exposure, on differentials in vulnerability to risks, and on the unequal consequences of illness.

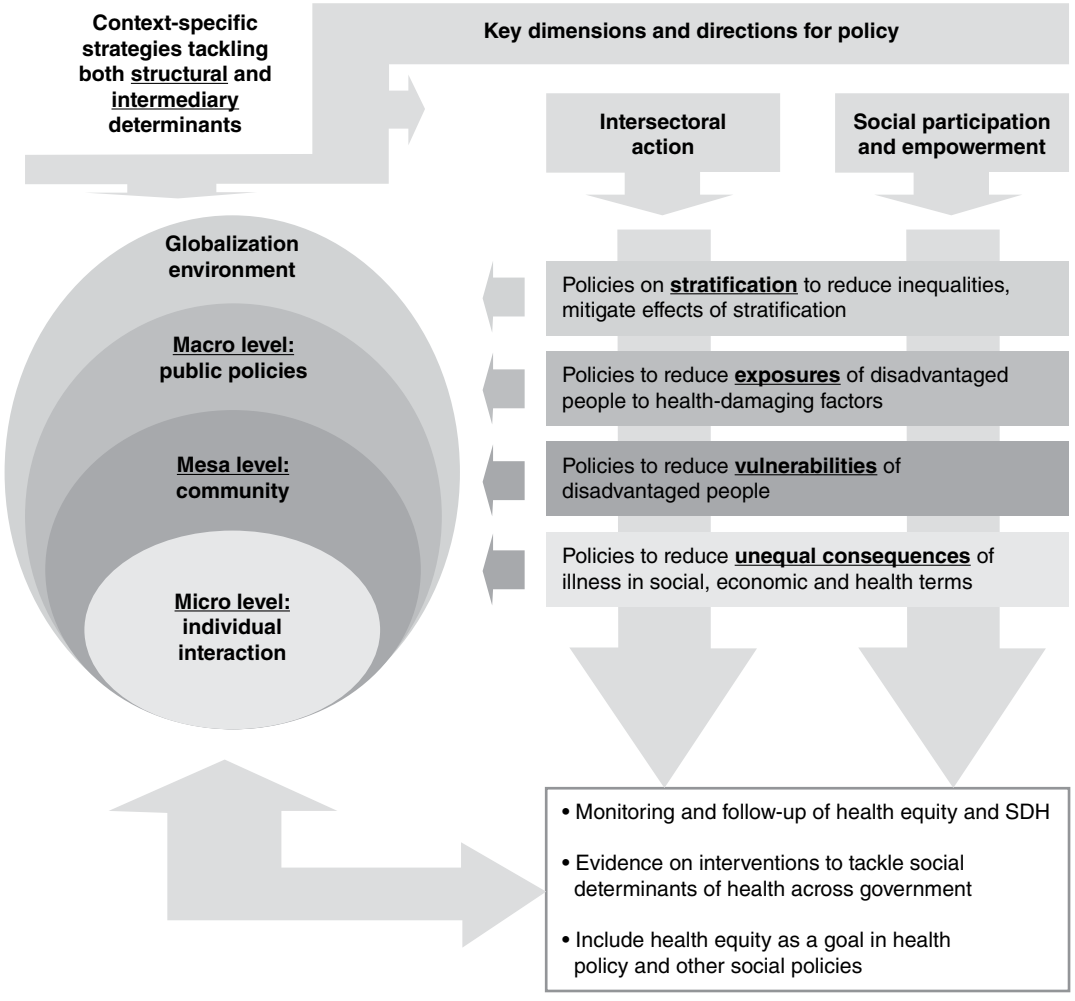

FIGURE 4-3 The CSDH framework for tackling inequalities in health.

Reproduced from Solar, O. and Irwin, A. (2010). *A conceptual framework for action on the social determinants of health. Social Determinants of Health*. WHO Discussion Paper 2 (Policy and Practice), Geneva, Switzerland: WHO. http://www.who.int/sdhconference/resources/ConceptualframeworkforactiononSDH_eng.pdf (accessed 22 June 2017).

Across each of these dimensions, identifying and taking action on SDH to reduce health inequities may have the following benefits:

- Remedy health disadvantage among specific populations—as, for example, in SDH interventions for the Roma community, outlined in Exhibit 4-7
- Close health gaps between two groups, usually the worse-off and better-off groups, as intended in the work of community health workers in Guatemala to improve service uptake in poorer groups, described in Exhibit 4-7
- Address the social health gradient across the whole population—as, for example, is a policy intention of the various features of universal health systems described in later in this chapter

These approaches are not mutually exclusive, but rather may bring together action on different SDH at different levels. As discussed later in this chapter and in Exhibit 4-1, strategies that tackle one or more of these outcomes may be complementary, such as when additional measures for single mothers are embedded within general social protection schemes. Such action on SDH calls for input from multiple sectors, as explored later in this chapter.

Understanding the SDH that affect how different social groups access or experience universal interventions can point to specific additional measures that need to be integrated to close the gap or gradient. Such analysis, as a form of "equity proofing," can, for example, be integrated in health impact assessments (HIA) to check for the likely equity implications and consequences—both intended and unanticipated—of a particular action, policy, or intervention, and to recommend proactive measures to improve health equity (Simpson, Mahoney, Harris, Aldrich, & Williams, 2005).

In all of these models, applying an equity lens to SDH to identify and address these social determinants of health equity calls for robust evidence on the distribution of health and its determinants, and for monitoring and evaluation systems that contribute such evidence to policy decision making. Evidence on SDH often extends beyond familiar health indicators, and assessing changes in health gradients and across social features, areas, and time can be complex.

Solar and Irwin (2010) observe that there is a dearth of evidence, including data on impacts, to support policy action on SDH and inequities in health. Cochrane reviews of studies of tobacco control, for example, rarely assess the impact of policies or programs in relation to socioeconomic dimensions (Oxman, Lavis, Lewin, & Fretham, 2009). As noted earlier, the interventions are often multifaceted, combining different levels of SDH and sectors, relative to the often narrower biomedical/clinical health interventions. The former are context dependent, are delivered within a constantly changing health and social policy environment, and involve diverse disciplines (Oxman et al., 2009). While there is growing recognition of and research on these SDHE, further development of methods that take the complexity of such interventions into account is still needed, and funding for this research is still limited relative to that allocated for the biomedical sciences (CSDH, 2008). The CSDH (2008, p. 186) has noted that "action on SDH is best served through developing a rich and diverse evidence base." This chapter thus includes evidence from multiple disciplines and methodological traditions, ranging from analysis of repeated household surveys, to qualitative studies, policy analysis, studies of power relations, practice reviews, and system-level evaluations.

The conceptual frameworks discussed in this section also suggest that social processes and power differentials play an important role in the social hierarchies that stratify people and in acting on SDH that affect health equity, as exemplified in the case of indigenous people in **EXHIBIT 4-2.**

EXHIBIT 4-2 Understanding Systematic Discrimination Against Indigenous People as an SDH

Indigenous people in Australia (as in other countries) are not merely "disadvantaged citizens." The poverty and inequality in health that they experience reflect the association with systemic discrimination over centuries. Thus, addressing these issues is not simply a matter of provision of material or service inputs, but rather requires addressing ways to increase their control over their physical environment, their dignity, and their community self-esteem, and the matter of justice (Calma, 2007). Such systemic processes of discrimination and disempowerment cannot be simply understood as historical events reflected in poorer current health outcomes for indigenous people, but must be recognized as persistent in their social consequences and within current sociopolitical contexts, with continued negative impacts on health outcomes (Axelsson, Kukutai, & Kippen, 2016). The CSDH (2008) and the indigenous health research community have called for such effects of colonialism to be more explicitly incorporated into epidemiologic analysis and monitoring systems.

Health interventions and systems are thus not simply technical or biomedical in nature, but rather affect social power and status and reflect procedural justice, such as through decision-making processes that are transparent to, accessible to, and inclusive of the input of those affected by them. The next sections explore further how intervening on SDH to promote equity calls for institutions and processes that provide opportunities and spaces for disadvantaged and marginalized groups to engage in decisions that affect their health, that are responsive to need, and that recognize and deliver on health rights, as noted in the 2008 CSDH report: "Changing the social determinants of health and health equity is a long term agenda requiring sustained support and investment . . . recognising that . . . at the centre of this action should be the empowerment of people, communities and countries that do not have their fair share" (p. 23).

Integrating concepts of power into the analysis of SDH and into the responses to the resulting inequities in health both clarifies and complicates frameworks. Solar and Irwin (2010, p. 21) argue that while power is "arguably the single most important organizing concept in social and political theory," it is also contested and subject to diverse and often contradictory interpretations. It draws public health professionals into the sometimes less familiar terrains of social justice and rights–based approaches, of sociopolitical and systems theory, and of activism, discussed further in the chapter.

Relationships Between SDH, Gender Equality, and Human Rights

The conceptual frameworks highlighted earlier indicate that SDH intersect with the distinct but linked concepts of gender and human rights, particularly when applying an equity lens. While sex is a biological determinant, gender refers to the socially constructed roles, rights, responsibilities, and limitations assigned to women and men, boys and girls—which often privilege male power or characteristics (WHO, 2011). These aspects of gender are socially constructed and amenable to change, as an SDH that leads to *differentials in exposure and vulnerability* to conditions that affect health and thus health equity (Sen & Ostlin, 2011).

Gender norms, roles, and relations can affect (health) risk and vulnerability, health-seeking behavior, and health outcomes for men and women of different ages and social groups, including through stereotypes, discrimination, and the gender-based division of labor (Sen & Ostlin, 2011; WHO, 2011). Gender norms and relations are a persistent basis of the social hierarchies and stratification mentioned earlier, intersecting with social class, ethnicity, education, occupation, and income; influencing socioeconomic position and the distribution of other SDH; and being influenced by the wider socioeconomic and political context, culture, and societal norms and values (Sen & Ostlin, 2011). The Definitions box summarizes the related concepts of *gender equality* and *gender equity*. Within universal policies such as "health for all," the "all" are not the same. Gender-related differences that lead to inequities in health arise from the different health needs and challenges that men and women face across their life course and the ways in which they intersect with other SDH. Gender-related differences exist in a range of SDH, including living and environmental conditions, employment and income opportunities, and control over decisions about and uptake of health services (WHO, 2011). Gendered norms, behaviors, and socially constructed roles intersect with other SDH to generate differential social and health outcomes.

Many of these differentials derive from women's status in society, and their control over a range of areas affecting health, including over their own bodies, their reproductive health, and their working conditions and income (for example, see **EXHIBIT 4-3**). Women are at greater risk of physical violence and sexual abuse and face deficits in protection in law or its enforcement (Sen & Ostlin, 2011). In addition, female, lesbian, gay, bisexual, transgender, and intersex (LGBTI) people risk poorer health outcomes than males or people who are not LGBTI because of gender power relations (Sen & Ostlin, 2011).

DEFINITIONS

- *Gender equality* refers to women and men having equal conditions and opportunities to realize their rights and potential to be healthy, to contribute to health development, and to benefit from the results. Gender inequality puts the health of women and girls at risk globally. Improving gender equality in health enables the improvement in the health of women.
- *Gender equity* refers to fairness and considers women's and men's different needs to achieve gender equality. It implies the different treatment needed to ensure equality of opportunity. Both gender equality and gender equity are needed to achieve health equity (Sen & Ostlin, 2011; WHO, 2011).

EXHIBIT 4-3 Child Marriage and Its Gendered Health Effects

Child marriage is a union (official or not) of two persons, at least one of whom is younger than 18 years of age. It is driven by gendered values and beliefs about girls' roles and contributions, affects girls and boys differently, and is more prevalent among girls. In Niger, for example, 77% of women age 20 to 49 were married before age 18, compared to 5% of men in the same age group. Collecting data on such unions poses a challenge, because child marriages are often not registered. However, worldwide, more than 700 million women in 2014 were married before age 18, and about 250 million before age 15, with the highest rates found in South Asia and sub-Saharan Africa. There are educational, regional, urban–rural, and wealth differences in this practice: In Malawi, nearly two-thirds of women with no formal education were child brides compared to 5% of women with secondary or higher level schooling; in Amhara, northern Ethiopia, the rate of child marriage is 75%, compared to 26% in Addis Ababa; and girls in the poorest quintile are 2.5 times more likely to marry in childhood than those in the wealthiest quintile.

Girls who are married before age 18 experience greater negative impacts on physical and mental health and well-being than do boys in this situation, primarily due to complications from early pregnancy and childbearing, increased risk of and vulnerability to human immunodeficiency virus (HIV) and other sexually transmitted infections, and gender-based violence and discrimination. Complications during pregnancy and childbirth are the second leading cause of death for 15- to 19-year-old girls globally. Adolescent mothers are often socially isolated from family, friends, and other sources of support, such as health services; have limited opportunities for education and employment; and may be less empowered to break the cycle of poverty due to their lower levels of education. Early maternal age affects infant mortality and growth, compounding intergenerational inequality. Furthermore, unregistered child marriages may mean that the child's birth is also unregistered, potentially affecting the child's access to health, social, and educational services (UNICEF, 2014, 2016; WHO, 2014; WHO Regional Office for Europe [WHO Europe], 2016).

In terms of reducing health inequities,

> [because] of the numbers of people involved and the magnitude of the problems, taking action to improve gender equity in health and to address women's rights to health is one of the most direct and potent ways to reduce health inequities and ensure effective use of health resources. Deepening and consistently implementing human rights instruments can be a powerful mechanism to motivate and mobilize governments, people and especially women themselves. (Sen & Ostlin, 2011, p. 74)

International human rights instruments provide a framework for universality and a legal obligation for states to ensure policies that support conditions and opportunities for health for all (Braveman & Gruskin, 2003). Human rights–based approaches thus raise the relevance of acting on SDH for improved health, so as to meet the 1948 Universal Declaration of Human Rights Article 25 provision: "Everyone has the right to a standard of living adequate for the health and well-being . . . including food, clothing, housing and medical care and necessary social services" (United Nations, 1948).

A human rights–based approach also draws attention to the SDH that affect health equity, to ensure the "right to the enjoyment of the highest attainable standard of health . . . without distinction of race, religion, political belief, economic or social condition" for all, as provided in Article 12 of the 1966 International Covenant on Economic, Social and Cultural Rights (ICESCR) (United Nations, 1976). The ICESR General Comment 14, in addition to identifying universal access to specific SDH for the whole population, identifies the core state obligations in relation to health as ensuring *nondiscriminatory access* to health facilities, goods and services, *especially for marginalized groups* (United Nations, 2000). The right to health provides for claims by people as rights bearers to key SDH, including health care, and its achievement depends on the realization of these entitlements and freedoms (Gesellschaft für Internationale Zusammenarbeit [GIZ] & WHO, 2011a). While some rights violations, such as access to safe water, are measurable and have clear health consequences, there is some debate on what the right to "the highest attainable standard of health" means in practice. It has been argued that one dimension of this is closing avoidable inequalities in health within and across countries (EQUINET, 2012).

Rights-based approaches in health imply not only intervention on intermediary SDH, but also processes that include participation, information sharing, and accountability in setting priorities, planning and design, and implementing and monitoring policies and programs that are set in more structural SDH. They imply that states and others charged with duties

The United Nations Human Rights-Based Approach (UNHRBA, 2003) to development has as its purpose to assist UN agencies in mainstreaming human rights into their activities and programs within their area of work with the expected outcome of realization of one or several human rights (e.g., the right to health). Human rights principles should guide programming in all sectors, and include capacity building of rights holders to make their claims and of duty bearers to meet their obligations (UNHRBA, 2003).

have the resources and capacities to meet their obligations; and that social groups—particularly vulnerable groups—have the information and capacity to claim their rights, with access to redress mechanisms such as human rights commissions, policy reviews, audits, and courts to pursue violations.

Nevertheless, the resource constraints facing states, particularly in low-income countries, also generally imply a principle of progressive realization of the right to health (and its determinants)—that is, to move as quickly and effectively as possible toward their achievement. ICESCR General Comment 14 refers to core obligations that require immediate action versus obligations that can be progressively realized, supported by measures to show constant progress (United Nations, 2000). States need to demonstrate that they are taking deliberate, concrete, and targeted steps towards realizing these health and SDH rights, to put all appropriate and available means in place for this progress, and to monitor and report on their implementation against agreed benchmarks (GIZ & WHO, 2011b).

There is an interaction between gender and human rights frameworks in addressing SDH. Human rights principles of equality, participation, and nondiscrimination applied in addressing SDH address gender inequalities and gender equality not only as an SDH, but also as a human right. Addressing gender inequalities is, further, essential to realizing human rights, including the right to health (WHO, 2011). Gender mainstreaming as a strategy thus applies a human rights–based approach, in analyzing the impact of gender norms, roles, and relations on rights to health, and in implementing measures to address rights violations and institutionalize gender equality, in a manner that integrates the participation of affected women (WHO, 2011).

Hence, despite their differences in focus, SDH, gender equality, and human rights frameworks share some common features: All are explicitly guided by an ethical (normative) foundation that values and promotes procedural justice; all identify health outcomes as the result of wider social and material conditions (and seek to generate evidence and analysis on this relationship); and all recognize the role of social processes and power differentials in creating health inequities. Moreover, all three see the state and participation of affected populations as central in the response to health inequity and action on the SDH, through actions across numerous sectors, including the health sector.

Addressing SDH Through Intersectoral Action and Health in All Policies

The diversity of SDH noted in the frameworks introduced earlier in this chapter implies that actions on SDH call on many sectors. The concept of *intersectoral action for health* was formally introduced at the 1978 International Conference on Primary Health Care (PHC) in Alma-Ata. The PHC approach explicitly identified the need for both comprehensive health services and joint action with other sectors to tackle the SDH and root causes of poor health (Public Health Agency of Canada [PHAC], 2007), with subsequent global processes further stressing the importance of dialogue and joint action with other sectors (CSDH, 2008)

Many SDH lie outside the remit of the health sector (CSDH, 2008). For example, a global review of evidence on the determinants of diabetes identified that improving health outcomes for this condition involves the following measures: (1) limiting the availability of unhealthy food and environments; (2) tackling the obesogenic environment through improving urban infrastructure to promote physical activity; and (3) reducing exposure and addressing increased vulnerability among certain groups by improving

DEFINITION

Intersectoral action refers to processes in which "the objectives, strategies, activities, and resources of each sector are considered in terms of their implications and impact on objectives, strategies, activities, and resources of other sectors." It is advanced as a means for overcoming policy fragmentation; as a way to plan, implement, and monitor service delivery; and as a means to address "upstream" the determinants of health (Loewenson, 2013a, p. 8).

screening and access to and uptake of health care (Whiting, Unwin, & Roglic, 2010). The health sector thus needs to cooperate with other sectors to improve health outcomes, as demonstrated in **FIGURE 4-4** in regard to the actions needed to tackle the health burdens from exposure to air pollution.

Such intersectoral action to address SDH can be located as a shared goal across government, with "Health in All Policies" (HiAP) being one such approach. A HiAP approach is driven from within government as a whole, linking specific programs and measures to wider government policy agendas

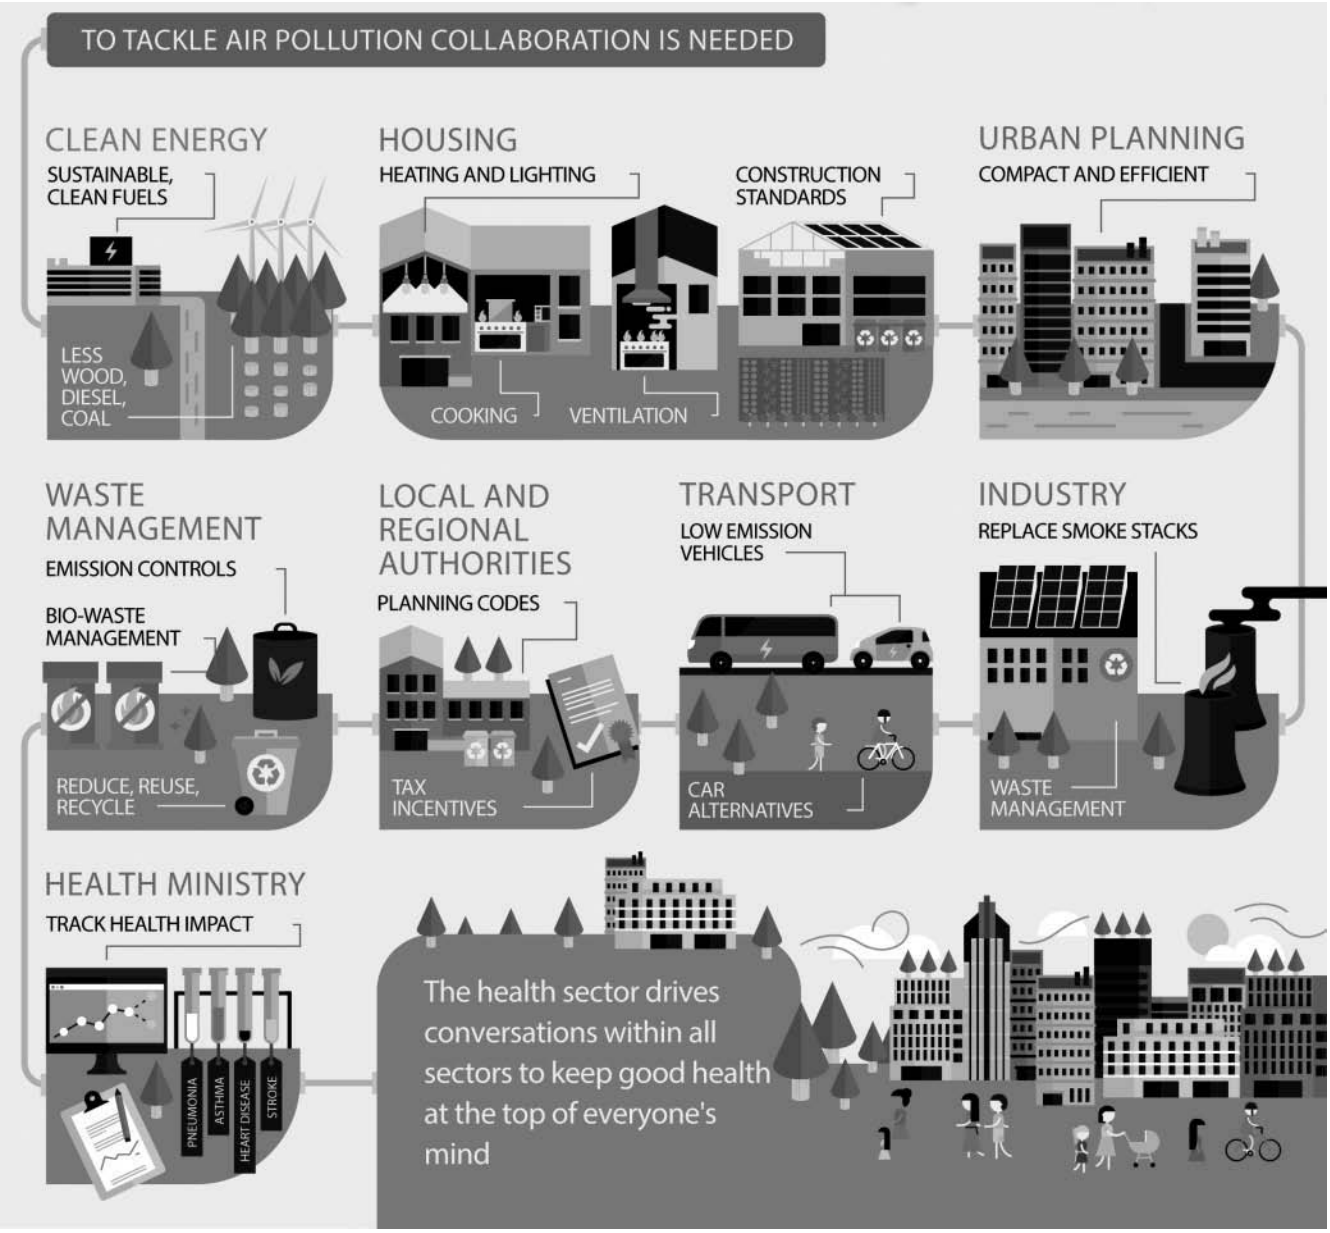

FIGURE 4-4 Intersectoral collaboration on air pollution.

Reproduced from WHO. (2015). *What is health in all policies?*, Infographic on air pollution. http://who.int/social_determinants/publications/health-policies-manual/HiAP_Infographic.pdf?ua=1 (accessed 19 May 2017).

DEFINITION

Health in All Policies is an approach to public policies across sectors that systematically takes into account the health and health systems implications of decisions, seeks synergies, and avoids harmful health impacts, with the goal of improving population health and health equity. A HiAP approach is founded on health-related rights and obligations.

(Ollila, Baum, & Peña, 2013, p. 6)

(Shankardass, Solar, & O'Campo, 2012). While formally articulated as policy concepts from the 1970s, HiAP and intersectoral action for health have their roots in the early history of public health and "healthy public policy." HiAP builds on experiences of intersectoral action and health promotion, and has been given a greater international profile since 2000 (Friel, Harris, Simpson, Bhushan, & Baer, 2015; PHAC, 2007).

EXHIBIT 4-4 provides an example of HiAP in South Australia, located within the overall state strategic plan. Applying HiAP calls for information systems and strategic review involving all relevant sectors to gather evidence and evaluate how joint actions are affecting the distribution of SDH as well as the social gaps and gradients in health, so as to adopt appropriate responses (Loewenson, 2013a; WHO, 2013a).

As noted in Exhibit 4-4, intersectoral action calls for measures to build collaboration and coordination across sectors, often departing from the administrative, budgetary, and functional siloes that exist within states. It involves whole-of-government approaches, which lever action across all levels and sectors of government, and whole-of-society approaches for public outreach, including through parliaments/legislatures, civil society, and the private sector (Delaney et al., 2016; WHO Europe, 2013). A review of experiences in more than 15 countries identified key measures for the successful implementation of intersectoral action, shown in **EXHIBIT 4-5** (PHAC, 2007; Rasanathan, 2011).

The HiAP approach and the implementation steps in Exhibit 4-5 can be applied to embed health equity as a goal across all relevant national policy, law, and

EXHIBIT 4-4 The South Australian Approach to Health in All Policies

HiAP in the South Australian government, as adopted in 2008, was developed as a central process of government, rather than one run by and for the health sector. It was integrated in the implementation of the South Australian Strategic Plan, which aimed to improve prosperity and well-being, foster creativity, build communities, and sustainably expand opportunity. The approach sought to better utilize social, economic, and environmental levers to influence population health, and in turn to contribute to achievement of the overarching government vision for South Australia as articulated in the strategic plan. HiAP is thus deliberately and strategically positioned as a central process of government, rather than a process run by the health sector to achieve solely its objectives. A range of agencies use HiAP in partnership with South Australian Health as a mechanism for achieving their own goals, aligned to the objectives and related targets of the strategic plan. The implementation of HiAP is supported by central government, in partnership with the health sector.

The 2011 South Australian Public Health Act provides for the systematic integration of HiAP approaches in government functions and for mechanisms for embedding health considerations in government decision-making processes. The act mandates use of HiAP in public health planning by local municipalities and in health impact assessments and any other measures that they use, such as a health lens analysis. Health lens analysis builds on traditional methods for health impact assessment and incorporates additional methods used by other sectors, such as economic modeling. Such analyses have, for example, focused on water sustainability, regional migrant settlement, digital technology access and use, healthy weight, and active transport. A small HiAP unit was established within South Australian Health to facilitate health lens analysis and sustain the partnership with other government agencies in applying HiAP to their targets (Bucket, Williams, & Wildgoose, 2011; WHO, 2013a).

EXHIBIT 4-5 Measures for Steps Necessary for Successful Implementation of Intersectoral Action for Health

1. Create a policy framework and an approach to health that are conducive to intersectoral action.
2. Emphasize shared values, interests, and objectives among all partners and potential partners.
3. Ensure political support, building on positive factors in the policy environment.
4. Engage key partners at the very beginning.
5. Ensure appropriate horizontal linking across sectors and vertical linking of levels within sectors.
6. Invest in the alliance-building process by working toward consensus at the planning stage.
7. Focus on concrete objectives and visible results.
8. Ensure that leadership, accountability, and rewards are shared among partners.
9. Build a stable team of people who work well together, with appropriate support systems.
10. Develop practical models, tools, and mechanisms to support implementation of intersectoral action.
11. Ensure public participation through education and awareness raising of SDH and intersectoral action.

Reproduced from WHO. World Conference on Social Determinants of Health. Closing the Gap: Policy into Practice on Social Determinants of Health. Retrieved from: http://www.who.int/sdhconference/Discussion-paper-EN.pdf

programs, when specific focus is given to those SDH that have a role in closing the gap or gradient. For example, in 2007, a Norwegian parliament whole-of-government approach aimed to reduce social inequalities in health in 2007–2017 by "leveling up" across the social gradient. The strategy linked efforts to reduce social inequalities in health to government policy initiatives to improve employment, welfare, and inclusion, and to support early intervention for lifelong learning (Norwegian Ministry of Health and Care Services, 2007). Another example of such a "whole-of-government" approach in Mozambique is described later in Exhibit 4-12.

While there may be technical evidence or consensus on the relevance of specific SDH to health outcomes, not all countries have the high-level leadership support, policy space, or institutional systems to support such whole-of-government approaches to cooperation across sectors. Where this is the case, intersectoral action may be built by the health sector itself collaborating with one or more sectors to support the shared goals of both sectors. For example, education measures that support secondary school completion rates for girls, such as those described later in Exhibit 4-9, contribute both to improved education outcomes and to improved adolescent health, with longer-term health, socioeconomic, and well-being gains for girls—and their future children—extending into adulthood (Loewenson, 2013b).

These approaches help to build the confidence in, relationships for, and systems to support intersectoral action for health. Tackling health inequities, and particularly those that are affected by structural determinants, often demands the deeper and more sustained levels of collaboration through the whole-of-government approaches described earlier, as found in a review of experiences of 19 countries in Africa, Southeast Asia, and the Western Pacific (WHO, 2013a). In one such experience, described in **EXHIBIT 4-6**, Vietnam sought to improve road safety and to alleviate traffic congestion, both of which had the potential to have positive impacts on health and health equity.

Advancing intersectoral action calls for governance arrangements and systems to design and implement coherent multisectoral and cross-sectoral policies on SDH. This is often a challenge, particularly when health professionals are perceived to be overlooking other sectors' goals and challenges and drawing resources *from* other sectors *to* a health sector agenda, rather than as efforts to mutually improve each sector's policies (Rasanathan, 2011). The goals of other sectors should thus be used to orient analysis and explore areas of mutual interest across sectors. WHO's SDH Sectoral Briefing Series (covering housing, education, transport, energy, and social protection) provides further information

EXHIBIT 4-6 Multisectoral Collaboration Through the National Helmet Law in Viet Nam

The motorcycle is the primary mode of transportation in Viet Nam and contributes to more than half of all road traffic fatalities (Passmore, Tu, Luong, Chinh, & Nam, 2010). Passengers, particularly children, are vulnerable to injury due to widespread lack of helmet use. Despite helmet legislation since 1995, with amendments in 2000, 2001, and 2003, the National Traffic Safety Committee charged with implementation of this law faced challenges due to legislative loopholes. A 2007 law sought to close these loopholes by requiring all riders and passengers to wear helmets on all roads without exception and by increasing penalties tenfold. Although 50,000 helmets were distributed to low-income families nationwide, more loopholes were identified after introduction. For example, no reference was made to the correct use of helmet wearing, and the existing legislation meant neither children younger than 16 years of age nor adults carrying them could be fined. These legislative loopholes were subsequently addressed and attention given to barriers to effective helmet use, including improved availability and quality of helmets for the climate, raising public awareness, and changing beliefs about the impact of helmet use. Multisectoral collaboration was built across government agencies and with key nongovernmental organizations and the private sector. This resulted in three national mass-media campaigns and distribution of free helmets to school-age children sponsored by private companies. Monitoring showed helmet-wearing increased from less than 30% to more than 95%, with this change estimated to have saved more than 1,500 lives and prevented almost 2,500 serious injuries.

This example illustrates an approach to policy change backed by strong political support, integrating legislative, research, and media work and strategic alliances. There was cross-sectoral support because the actions were seen to yield benefits for a range of sectors, including road safety, alleviation of traffic congestion, improved health, and reduced costs to the state and families from serious injury and potential loss of income. Focusing distribution of helmets on low-income families aimed to support equity by facilitating compliance with the law among those who were least able to afford a helmet, but most reliant on motorcycle travel (Nguyen, Passmore, Cuong, & Nguyen, 2012; Passmore, Tu, Luong, Chinh, & Nam, 2010; Passmore, Nguyen, Nguyen, & Olivé, 2010; WHO, 2013a).

to support such collaboration with sectors outside health, such as in supporting transport authorities' banning of lead and sulfur in gasoline as not only a health-promoting measure, but also as a contributor to improved air quality and a sustainable environment (WHO, 2017a).

Implications for Health Systems and Services

As further elaborated in *The Design of Health Systems* chapter, effective health services are a determinant of population health, contributing to reducing mortality and increasing life expectancy, particularly through preventive services and health promotion (Loewenson & Whitehead, 2012; WHO Regional Office for Europe [WHO Europe], 2011). They encompass various functions, including stewardship, resource mobilization, financing, and service delivery, and involve a network of public and private organizations, institutions, and resources (WHO Europe, 2011).

Health systems not only provide individual- and population-level services that position them as an intermediary SDH, but, as outlined earlier in this chapter and in Figure 1.1, they can also influence the policies and coordinate with the actions of other sectors to address SDH, thereby providing a site from which to contest social inequalities (Solar & Irwin, 2010; WHO Europe, 2011). Health services and institutions can address differences in exposure and vulnerability, take a leadership or facilitating role in intersectoral action, and mediate or mitigate the financial, social, and physical consequences of illness in people's lives.

This role of the health system in addressing both disease and its underlying SDH is consistent with the application of the PHC approach as an organizational strategy and an underlying philosophy. Within the healthcare system, PHC requires the provision of comprehensive, integrated, and appropriate health services, emphasizing prevention, promotion, and the role of primary care and the role of the health sector in intersectoral action for health (Gilson, Doherty, Loewenson, & Francis, 2008). While past experience of the application of PHC has produced mixed outcomes, evidence of its potential to improve health equity—compiled, for example, by CSDH—has sustained and increased calls for its implementation (Gilson et al., 2008).

There are a range of ways that health systems can achieve positive outcomes and influence the distribution of health and well-being, summarized in **FIGURE 4-5** overleaf. In the figure, the solid arrows show drivers of health inequity, whereas the dotted arrows show how the health system can mitigate these effects or promote health equity. Health systems can promote health equity when they tackle the physical and social environments that affect differential exposure and vulnerability to ill health, including through intersectoral action. They can reduce social gaps and gradients in health by influencing how health services perform, how different social groups experience the services they receive, how widely their uptake or contact translates into effective coverage and care, and whether health funding protects against impoverishment when people fall ill (Gilson et al., 2011).

In a rights-based approach, health systems can provide space for people to exercise their rights, to have an informed say in decisions and actions on health, and to hold the system accountable for its performance. Health systems directly influence other SDH, such as local employment and economies, gender equality, and organizational policies, by their own behavior and organization, in the way they help patients to claim welfare benefits; provide rehabilitation to enable people to keep jobs; manage personnel; procure inputs locally; and champion or facilitate political support to introduce or sustain actions that address SDH and promote health equity (Loewenson & Whitehead, 2012).

While the manner and extent to which these measures are implemented depends on the specific country and sociopolitical contexts, some principles and areas of learning apply more broadly in terms of how the health system implements its role in SDH and health equity.

Investing in Primary Health Care-Oriented Services at the Local Level

Addressing health equity and SDH implies that health systems will pay attention to and direct resources toward health promotion and prevention of disease

DEFINITION

Health systems encompass all the activities whose primary purpose is to promote, restore, or maintain health. They comprise the public and private organizations, institutions, and resources that aim to prevent disease, promote health, and provide health care, and they shape wider societal norms and values (Gilson, Doherty, & Loewenson, 2011).

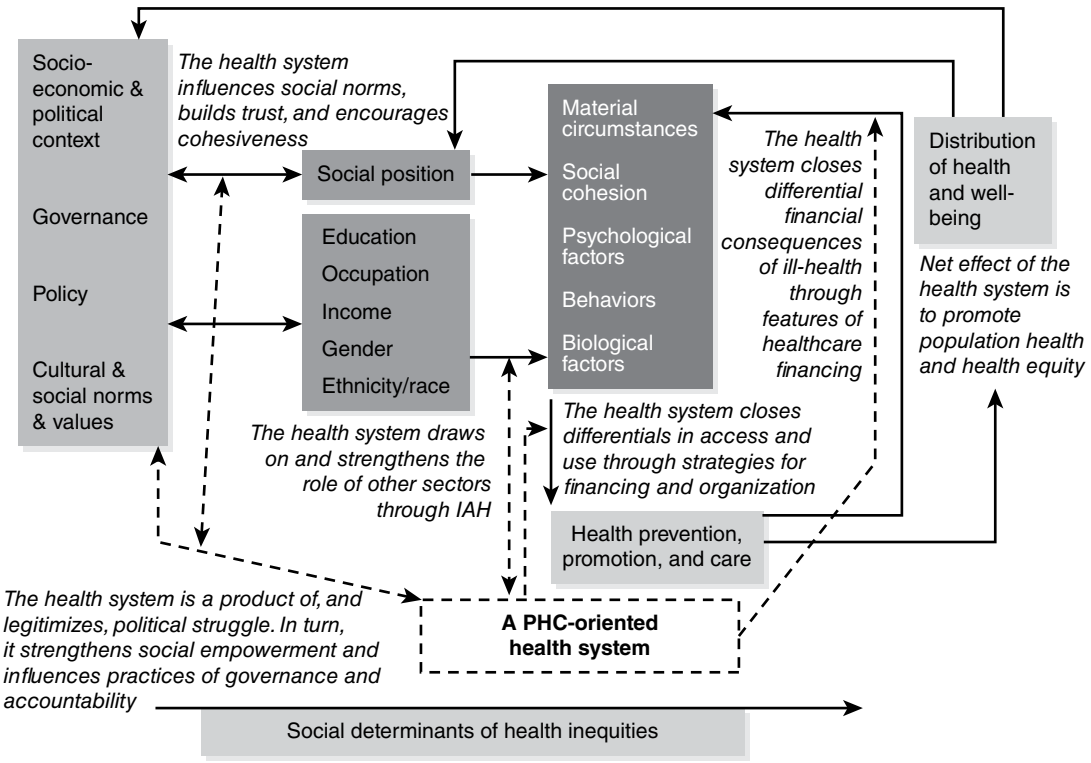

FIGURE 4-5 The health system as a social determinant of health.

Reproduced from Gilson, L., Doherty, J., and Loewenson, R. (2011). 'Challenging inequity through health systems,' in J. H. Lee and R. Sadana (Eds.). *Improving equity in health by addressing social determinants*. Geneva, Switzerland: World Health Organization (WHO). http://apps.who.int/iris/bitstream/10665/44793/1/9789241503037_eng.pdf (accessed 22 June 2017).

at both the individual and population levels, rather than focusing exclusively on individual curative or emergency care. Doing so requires investment in community- and primary care–level services and activities, to open up opportunities for engagement with civil society, communities, and other local services or interventions needed by marginalized groups (Gilson et al., 2008). It is at this level and in this kind of local interaction that many of the SDH and access barriers affecting service uptake can be most directly recognized and addressed, including cost, social, gender, and cultural and other barriers and discrimination; lack of information and knowledge; lack of voice or power; and unresponsive or poorly oriented service providers. This is especially the case if services are to reach and address the health needs of the most marginalized groups (Gilson et al., 2011).

As noted earlier, for health systems to address SDH successfully, they also need to provide public health leadership for and work with other sectors to address the wider social and economic determinants of health, so that people do not repeatedly need treatment after returning to the same conditions that made them ill. This is not simply a matter for those working in community health or health promotion. Rather, it is affected by the continuity and comprehensiveness of the healthcare system as a whole: how well it is able to link preventive, treatment, and rehabilitation services; cover immediate- and longer-term mental, physical, and social health needs; and coordinate pathways from primary care to referral to secondary and specialist services around individuals and populations (Gilson et al., 2008, 2011; Loewenson & Whitehead, 2012; Training and Research Support Centre [TARSC], 2014). It calls for leadership, communication, and facilitation capacities; for the decision-making space and resources to make and manage links with the public and other sectors; and for the political and social awareness and support for health personnel when they act on public health needs (Gilson et al., 2008; Loewenson, 2016; WHO, 2008).

Organizing Equitable and Universal Provision and Financing

In a universal system, everyone in a country should be able to access the same range of services on the basis of their need and pay for these services on the basis of their income. Universal health systems are generally publicly funded largely through general taxation or mandatory insurance and provide care for free or at very low cost at the point of delivery. To support equity, wealthier (and relatively healthy) people cross-subsidize the use of health care by poorer people, who are also more

likely to be ill. This transfer of resources from wealthier to poorer groups in redistributive health systems can also assist to close gaps in income and living standards between poorer and wealthier groups (Mackintosh, 2007). Universality is a key goal of the UN Sustainable Development Goals, expressed as achieving universal health coverage (UHC)—a system in which all people and communities can use the promotive, preventive, curative, rehabilitative, and palliative health services they need, of sufficient quality to be effective, while also ensuring that the use of these services does not expose them to financial hardship.

How countries achieve this goal varies across settings and may change over time. Many countries have funded health from general tax revenues or national mandatory insurance, in large pooled funds that allow for both cross-subsidies and the range of promotion, prevention, and care approaches necessary for addressing the social determinants of health equity. Currently, new prepayment approaches are being explored to secure adequate public funding, including for health promotion, taking into account not only how progressive they are, but also how they will impact on the goods, services, and behaviors that affect health. Such innovative financing sources include taxes on financial transfers, air travel, high-sugar products, tobacco, and alcohol, which may also be earmarked for specific purposes. In situations where formal and informal private payments for health services have risen, especially when arising as a result of inadequate or falling public funding, there are challenges for how to organize private payments into the forms of pooled prepayment that support universal systems and health equity and that invest in areas of public health that have less immediately perceived personal benefit (WHO, 2005). Organizing PHC-oriented, equitable, and universal health systems is not only a matter of how money is raised. It is also affected by whether resources and commodities are allocated according to need and invested in addressing social and service barriers to coverage, and whether there are mechanisms, such as health technology assessment, that bias public spending toward services with proven cost-benefit (Loewenson & Whitehead, 2012). Moreover, it depends on whether there is a motivated, competent health workforce deployed to areas of health need, trained and supported to implement actions on SDH and health equity.

Addressing Barriers to Equity *Within* Universal Policies

As noted earlier, policies for universal coverage do not necessarily lead to equity of access or impact on the SDH that affect uptake of care. Additional measures may be needed. Some measures for such "leveling up" have already been mentioned, such as ensuring that services are free at point of care, either universally, or at least for specific disadvantaged or high-need groups; providing infrastructure and staff in under-served areas; and ensuring a strong community and primary care services system that provides accessible entry points for health promotion, early detection, and care and that coordinates use of other levels of the health-care system. There may be demand for specific subsidies or tax exemptions for commodities consumed or used more by disadvantaged groups, such as basic foods. However, not all of the interventions are technical or on the supply side. Many address determinants that discourage uptake of services, such as by working with indigenous health systems and local civil society organizations (CSOs); providing joint entry points or working as multidisciplinary teams across health and other sectors, together with local political and community leaders and volunteers; creating entry points for health actions in settings (e.g., schools, workplaces, communities, marketplaces, areas) that people frequent; and sharing information and building a more participatory culture to involve community members in decisions and actions on their priority health needs (Gilson et al., 2011; Loewenson & Simpson, 2014). **EXHIBIT 4-7** provides some examples of programs that address the SDH affecting equity in health systems.

Actions such as those described in Exhibit 4-7 can strengthen, or protect, equity-promoting features of health systems and are often connected with wider struggles for social justice and transformation (Rede Brasil de Direitos Humanos, n.d.). For example, wider struggles for democracy in southern Africa set the political basis for post-independence comprehensive PHC approaches (EQUINET SC, 2007), while struggles for participatory democracy in Brazil shaped the entitlements and governance arrangements established in the Brazilian universal health system (SUS) in 1998 (Cornwall & Shankland, 2008). A study of primary care in 31 European countries found that sustained social support for government's responsibility for welfare provision was important to enable the longer-term reforms that strengthened the comprehensiveness and equity of primary care services (Kringos, Boerma, Zee, Van der Zee, & Groenewegen, 2013). In the United Kingdom, a redistributive publicly funded National Health Service has been sustained over more than 60 years by social and cross-party support (Pennington & Whitehead, 2014). In in other countries, rights-based approaches have been used to clarify state duties and public entitlements and responsibilities (Loewenson & Simpson, 2014).

EXHIBIT 4-7 Addressing the SDH That Affect Equity in Health Systems

In Spain, the *Health Promotion among Navarre Ethnic Minorities* program aims to reduce health inequities by improving the health of the Roma community in one area; the Roma are one of Europe's most disadvantaged social groups. Efforts are being made to design and implement prepayment schemes and to raise awareness with the Roma community about their health entitlements. Issues raised by the Roma community are integrated into training for health workers. The health information system carries out health equity surveillance, including for Roma populations, and the evidence is used to review and share practices across sectors and across countries. People from within the Roma community are trained as mediators and act as peer educators and as a liaison between the community and the central health, social, and education services. These mediators play a key role in documenting the health history of families in the area covered and drawing up a health plan in cooperation with the appropriate service providers. They highlight areas in which they need more information or education, as identified through the Roma associations—for example, on outbreaks of communicable diseases or issues related to lifestyle, life transitions, chronic diseases, and prevention. Staff from the relevant agencies meet once a year to incorporate additional items into the annual training program (Perez Jarauta, Goya Arive, & Merino Merino, 2010).

In England, *health champions*, local people trained by a U.K. nongovernmental organization, work with others in their communities to improve health. Health champions work with primary care personnel on health actions in the community; visit schools and community centers and bring local community members to health meetings; link local networks, knowledge, and experience with the practice knowledge and resources; use culturally relevant methods to gather local people to work with general practice staff; and explain to other patients how to make best use of the facilities and services provided. Health champions are reported to have improved input to local commissioning decisions, to have set up social and support groups for young mothers and for people with chronic conditions, to have improved individual and community literacy on prevention initiatives such as immunizations, and to have supported the use of appointment guides and other practice tools, especially for those persons for whom English is a second language. Their work is reported to have led to service and quality improvements (Pennington & Whitehead, 2014).

In rural Guatemala, *promotoras* (community health workers) have supported health service access and uptake. Low literacy rates, high rates of poverty, and gender inequalities impact on the uptake of child health services by indigenous Mayan women in the highlands of Guatemala. Indigenous leaders within the community—usually women who understand the local dialect and culture—have been trained as *promotoras*. The training is culturally adapted and recognizes local experience and environments. It includes space for the community to teach the teachers, such as on knowledge about the use of folk medicine to treat common ailments, while the *promotoras* are given information and skills to improve and manage basic health issues. An evaluation found these community health workers have had a positive impact on health and well-being, and the authors suggested that this experience may be relevant to meeting the health needs of immigrant populations in the United States.

Another paper describes how a needs assessment by the Organization for the Development of Indigenous Maya found diabetes to be a priority concern in indigenous communities. In 2012, the Organization for the Development of Indigenous Maya worked with community health workers trained as diabetes health promoters linked to primary care. Each worker had a caseload of 15–20 patients with whom they held a weekly diabetes club meeting, providing the attendees with information on self-management and group exercises. The community health workers also conducted weekly home visits and preconsults in the clinic to monitor each patient's progress and discuss specific challenges, create goals, and tailor exercise and nutrition plans. A significant decrease was found in mean blood glucose levels between baseline and follow-up in the people involved (Amerson, 2013; Micikas et al., 2015).

In recent decades, neoliberal globalization-related economic policies have dominated health system development in many countries. Given a more individualistic and consumerist society combined with conflicting political forces and values, these policies have challenged, fragmented, and weakened the universality and equity of health systems (Gilson et al., 2011; Mackintosh & Koivusalo, 2005). Thus, acting on SDH increasingly demands action to build public, professional, and political support, while also raising the role of social agency and power as a social determinant of health equity, as discussed further in the next section.

Social Exclusion, Social Agency, and Power as a SDH

As noted earlier in this chapter, people attain different positions in the social hierarchy, often characterized

by their social class, educational achievement, occupational status, and income level, or based on gender. Socioeconomic position can derive from the following sources:

- Resource-based measures, referring to material and social resources and assets, including income, wealth, and educational credentials, as well as poverty and deprivation
- Prestige-based measures, including the level and quality of access to and consumption of goods, services, and knowledge; occupation; and education (WHO, 2016)

Beyond resources and prestige, stratification arises due to discrimination on social factors such as race, gender, color, sex, language, religion, political or other opinion, national or social origin, or property (WHO, 2016). As social beings, humans need to feel valued and appreciated, and to derive meaning from and exercise a degree of control over their work and life conditions (AIHW, 2012). These drivers of social position are linked. Material deprivation generates social exclusion and stigma. Social power affects the ability people have to influence and make choices over health inputs and to use these inputs to improve their well-being (EQUINET SC, 2007). These factors and their role in stratification and power are summarized in **FIGURE 4-6**.

Social exclusion—and, conversely, social cohesion—has grown in profile as a conceptual lens through which to view problems of inequality, poverty, and disadvantage. Social exclusion has the following characteristics:

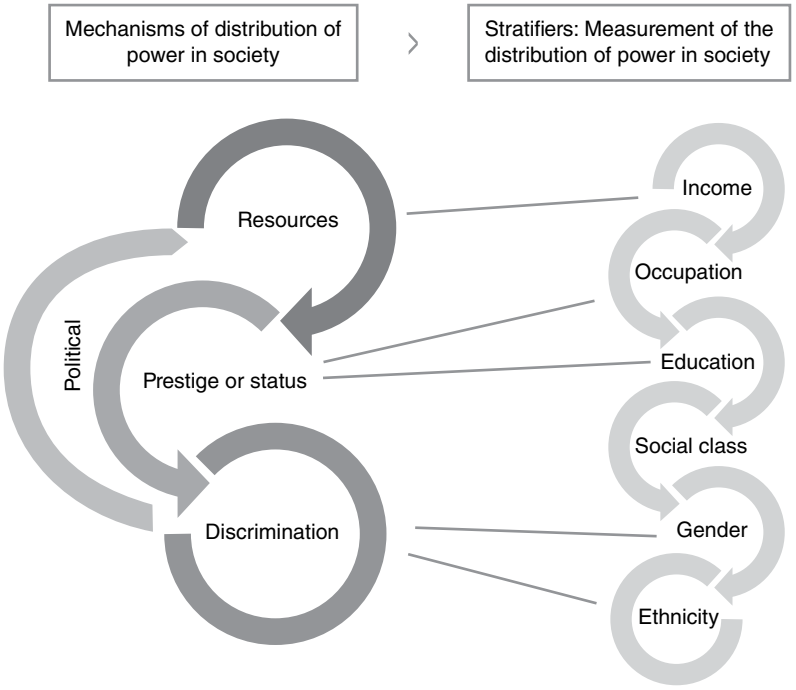

FIGURE 4-6 Mechanisms of distribution of power and their stratifiers.

Reproduced from WHO. (2016). *Innov 8: The Innov8 approach for reviewing national health programmes to leave no one behind*, Geneva, Switzerland: WHO http://apps.who.int/iris/bitstream/10665/250442/1/9789241511391-eng.pdf?ua=1 (accessed 22 June 2017).

DEFINITION

Social cohesion refers to the mechanisms and perceptions that exist in a society regarding social integration across various differentials and for confronting discrimination. It affects the sense of belonging within society, together with features of trust, participation, and reciprocity (WHO, 2016). This concept is applied differently in different regions, contexts, and communities. The European Commission's (2016) concept of "active inclusion" means that every citizen, including the most disadvantaged, fully participates in society. It means having adequate opportunity for work, support for income and employment, and access to quality services that enable active participation in society, including through investment in individuals' capacities and opportunities for participation. In contrast, in post-independence South Africa, social cohesion has been identified with nation, peace-building, and diversity in a democratic dispensation, as a response to past racism and inequality (Palmary, 2015).

- Multidimensional, encompassing social, political, cultural, and economic dimensions, operating at different social levels. and potentially reflecting violation of social rights to participation and inclusion
- Dynamic, impacting populations in different ways and to differing degrees at different social levels over time
- Relational, focusing on exclusion as the rupture of relationships between a group of people and the wider society (Popay et al., 2011)

On the one hand, "exclusion" may be seen as a less stigmatizing label than "poor," and to make clearer links to concepts of social rights and justice. On the other hand, a focus on social exclusion can place too much emphasis on the social inadequacies of specific groups of people, rather than on the environments and processes that generate poverty and inequality (Popay et al., 2011).

The CSDH framework shown in Figure 4-1 positions social cohesion as an SDH that is structural, generating social differentials, and intermediary, as a condition. Popay et al. (2011) argue that applying an equity lens to the analysis of and response to SDH is more effective when social exclusion is understood in terms of processes that embed unequal power relationships and produce social inequalities, rather than as a static "state" in which particular groups are labeled as "excluded."

This perspective places inclusion and exclusion on a continuum that is a result of the distribution of social, economic, political, and cultural resources, capabilities, rights, and opportunities (Popay et al., 2011). This chapter points to various ways that such exclusionary processes manifest and affect health outcomes, such as in the transmission and response to the HIV epidemic in east and southern Africa (**EXHIBIT 4-8**), in slower and reduced access to services, in the impact of gender norms, or through precarious environments or displacement of people by large extractive industry projects.

Responding to processes and conditions that generate social exclusion is not a straightforward matter, and the responses are themselves affected by social determinants. In Colombia, for instance, people displaced by war were required to register with civil or military authorities as a means to access services, political rights, and social integration programs. Unfortunately, such registration also made people more visible, increasing their risk of discrimination and victimization and discouraging service uptake (Ojeda & Murad, 2005; Popay et al., 2011). Similar barriers to

EXHIBIT 4-8 Social Determinants in the HIV Epidemic

The HIV and AIDS epidemic illustrates the complex relationship between exclusionary processes and health disadvantage. To start with, the epidemic has been most prevalent in countries (particularly in sub-Saharan Africa) that already experience social, economic, cultural, and political disadvantages. In the initial stages of the epidemic in east and southern Africa, HIV transmission was associated with more mobile, urban populations and adult HIV prevalence was higher in wealthier, more educated, and urban groups. The transmission reflected social differentials, however, such as in power and income between older men and younger women. As a reflection of the gender inequalities described earlier in this chapter, the HIV prevalence in young women age 15–24 years was more than twice that of their male counterparts in southern Africa in 2003. The changes in both HIV transmission and survival reflected common social differentials: The distribution of prevention and treatment interventions followed typical social differentials in the region, with lower coverage levels among rural, poorer people with lower education levels, raising their susceptibility and vulnerability. By comparison, urban, wealthier people lived longer lives with HIV—sustaining their prevalence rates—due to their better nutritional status and uptake of services and greater mobility.

A number of studies revealed the negative impact on these SDH on the epidemic, with households affected by AIDS facing higher levels of falling household assets, income, social security, food consumption, and increased social exclusion. The stigma and discrimination associated with HIV, combined with other exclusionary processes, exacerbated social, economic, political, and cultural inequalities, interfering with prevention, diagnosis, and treatment. The initial social characterization of HIV/AIDS as a moral issue exacerbated a culture of silence and denial by people living with HIV because of fear of rejection and isolation. Household survey data from four sub-Saharan African countries with different epidemic patterns (Ghana, Kenya, Swaziland, and Zambia) showed that AIDS increased the share of the population living in income poverty, with the strongest effects occurring in those just above the poverty line, placing demands on and further eroding the community-level safety nets and social support networks on which disadvantaged communities depend on (EQUINET, 2012; Rispel, Molomo, & Dumela, 2008; Salinas & Haacker, 2006; Southern African Development Community [SADC], 2003).

uptake have been found in programs that profile conditions that have been associated with social discrimination (e.g., HIV).

State-led responses to social exclusion are generally organized through a range of approaches. For example, *universalist policies*, reflecting values of social solidarity, extend rights to publicly funded services to all citizens, such as publicly funded national health services that are free at point of care. Universalist policies may address SDH and processes that drive social exclusion, as, for example, is intended in the health-promoting schools described in **EXHIBIT 4-9**. As noted earlier, they may need to be complemented by specific measures to address barriers to uptake or coverage in different social groups.

A second approach is through *policies targeting specific social groups*. These policies are specifically designed for disadvantaged groups, and intended to remedy health disadvantages. In some cases, they take the form of c*onditional targeted transfers*, involving some form of testing so as to target scarce services and health resources to those groups most in need, or to incentivize particular behaviors. They include social approaches, as exemplified in Exhibit 4-7. Targeted transfers include conditional transfers of cash or services, or a link between the two. As an incentive for service uptake in Brazil's Bolsa Familia, for example, recipients meeting the means test for a cash transfer must also ensure that their children attend health centers and school. Whether providing cash and/or services, these measures can bring resources to local services providers and promote economic inclusion. They are also documented to have limitations, however. For example, they are often insufficient to provide sustainable pathways out of low-income living, may impose bureaucratic barriers for some persons

EXHIBIT 4-9 Universal Measures to Address Social Exclusion: The Healthy Schools Program in South Africa

In South Africa, schools have been a focus of community-based prevention of negative social factors—including social power imbalances, poverty, violence, and substance abuse—that place learners at risk, including for health problems such as HIV and AIDS. South Africa has the paradox of relatively poor health outcomes despite the country's relatively high aggregate gross domestic product and level of health expenditure. Inequalities in health stem from a history of racial and gender discrimination, a migrant labor system, and high levels of income inequality. The country has sought to address social, racial, and gender disparities and realize social rights through redistributive policies, largely in the social sector.

The percent of adults in South Africa without schooling fell dramatically from 18% in 2001 to 7% in 2010, although with continuing inequality in access to education by region and racial group. Western Cape province, for example, despite being the second richest province in South Africa, has high rates of poverty, economic inequality, unemployment, crime, commercial sex work in teens, and substance abuse, contributing to social exclusion and poor health outcomes. As one response to these conditions, education was seen by the community as a key asset supporting social inclusion and autonomy, promoting the sexual autonomy of girls, and reducing their risk of contracting HIV. Despite this, a large proportion of high school students drop out before completing secondary school and school-age pupils have been found to engage in cigarette smoking, drug and alcohol abuse, interpersonal violence, and unsafe road-related and sexual behavior.

Education policy in the country has sought to strengthen universal access to education, and to support schools as sites for reaching adolescents and helping them acquire health-promoting skills and orientation. Based on the national health-promoting schools policy and approach, a program was initiated Western Cape in 1995 in which program leaders worked with community leaders, school staff members, school health nurses, parents, and the community to make schools a healthy and health-promoting environment for young people. The program integrates broad health promotion and education services, and promotes individual and social well-being for those at school and their families and community. It tackles content issues affecting social determinants, such as road safety, personal hygiene, substance abuse, HIV, and nutrition, and develops and supports alternative youth (and youth-led) activities such as teenage clubs, cultural activities, and camps. It incorporates local social and cultural resources, integrating local and indigenous knowledge, mentoring, and storytelling.

McNab (2013) found that this type of work depends more on a change in mindset rather than on the provision of major new resources, and on making a link between the "top down" influence of public policy and the "grass roots" approach of constructive community engagement. The social dimensions of the Western Cape program were seen to be a central element of its success: At a 2006 national conference, many presenters and participants highlighted the need to listen to and strengthen all voices in the program, and particularly the marginalized voices of local communities and indigenous wisdom, and of the learners themselves (Loewenson, 2013b; University of Western Cape, 2006).

with high health needs, and, as individual-based strategies, may have limited impact on promoting sociopolitical rights or building more inclusive political cultures (Lauthier, 2005).

A third strategy, *market approaches*, seeks to use private or state subsidies to support choices in the consumption of services by poor people to address economic or social barriers to such choices for the most marginalized households. For example, disadvantaged groups may obtain subsidies in insurance schemes to support their access to services or subsidies to address health determinants such as housing. This kind of market support is argued to face similar barriers as those detailed in relation to targeted transfers, and may potentially lead to poorer-quality services for subsidized groups and neglect deeper determinants of such disadvantage (Popay et al., 2011).

Whatever the overall approach, as the example in Exhibit 4-9 suggests, involvement of the people who are the intended beneficiaries of policies and actions that aim to reverse exclusionary processes is essential, as both as a resource and as a right. This implies building a deeper understanding of social power and agency as both determinants and key dimensions of successful policy and action. It suggests that actions that seek to tackle exclusionary processes should strengthen the power and capacity of those affected to engage in meaningful participation, while addressing resistance from professional workers who see it as a challenge to their technical power.

The demand for social participation, power, and agency in health has grown with increased social literacy and with democratic pressures for people's values and preferences to be incorporated into public decision making. The CSDH (2008) identified participatory approaches as a critical feature of health system action or intersectoral action for health to tackle SDH. Social participation has been integrated as a demand-side "intervention" to address barriers to access and acceptability of services and as a means to involve people as active participants in their own health care (Mittler, Martsolf, Telenko, & Scanlon, 2013). As a pragmatic measure, participation is seen to contribute to a range of areas necessary for the effective functioning of health systems:

- Community health literacy, public information, and the use of community knowledge on health
- Assessment, identification, and prioritization of health needs
- Health planning and decision making on spending priorities, resources, and budgets
- Policy deliberation and formulating strategic policy direction
- Co-design, coordination, and coproduction/implementation of health actions
- Oversight, monitoring, evaluation, review, and improvement of services, actions, and quality, including measures of social outcomes (Cornwall, 2008; Gilson et al., 2008; Loewenson & Gilson, 2012; Loewenson et al., 2014)

In a pragmatic and sometimes depoliticized approach, people as consumers or as volunteers may have minimal control over policies affecting structural determinants, but assume responsibility for implementation of compensatory actions. There may be limited change in current norms, processes, and mechanisms. While people may exercise oversight by monitoring, reviewing, and holding services accountable for their performance, they may not have the power to make the decisions that shape these services and may as volunteers take on unpaid burdens of care (Loewenson, 2016).

Participation has also been a product of political drivers, including through the actions of popular movements that have generated demand and sometimes conflict around health and around codetermination and accountability (Amar Amar & Echeverria Molina, 2008). As noted earlier, participation is viewed as the right to guide the duty bearers (states) in their implementation of other human rights. Citizens, including those engaging as health activists or in social movements, have pursued these rights through collective demands for change in areas of power, discrimination, beliefs, policies, and practices that are perceived as inequitable or as limiting their well-being, whether in relation to access to services or the SDH that affect the health of different social groups, or as a claim for shared decision making and oversight (Cornwall & Leach, 2010; Loewenson, 2016). The power, voice, and agency of affected groups can be found in invited spaces—created by external actors and in which people are invited to participate—or in *claimed/organic spaces*—created by people themselves, often as collective and popular self-organizing spaces around a common cause (Cornwall & Leach, 2010).

There are thus different conceptualizations of participation, taking different forms that express the different power relations that exist and the control that people have over events and resources. For example, a group may exert power "over" another group (such as when men control women's use of reproductive health services), may claim the power to be part of processes (such as when people living with HIV participate in price setting for treatment), may exert a shared power "with" each other (such as when communities organize as a group to engage service providers on delivery), or

may build a shared consciousness of themselves and their conditions in the form of a power "within" (such as when youth identify and call for changes in the way mental health services are organized to reflect their needs). In participatory processes where communities express their own collective voice and agency to an increasing degree, they build shared power as well as a consciousness and confidence to act. In contrast to fears that this paradigm diminishes the power of technical actors, it can be shown to create complementary forms of power that enable positive change, especially for community-level and frontline services, as exemplified in the case of Zambia described in **EXHIBIT 4-10**.

A growing number of studies using experimental or quasi-experimental designs in LMICs have demonstrated the potential of participatory interventions to generate health and health equity gains (Pronyk et al., 2006; Wallerstein, 2006). It is not easy, however, to be prescriptive about the specific mechanisms and measures to achieve these changes, as they are context

EXHIBIT 4-10 Social Participation and Power in Improving SDH in Lusaka, Zambia

Zambia is a lower-middle-income country; Lusaka is its capital city and home to 1.7 million people. The Lusaka District Health Office (LDHO) is the local health authority within Zambia's Ministry of Health. For more than a decade, LDHO has used participatory reflection and action (PRA) approaches to strengthen health services delivery at the primary care level and the role of neighborhood health committees (NHCs) as a more formal, sustained space for participatory interactions. As a matter of policy, NHCs involving elected community members are expected to identify and voice community health needs and to support information exchange between health services and communities.

In 2005, however, planning and budgeting for PHC was not participatory, and these committees were often poorly organized or not effective in their role. Growing public health problems in Lusaka motivated community members, health workers, and LDHO to address these shortcomings. Various participatory tools were used to identify needs, system barriers, and areas for change, and to build a shared identification of problems and actions to remedy them across health workers and community members. Information sharing between health workers and community members increased, community members became more confident in approaching health workers for information, and health workers provided the needed information to them for planning and resource allocation purposes. A range of actions were taken, including a cholera prevention strategy that led to significantly fewer cholera cases and deaths than in previous years, despite the heavy rains. By the end of this first phase of work, the community members had developed greater confidence and enthusiasm in seeing the process move forward. Likewise, health workers noted the benefits of improved communication with the community, though some feared losing power.

In 2008–2009, the same PRA approaches were used to scale up the health system by establishing new health centers in the city, while consolidating and building capacities to institute the approaches in existing ones, and building partnerships with a range of other sectors in areas such as clean-up campaigns, solid waste management, healthy food production, and services performance and uptake. These efforts were complemented by a range of approaches to organize and use community evidence. Photovoice (community photography), for example, presented evidence on community concerns with blocked sewers, health facility corruption, poor water supplies, and solid waste management during clinic and district health meetings held to trigger actions to resolve these problems. A wider community-level health literacy process with Lusaka residents drew evidence from their lived experience, facilitating community-level diagnosis, providing relevant health information, and stimulating action and engagement with health systems, in partnership with service providers, civic leaders, and the local authority. These approaches positioned the communities as change agents. Every three months, those working on the action plans met to review their work, reflect on their experience, and evaluate their progress.

Pre- and post-intervention surveys and reports from health workers and communities about the initial 2006–2008 PRA work found improved interactions between health workers and community members and partnerships with other actors, and increased confidence of community members in providing inputs to planning processes in support of action on health. There is also some evidence of positive health outcomes associated with this work. For example, the clinic catchment areas where these activities took place had no cases of cholera in 2012–2015, at a time when other areas still reported cases. While it is not possible to solely attribute the positive outcomes to the PRA program, the removal of waste sites that were once a site of disease and the measures to increase community health literacy and action were perceived to have made an important contribution. The health literacy work and the engagement with neighborhood health committees is now being expanded beyond Lusaka in a national scale-up in light of the positive outcomes from the work done in Lusaka District (LDHO & TARSC, 2016; Lusaka District Health Management Team &TARSC, 2015; Mbwili-Muleya, Lungu, Kabuba, Zulu Lishandu, & Loewenson, 2008; Ministry of Health Zambia, LDHMT, & TARSC, 2012).

dependent. Many of the approaches are triggered by or involve action outside the health system, in other sectors and organizations, and within the community itself. Various features of health systems have, however, been found to support the spaces and shifts in social power that enable effective participation. These approaches include the following:

- Setting health interventions in sites that are familiar to communities, such as markets or schools
- Integrating community mapping, monitoring, and preferences in health planning
- Producing accessible information (such as through newsletters, meetings, and social media) that shares local experience and responds to perceived needs
- Using socially appropriate and participatory methodologies that build on and validate local experience and knowledge
- Involving and supporting community-elected and -located community health workers to strengthen communication and linkages between health systems and communities
- Providing opportunities for dialogue on community perceptions of services, through community audits, health watches, community councils, participatory research, and legal action
- Devolving meaningful budgets to lower levels of the health system to facilitate and support social roles
- Enabling communities to shape the "rules of the conversation" by giving them the ability, resources, and opportunity to define the terms and processes in which they participate and the issues they want to address, and to have input into national laws and policies
- Investing time and resources in, and providing management support for, health worker competencies and incentives for participatory processes (Benequista, Gaventa, & Barrett, 2010; Cornwall & Leach, 2010; Gilson, 2007; Loewenson, 2016; Loewenson et al., 2014; Mbwili Muleya et al., 2008).

Implementing such measures depends on wider contexts, including the political freedom, spaces, and capacities that groups have to voice their views and to exercise influence; the constitutional, legal, and policy frameworks, social organizations, and systems that enable participation and support an active and democratic culture; the sociocultural conditions and relations within communities and families; and a comprehensive understanding of health and well-being that integrates and is accessible to society (Arenas-Monreal, Piña-Pozas, & Gómez-Dantés, 2015; Loewenson, 2016). These factors are not just shaped at local and national levels. That is, the local SDH and the social, institutional, and technical processes that affect them are increasingly influenced by global processes, and by decisions made by global and international actors. This topic is discussed in more depth in the next section.

Global SDH, Local Impact: Experiences of Extractive Industries in East and Southern Africa

As noted earlier, globalization is transforming many of the social conditions that have the greatest impact on health, while also affecting the public policies and programs that target these determinants. Many of the elements identified within the socioeconomic and political context in Figure 4-2 are now influenced by global policies, institutions, and processes.

A review of international evidence on globalization and SDH identified that while globalization has both positive and negative impacts on health, its benefits are unevenly distributed (Labonte & Shrecker, 2008). In this review, the benefits were reported to have been primarily obtained by countries and communities that already had financial, land, physical, institutional, and human capital assets. While globalization has certainly brought opportunities, such as the flow of information and new global funding to address health issues, the rules of current forms of globalization were found to favor already rich countries and people, which have greater resources and power to influence their design (Labonte & Shrecker, 2008; World Commission on the Social Dimensions of Globalisation 2004). In sub-Saharan Africa, globalization policies were associated with debt crises, capital flight, and structural adjustment programs that were reported to have contributed in part to increased inequality in health and reduced gains in life expectancy (Labonte & Shrecker, 2008). Examples of the mix of positive and negative outcomes are shown in **EXHIBIT 4-11**.

With the growing impact of global determinants on health, an analysis of globalization and SDH merits deeper attention than a subsection of a chapter. The distribution of positive and negative impacts of global determinants of health is further discussed in the *International Trade and Health*, and *Global Health Governance and Diplomacy* chapters in this text, and

EXHIBIT 4-11 Globalization, Women's Occupational Roles, and Nutrition in Sub-Saharan Africa

A 2010 review of 62 peer-reviewed publications on pathways between globalization, women's occupational roles, and nutrition found a mix of positive and negative outcomes, although with greater documentation of negative outcomes for women's health and nutrition.

At the global and national level, 5 papers reported largely positive outcomes for SDH, with globalization-related innovations in technology and information, global normative commitments, and improved incomes, markets, and opportunities for improved diets from investments where women are involved in export-oriented farm production. However, 24 papers reported largely negative outcomes, with trade liberalization, terms of trade, market access, and value-added food chains largely benefiting existing wealth and foreign corporations; gender inequity in access to investment, technology, and extension services due to "gender-neutral" trade policies; shifts to imported foods and processed foods displacing local food crops with livelihood losses for women; and diminishing healthcare resources raising the costs of care.

At the community and household levels, 7 papers noted largely positive impacts in terms of improved returns from new technologies in crop yields, increased nonfarm employment, and information flows that challenged gender-related discrimination improving women's conditions, with positive returns for household nutrition. Here, too, however, the larger number of papers (34) pointed to negative impacts at the community and household levels from determinants related to global trade, arising due to weak consideration of existing gender inequities in access to and control over production inputs in policy and program design; insecurity of and poor wages in new forms of employment; decreased time for household needs and neglect by women of their own well-being to meet time and resource demands; and decreased availability of local foods and increased consumption of higher-cost and poorer-quality imported and processed foods (Loewenson, Bambas Nolen, & Wamala, 2010).

so is not covered in detail here. This section explores global drivers of local SDH and the responses to them through the example of the extraction of mineral resources from Africa, largely through global corporations and interacting with global capital markets. It also highlights how global and regional norms can be positively applied to address negative health outcomes.

In 2009, Africa's oil, gas, and minerals exports were worth roughly five times the value of international aid to the continent ($246 billion versus $49 billion), with African oil and mineral resources sought after by high- and middle-income countries, including the emergent economies of China, Brazil, and India (Loewenson, Hinricher, & Papamichail, 2016). A surge in demand led to exploration and development of many new mining sites and new agreements exchanging investment in infrastructure for mining rights to oil, coal, and various strategic minerals (Besada & Martin, 2013; Shelton & Kabemba, 2012). As a consequence of this activity, African countries are increasingly engaging in global markets. At the same time, the rewards from these ventures are reported to be skewed toward those countries and individuals who have existing economic power (Birdsall, 2005). African countries that are rich in these mineral resources have experienced high levels of inequality and poverty—often referred to as "the resource curse" (Global Witness, 2012). A literature review of the health and SDH related to extractive industries in east and southern Africa found that they are significant economic actors in the region, but with limited forward or backward linkages into the national economy and limited job creation outside the sector, unless specifically stimulated (Loewenson et al., 2016).

This finding draws attention to how extractive industry (EI) activities, as a determinant of health, meet their responsibilities to protect against harm to health and make fiscal contributions to health care for the populations who work in or are affected by them. Corporations have duties to assess the potential risks of their activities to workers and surrounding communities, and to prevent and manage these risks. In recent years, more attention has been given to environmental risks associated with EIs, to EI company's duties to populations displaced by their activities, and to the duties that they have to inform and enable co-determination and participation of those affected in making the decisions that affect their health (International Labour Organisation, 2014; Murombo, 2013).

The health benefits of EIs have largely come from employment, income, and some service provision, generally for those persons who are directly employed by the mining companies and their families, and from EI fiscal contributions to public services. Nevertheless, tax exemptions often reduce their contributions to social funding. EIs also bring risks to health: They have been found to lead to accidents, hazardous

working conditions, environmental hazards, degradation of ecosystems, poor environmental health infrastructure, and displacement of local people—all of which increase the risk of disease. The literature reports the spread of communicable diseases (such as tuberculosis) and cholera epidemics from poor environmental health infrastructure, sexually transmitted diseases, and HIV in communities surrounding the mines (Aaboe & Kring, 2013; Catholic Relief Services [CRS], 2011; Loewenson et al., 2016).

Poor communities living around the mines are reported to be particularly vulnerable to pollutants, given their poor living conditions, with less recognition or monitoring of their risks. They are also least able to obtain reliable information on these risks, or to register their concerns with decision makers (CRS, 2011; von der Goltz & Barnwal, 2014). Mining is associated with (sometimes forced) displacement of communities, with reports indicating several thousand families having been resettled to facilitate mining in some countries (Global Environment Facility [GEF], Open Society Initiative for Southern Africa [OSISA], & United Nations Development Programme [UNDP], 2013; Human Rights Watch [HRW], 2013). As a health determinant, poor planning of such displacement is reported to have led to loss of livelihoods; loss of access to water, flora, arable land, and pastures for livestock for these communities; and substandard living conditions. Affected communities were poorly consulted on plans discussed with government, making it difficult for them to hold companies accountable when they did not deliver on commitments, and generating social frustration (HRW, 2013). For those living near mines or displaced by mining, exclusion from decision making on measures to address the health and social impacts, noted in many reports, is reported to have led these groups to "bear a disproportionate share of the costs of mineral development without adequate compensation, and to receive an inappropriately small share of the economic and social benefits" (International Institute for Environment and Development, 2002, p. 208).

As a key structural determinant, the policies and actions of the state play a vital role in protecting the health of populations caught in the midst of these global processes. For the health sector, this calls in part for public health leadership to leverage cross-sectoral health-promoting actions to manage health risks. **EXHIBIT 4-12** overleaf tells the story of one such response—that is, the experience of Tete in Mozambique. Other examples exist of state action in the east and southern Africa region, including using environment and health impact assessments to assess health risks, implementing audits to review the performance of EIs as in Zambia, and setting contract/lease renegotiations or renewals to review, require, or impose new obligations in Democratic Republic of the Congo, Zimbabwe, South Africa, and Mozambique (De Backer, 2012; GEF et al., 2013; Kabemba, 2014). While EI contributions for health and social welfare are generally identified as areas of voluntary corporate social responsibility (CSR), Democratic Republic of the Congo introduced a micro-levy on EIs in September 2014 to fight chronic malnutrition; in the same year, Zimbabwe lifted the exemption on the sector that had allowed EIs to avoid contributing to the AIDS Levy Fund (Loewenson et al., 2016).

As multinational EIs are themselves global actors, managing health in conjunction with EIs also calls for global governance arrangements to recognize and integrate social obligations for addressing SDH. At the global level, there are now numerous international standards, codes, or guidance documents related to the practices of EIs and multinational enterprises. These exist at the UN multilateral level, from Organisation for Economic Co-operation and Development (OECD) countries, at the African Union level, from financial institutions, and in CSR standards developed by international business and by civil society. Some regions, such as the Economic Community of West African States (ECOWAS) in West Africa, have moved toward a "strength in numbers" approach, with efforts to harmonize laws relating to EIs, including laws targeting health and social protection at the subregional level (Loewenson et al., 2016). The inclusion of these global norms as legal provisions in east and southern Africa and their strengthened implementation and oversight with accountability at the global, regional, and national levels, including in the source countries of EIs, have been identified in the literature as important measures to address the local health impacts of such global-level determinants (Loewenson et al., 2016).

The focus on EIs in this section presents one example of global-level SDH. Many others could be cited, including in the various dimensions of trade and health and climate change discussed in other chapters in this text. The experience in Tete described in Exhibit 4-12 and that of other countries in east and southern Africa in managing these challenging contexts suggests that while local communities and services may be organizing cross-sectoral responses to such global drivers, more attention is needed to determine how best to ensure that global standards are enforced, including by transnational, private actors.

EXHIBIT 4-12 Managing SDH in the Context of a Growing Extractive Sector: Tete, Mozambique

Tete province's geographical positioning, significant natural assets, and influx of investment, people, and capacities offer opportunities for addressing health needs in this region. Investments in hydroelectric power and coal mining have dominated recent investments in Tete, such that the province had the second highest provincial GDP growth in Mozambique between 2002 and 2008, largely driven by extractive industries. While these investments have brought economic benefit, they have also placed demands on infrastructure and services, led to displacement of people, and increased risks of injury, ill health, and social risks from displacement, harmful alcohol use, and road traffic accidents. Within the context of the communicable, reproductive, and other health burdens in the province, there is evidence of high social deficits in the very districts that host these large projects. The population in Cahora Bassa, a district with significant new power projects, has poorer health status outcomes than the populations in districts with less investment; Moatize, where the mines are concentrated, has fewer health service resources and poorer coverage outcomes; likewise, Tete City, a richer area and the focus of economic activity, also has poor health status outcomes. Tete City, Cahora Bassa, and Moatize had calorie-adjusted poverty rates in 2007 that were higher than those in most other districts in the province, including districts that were worse off than these three districts in 1997.

These findings raise the question of how such economic investment can be better linked to improved population well-being. One route for managing these SDH is through upstream entry points, linking EI activities to value-added local production, including in small and household enterprises, and providing links to their markets and infrastructures. Further upstream entry points include improved corporate fiscal and other resource contributions for public spending on education, health, and other social services, and the integration of health and social impacts in environmental impact assessments prior to granting a mining license.

Within this context, an assessment of the SDH, opportunities, and deficits carried out in 2014–2015 with the Tete provincial department of health (DPS Tete) identified key areas of action for the five-year provincial health strategy, including the following:

1. Closing the gap in improved household living conditions implemented through an intersectoral mechanism; ensuring all schools and health centers are connected to the power network; promoting small enterprise production of clean technologies for household cooking and energy; earmarking budgets and levies from local businesses for rapid improvements in rapidly growing settlements, such as Tete City and Moatize; and monitoring risks, interventions, and health impacts.
2. Promoting and protecting worker and community health in production activities, with measures outlined to promote occupational and community health and protect against production-related risks, including through environment, social, and health impact assessments; involving health personnel in oversight of corporate duties related to resettlement; and integrating company roles and resources in health services and activities in their districts.
3. Coordinated multisectoral strategies to improve food security and nutrition.
4. Expanding and improving equity in access to PHC, and positioning the health sector as a key redistributive sector in inclusive development, including through entry points in schools and workplaces, through private-sector contributions to healthcare services, and by enhancing community health literacy.

The province is now building support within other sectors for wider cross-sectoral implementation of these actions under the leadership of the governor of the province and with representatives of sectors at the national, provincial, and district levels (Loewenson & Simpson, 2015; Ministério da Planificação e Desenvolvimento, 2013; Ministério de Saúde, Mozambique, 2014; Republic of Mozambique et al., 2016; Salvucci, 2014).

Evaluating Action on the Social Determinants of Health and Health Equity

This chapter has presented evidence on the diversity of SDH and on the analysis and actions being applied to tackle them, including measures to address health equity. WHO's CSDH was a culmination of longstanding efforts by policy makers, state officials, academics, practitioners, and civil society to improve knowledge and evidence on the nature and extent of social determinants of health equity and to identify and implement policy or program actions to tackle them (Simpson, Kelly, & Morgan, 2013). Evaluation of such interventions has been important to gather evidence and build learning from their implementation about options to address the social determinants of health inequities; one such evaluation is described in **EXHIBIT 4-13**.

One of the recommendations of the CSDH to "close the gap in a generation" was to "measure the

EXHIBIT 4-13 Evaluating Interventions to Reduce Health Inequities

A six-year program was implemented in the Netherlands in the late 1990s to systematize learning from policies and interventions to reduce health inequities. Twelve studies were commissioned to evaluate a range of interventions to tackle SDH known to contribute to health inequities *and* to reduce exposure of lower-socioeconomic groups to these factors (e.g., poorer working conditions). Methods used ranged from observational to quasi-experimental to experimental studies. Evaluation of seven interventions gave positive results, with the researchers finding an improvement in at least one health outcome and/or an intermediate outcome. For example, a rotation of tasks among dustmen (i.e., garbage collectors) reduced physical workload and sickness absenteeism. Overall, the program sought to contribute to an evidence-informed approach for developing a national response to health inequities. It recommended that evaluation studies using a variety of approaches be embedded in all future interventions on health inequities (Stronks & Mackenbach, 2005; Simpson et al., 2013).

DEFINITION

A *realistic evaluation* approach combines assessment of design, process, and outcome and attempts to provide answers not only about which interventions work to address SDH, but also how they work and in which context(s) (Kelly et al., 2007).

problem, evaluate action, expand the knowledge base, develop a workforce that is trained in the social determinants of health, and raise public awareness about the social determinants of health" (CSDH, 2008, p. 20). This includes ensuring routine local, national, and international monitoring of SDH and health equity; investing in and building capacities to generate and share new evidence on the relationship between SDH and population health and health equity, and on the effectiveness of interventions to tackle these SDH; and raising public awareness on the findings (CSDH, 2008).

To date, a significant body of evidence has been developed on the "problem," on the link between specific SDH and health outcomes (particularly for intermediary SDH), and on the associations between SDH and health equity. By comparison, progress has been slower in evaluating the effectiveness and equity impact of interventions, and in generating attributions of impact to health or health equity and structural SDH. In part, this is due to the complexity of the methods used and the evidence needed to assess the commonly multicausal and context-dependent nature of the interventions for the "problem." While there is increasing recognition of the value of implementation and health systems research using new methodological approaches, there has been a continued predominance of a biomedical paradigm in health research and the use of traditional evidence-grading systems to value evidence. This has led to intervention studies on SDH, and the qualitative methods used to understand contexts for and impacts of complex interventions on SDH, often being classified as "unscientific" and "value-laden," despite their reliance on accepted social science methods (Baum, 2010; Bonnefoy et al., 2011). That this situation is changing is evidenced, for example, by the growing efforts to measure action on SDH among and within countries, by the documentation of country-level action on SDH, and by the Cochrane Equity Methods Group guidance on explicitly addressing equity in systematic reviews (Campbell & Cochrane Equity Methods Group, 2017; O'Neill, Tabish, Welch, Petticrew, Pottie, Clarke et al., 2014).

The CSDH Measurement and Evidence Knowledge Network emphasizes that no single approach to the generation of evidence should be favored over others and that evidence should not be appraised on the basis of adherence to a single evidence hierarchy or method (Kelly, Morgan, Bonnefoy, Butt, & Bergman, 2007). Health impact and equity impact tools, such as those outlined earlier, and more comprehensive approaches such as "realistic evaluation," support evidence on SDH and health equity because they move beyond simply estimating the likely effect of policy, to constructing logic models that show the implementation chain from policy to implementation in practice (Kelly et al., 2007). A range of methods and evidence enable practitioners to understand the complexity of mechanisms and the multifactorial nature of determinants that apply in practice and can make explicit the theories upon which programs are based. Realistic evaluation, for example, helps to capture the linkages between the context (the necessary conditions for an intervention to trigger mechanisms), the mechanisms (the aspects of a particular intervention that lead to a particular outcome in a given context), and the outcomes (the practical effects produced by causal mechanisms being triggered in a given context) (Kelly et al., 2007).

As argued earlier in this chapter, evidence and analysis contribute to the building of the relationships and complexity of interventions often needed to address SDH, including for intersectoral action and HiAP. Having an explicit and shared conceptual framework and theory of change at the outset helps to clarify the pathways for change, to identify shared outcome measures for assessing performance and impact, to prioritize action, and to test the thinking, thereby informing subsequent IAH work (Loewenson, 2013a). Analytic frameworks that explicitly include the assessment of equity in the design, implementation, and assessment of outcomes, while important, are not always present in evaluations of intersectoral action on SDH (Shankardass, Solar, Murphy, Greaves, & O'Campo, 2012).

The South Australian program on HiAP described in Exhibit 4-2 has, for example, taken a two-phase approach to evaluating its work: The first is an evaluation of perceptions of, interests in, and processes for HiAP implemented through interviews with senior South Australian public servants from the beginning of the initiative and continued in tandem with the health lens analysis. The second is a more comprehensive approach implemented in three overlapping stages over a five-year period (2012–2016) and using mixed methods, including test of a logic model of and theories of change for the work, shown in **FIGURE 4-7** (Baum et al., 2014).

Semi-structured interviews were implemented with key political figures, officials, and other actors who have knowledge of the HiAP process to generate knowledge to support its development and implementation. In the second stage of the evaluation, the theories developed in the first stage were tested, and the program logic and practice of implementation of the HiAP examined in eight health lens analysis projects, with detailed analyses in two of these health lens analyses and online surveys of policy actors administered regularly over the five-year period. A final stage synthesized the evidence to produce transferable knowledge and disseminate findings in annual research forums for peer review and discussion (Baum et al., 2014).

The features of the South Australia evaluation, which included multiple methods, stages, and areas of

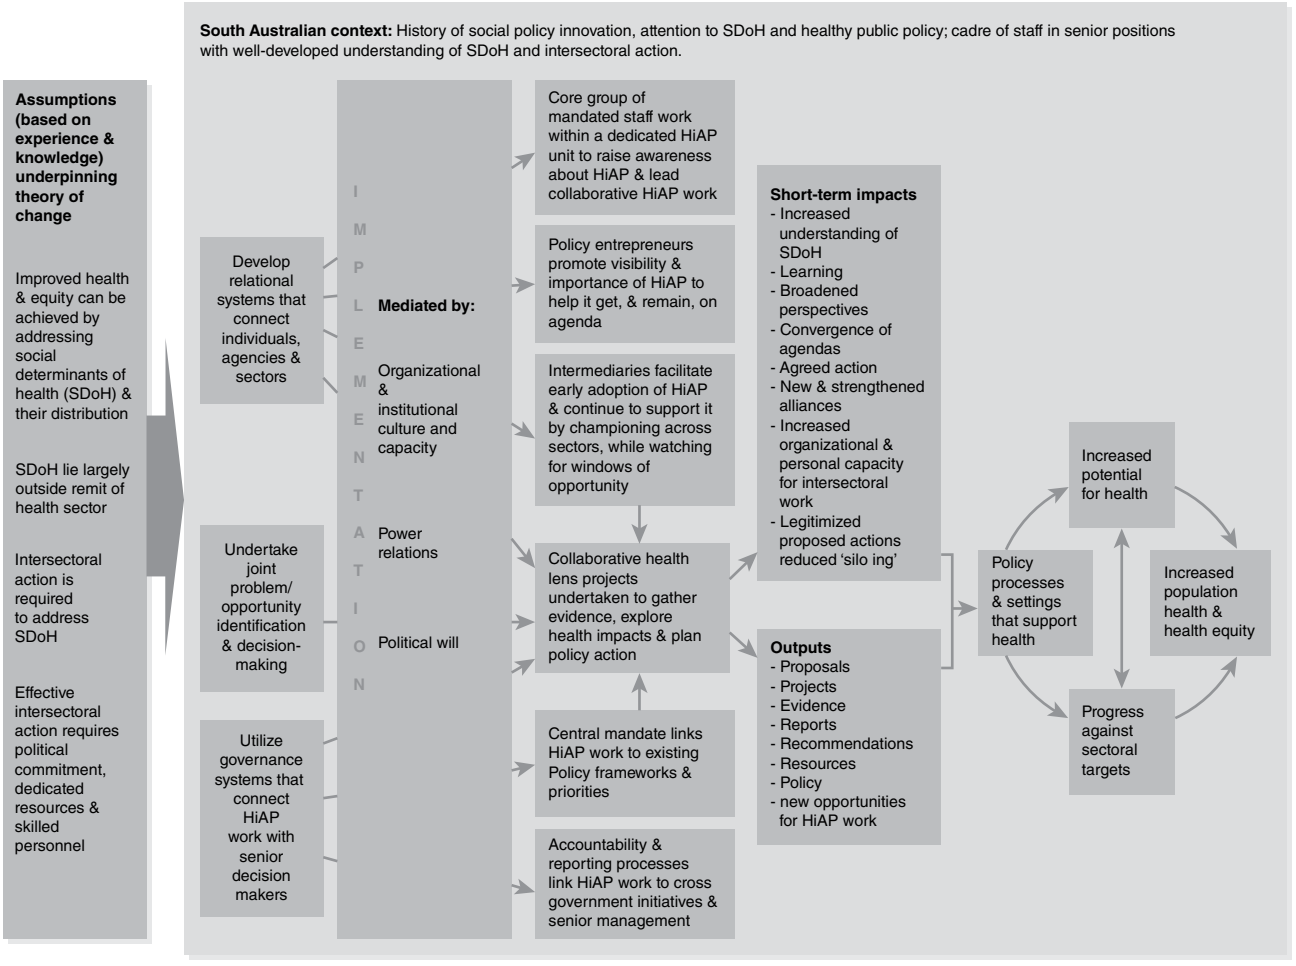

FIGURE 4-7 A preliminary program logic approach for evaluating HiAP in South Australia.

focus in the evaluation and multiple forms of evidence generated to support strategic reflection, are reflected in other processes for evaluating SDH. WHO has developed Innov8, an eight-step analytic process to be undertaken by a multidisciplinary review team to identify improvements in program performance and actions on SDH, health equity, and gender equality, as well as progressive realization of universal health coverage and the right to health. Innov8 applies realistic evaluations and integrates areas of human rights, health systems strengthening, and gender into its assessments. It builds a theory of change into the review analysis, including how and why interventions and activities are expected to produce results in these areas (WHO, 2016). A series of Innov8 publications and resources, including country case studies, are available that demonstrate application of this approach in areas such adolescent sexual and reproductive health, maternal and child health, and cervical cancer screening (WHO, 2016).

Routine collection, review, and reporting of data on SDH are as important as specific evaluations for effecting changes in and ensuring accountability of policy commitments made. Further, while increasingly sophisticated methods are available for measuring and analyzing social gradients in health and the impact of interventions, actually *using* such information in policy and stakeholder forums is critical to realize improvements in SDH and health equity. WHO (2013b) provides a resource for ministries of health to support the monitoring of social determinants of health equity, through a series of eight online presentations and a link to the Health Equity Assessment Toolkit (HEAT; a software application that facilitates assessment within and across countries using available data).

Equity Watch reports provide a further example of use of evaluations—in this case, analyzing routine, household, and available community data on SDH and health equity in Africa (**EXHIBIT 4-14**). Almost all ESA countries have made policy commitments to promote equity in health. In 2007, the Regional Network on Equity in Health in East and Southern Africa (EQUINET)—a network of professionals, civil society, state, parliament, and academic actors promoting health equity—analyzed and reported on health equity in the region, building a cooperation with the east, central, and southern Africa (ECSA) health community to gather and report on evidence on health equity (Rasanathan, 2011). In 2012, an "Equity Watch framework" of 25 priority indicators of health equity was used to organize evidence from 16 countries in east and southern Africa, complemented by Equity Watch work in countries (EQUINET, 2012). National teams in six countries in the region involving state and nonstate actors and working with EQUINET organized, analyzed, and presented quantitative and qualitative evidence to assess progress in addressing health inequities, to evaluate social determinants and health care, and to inform social dialogue on proposals for strengthening health equity. The national reports have been used to monitor implementation of equity in the implementation of the national health strategic plans (in Zambia and Zimbabwe) and to inform policy dialogue (in Kenya and Zimbabwe) and research (in Mozambique and Zimbabwe) (EQUINET, 2012; Rasanathan, 2011). The Equity Watch process is an evidence-driven approach to strengthening rights to participation and accountability on equity in relation to SDH and universal health systems.

A range of indicators are used in such processes for relative and absolute measures of health inequities (e.g., rate ratios and rate differences across two groups) and to gain insight into the patterns of health inequities in populations, such as through the Gini coefficient or the concentration index (Kelly & Doohan, 2014). The indicators used may be related to the following issues:

- Political and legal factors, such as the presence of constitutional rights to health or, conversely, the presence of constitutional or legislative barriers to health, such as early marriage
- Economic factors, such as the gross domestic product, level of tax revenues, and household poverty or wealth, often expressed in quintiles of the population

EXHIBIT 4-14 The Equity Watch in East and Southern Africa

An Equity Watch is a means of monitoring progress on health equity by gathering, organizing, analyzing, reporting, and reviewing evidence identified from policy commitments made and from research evidence deemed relevant for improving equity in health. In addition to areas of importance for specific countries, 25 progress markers are included in all Equity Watch reports:

- Five markers of advancing equity in health
- Seven markers of access to national resources and SDH
- Eight markers of resourcing redistributive health systems
- Five markers of a more just return from a global economy

Information and country and regional equity watch reports are available at www.equinetafrica.org (EQUINET, 2012).

EXHIBIT 4-15 The EU's SOPHIE Project

The EU's "Evaluating the Impact of Structural Policies on Health Inequalities and their Social Determinants, and Fostering Change" (SOPHIE) project sought to generate new evidence on the impact of structural policies (macroeconomy, welfare state, employment relations, unemployment, built environment, and housing policies) on health inequalities, and to develop innovative methodologies for the evaluation of these policies in Europe. The Gender group of SOPHIE developed guidance for assessing how gender intersects with other social, cultural, and economic determinants, and evidence on how gender-oriented and immigration-related policies affect health inequalities. This work enables strengthened and more comprehensive evaluations of the health equity impact of policy and interventions. The main findings of the SOPHIE project include the following: (1) Evaluating structural policies is a new methodological challenge; (2) mixed methods are essential to the evaluation of structural policies; and (3) realistic approaches help to address new and vital questions, while noting the need for a clear and efficient working protocol to be developed. Further information is available on the SOPHIE project at www.sophie-project.eu/project.htm (Palència, Malmusi, & Borrell, 2014).

- Services and entitlements, such as education completion, health service coverage, or social protection
- Living standards and material conditions, such as access to clean water, air pollution, traffic density, housing, and sanitation
- Social features, such as culture, residence, class, occupation, ethnic groups, age, gender, disability, and religion (Kelly & Doohan, 2014; Solar & Irwin, 2010)

Some key factors, such as power relations, social control/autonomy, and social support are less easily measured and often less effectively included in assessments. Factors such as gender may be intertwined with power relations and other SDH in generating health inequities. As noted at the beginning of this chapter, sociopolitical processes are themselves structural determinants that can persistently impact on health outcomes, such as the processes of colonization that negatively impact indigenous peoples' health (Axelsson et al., 2016). For this reason, research and evaluation of policies affecting determinants of health equity need to take all these dimensions and their intersections into consideration, as in the European Union's SOPHIE project (described in **EXHIBIT 4-15**).

It is important that the processes for evaluation, monitoring, and analysis strengthen the social power of those affected by these SDH, and do not alienate them. In part, this means explicitly including SDH prioritized by these groups, including those determinants that are difficult to measure, and directly involving affected communities as researchers and agents of change in analysis and learning from action, such as in participatory action research and participatory evaluation processes (Loewenson et al., 2014; SHaPeS Thematic Working Group of Health Systems Global et al., 2016).

Conclusion

This chapter has explored a range of country experiences and published reviews and papers to develop a conceptual understanding of the different levels and types of SDH; their relationship to health equity, human rights, and gender equality; and their implications for health systems and for intersectoral and whole-of-government actions directed toward health and health-in-all-policies systems. While clearly a "work in progress," the growing body of evidence on all levels of SDH and their association with health outcomes is opening a deeper understanding of the "causes of the causes" in health outcomes. It is also building knowledge on how SDH at a structural level generate social stratification and social differentials in a range of intermediary SDH with an impact on health. Where these social differences in health are avoidable and remediable, they call for action on the SDH underlying them as a matter of social justice and human rights. The SDH perspective draws attention to measures to frame, understand, and integrate into interventions factors such as social exclusion, social agency, and power.

Through these approaches, those working in health-related fields can promote health and well-being and address differences in exposure and vulnerability. They can take a leadership or facilitating role in intersectoral action, and mediate or mitigate the financial, social, and physical consequences of illness. This is not just a matter for local and national levels to address. As this chapter has pointed out, globalization is influencing structural and intermediary SDH at the national and local levels, driving the need for normative and other actions on such SDH from the local level to the global level, to ensure fair benefits and prevent harms.

This chapter concluded with observations on how the positive or negative impact of these actions may be monitored and evaluated, including in terms of their distributional impacts. Evidence on and analysis of the relationship between SDH and health (equity) outcomes, while raising measurement and method challenges, is important to inform action, and to support evaluation of interventions and processes that seek to "close the gap."

At the same time, these policies and actions need to be understood in terms of how they affect the social power and status of those communities affected by them, and how they impact procedural justice. Participatory processes, wherein communities document and express their collective experience, voice, and agency, can build forms of shared power and social support that enable and sustain action on SDH, and are a social asset and a right in processes that build knowledge and action on SDH. Addressing unfair, avoidable, or remediable differences in SDH and improving health equity outcomes among population groups is not simply a technical issue: It is an ethical issue, a matter of social justice, and an outcome of social power and action.

Acknowledgments

The authors acknowledge complementary work by Kelly and Doohan (2014) in a chapter on SDH in an earlier edition of this text, together with the contributions to this field of the work made by the Commission on the Social Determinants of Health, by WHO, by regional organizations such as EQUINET, and by the many country actors cited in the chapter. We are grateful to Victoria Saint for her peer review of an early version of the chapter.

Discussion Questions

1. What is the difference between health inequality and health inequity?
2. What are the key features and dimensions of conceptual frameworks that explore the relationship between social determinants of health and health equity?
3. What are the different ways that action on SDH can reduce health inequities? Provide an example of each.
4. What role does gender play in health equity? How does a human rights approach affect the way this issue is addressed? Provide examples to demonstrate your response to both questions.
5. What can health systems do to support the measures for successful implementation of intersectoral action for health? Which features of health systems have been found to facilitate these roles? Provide examples to demonstrate your response to both questions.
6. "Social power affects the ability people have to influence and make choices over health inputs and to use these inputs to improve their well-being." Explain, with concrete examples, the pathways through which social power may positively or negatively affect health equity.
7. What are the key features of approaches used to monitor and evaluate interventions on the social determinants of health equity?

CHAPTER 5

Reproductive Health

M. Omar Rahman, Jane Menken, and Dipak Kumar Mitra

Reproductive health in low- and middle-income countries (LMICs) has long been addressed primarily through family planning and maternal and child health programs, and through programs to prevent and treat sexually transmitted infections (STIs), particularly human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS).

Reproductive health is tied to policy concerns about population growth as well as health. In 1994, the United Nations (UN) sponsored the third decennial International Conference on Population and Development (ICPD) in Cairo. The previous two conferences had emphasized family planning and economic development, respectively, as the major focus of population policy—policy that was intended to reduce fertility and, thereby, population growth. The rationale for support of family planning programs included both the right of individuals to control their own fertility and the belief that reduced fertility would lead to reduced population growth, which would have benefits for individuals, nations, and the world. In 1994, for the first time, women's health advocates, including many from nongovernmental organizations (NGOs), played a key role in the ICPD and brought to the fore issues of reproductive health that went beyond family planning. They called for a fundamental redefinition of population policy that focused on the status of women and gave "prominence to reproductive health and the empowerment of women while downplaying the demographic rationale for population policy" (McIntosh & Finkle, 1995).

The 1994 ICPD adopted a Programme of Action that included the following definition of reproductive health:

> Reproductive health is a state of complete physical, mental and social well-being, and not merely the absence of disease or infirmity, in all matters relating to the reproductive system and its processes. Reproductive health therefore implies that people are able to have a satisfying and safe sex life and that they have the capability to reproduce and the freedom to decide if, when, and how often to do so. Implicit in this last condition are the right of men and women to be informed and to have access to safe, effective, affordable and acceptable methods of family planning of their choice, as well as other methods of their choice for the regulation of fertility which are not against the law, and the right of access to appropriate health-care services that enable women to go safely through pregnancy and childbirth and provide couples with the best chance of having a healthy infant. . . . It also includes sexual health, the purpose of which is the enhancement of life and personal relations, and not merely counseling and care related to reproduction and sexually transmitted diseases (United Nations, 1994).

This vision of reproductive health has—perhaps not unexpectedly—proved controversial and has not been achieved to the extent hoped for by its

proponents (see, for example, "Conference Adopts Plan on Limiting Population," 1999; "Population Control Measures to Aid Women Are Stumbling," 1999). Nor did donors uphold the pledges made at the Cairo conference. In 2003, the UN estimated that the international donor community had contributed far less than the pledges for reproductive health made at Cairo. Of the $6.1 billion promised by 2005, slightly more than $3 billion was provided through 2003 (Population Reference Bureau, 2004; United Nations Commission on Population and Development, 2004). However, since the initiation of Millennium Development Goals (MDGs) and other allied efforts, such as the "Global Strategy for Women's and Children's Health" and "Every Woman, Every Child" campaign, the situation has significantly improved. Commitments worth of approximately $45 billion were made to achieve MDG targets, of which $31 billion had been disbursed as of May 2015. Annual disbursement for women's and children's health increased from 2010 to 2013 by 25%, particularly in previously underfunded areas including family planning, where the increase was 50.5% from 2010 to 2013 (World Health Organization [WHO], 2015a).

A less controversial and more limited version of the vision for reproductive health guided the 1997 U.S. National Academy of Sciences report on reproductive health (Tsui, Wasserheit, & Haaga, 1997):

1. Every sex act should be free of coercion and infection.
2. Every pregnancy should be intended.
3. Every birth should be healthy for both mother and child.

Even so, no country, according to Tsui, Wasserheit, and Haaga (1997), met these more limited goals by 1997, and the problems were greatest in LMICs.

In 2000, the United Nations Millennium Declaration was adopted as a commitment to "making the right to development a reality for everyone and to freeing the entire human race from want" (United Nations General Assembly, 2000). Eight MDGs were established as part of the "Roadmap Toward the Implementation of the United Nations Millennium Declaration" (United Nations General Assembly, 2001). Goal 5 was to improve maternal health, with a specific target of reducing "by three quarters, between 1990 and 2015, the maternal mortality ratio." Despite significant improvements in maternal health during the MDG era (the world maternal mortality ratio [MMR] declined from 385/100,000 live births in 1990 to 216/100,000 live births in 2015), final estimates show that vast majority of LMICs failed to achieve the three-fourths reduction in maternal mortality required by MDG 5 (UNICEF & WHO, 2015). A wide variation exists in the reductions in MMR achieved in specific world regions. South Asian countries experienced the highest reduction, 67% (from 558/100,000 live births in 1990 to 182/100,000 live births in 2015), and sub-Saharan countries had the lowest reduction over the same period, 37%. The Sustainable Development Goals (SDGs) established as follow-ons to the MDGs have already been set, with the SDG being to bring down global MMR to 70/100,000 live births by 2030 (United Nations, 2016).

This chapter emphasizes both the older and the newer views of family planning and reproductive health. In the next section, which examines demographic trends, the focus is on population growth and change and the transitions under way around the world from situations of high fertility and high mortality to those of low fertility and low mortality. The ways in which people control their fertility and indices of the effects of various fertility determinants on overall fertility in a range of countries are then considered. The third section examines family planning programs and their role in the reduction of fertility and unintended pregnancy. The next two sections consider the role of fertility patterns in the health of children and women, respectively. The final section presents brief recommendations for future research and programs. Because the *Infectious Diseases* chapter focuses on sexually transmitted infections (STIs), including HIV/AIDS, these crucial aspects of reproductive health are mentioned only briefly here.

Demographic Trends and Fertility Determinants

History of Population Growth

To understand the context of the concerns about population and reproductive health in the world today, it is instructive to review the history of population growth and its associated impacts. **FIGURE 5-1** shows the growth of the world's population and, in particular, the extraordinary changes in growth rates over the past 200 years. The world population reached 1 billion just after 1800. By the turn of the twentieth century, it had reached 1.6 billion, and before 1930 it had surpassed 2 billion. Thus, it took less than 125 years to add the second billion people—an astounding feat given the long sweep of history needed to reach the first billion. World population passed the 3 billion mark in 1960. Each additional billion people has taken less time to add, so that by the year 2000, population had reached 6.1 billion. Thus, population doubled between 1960

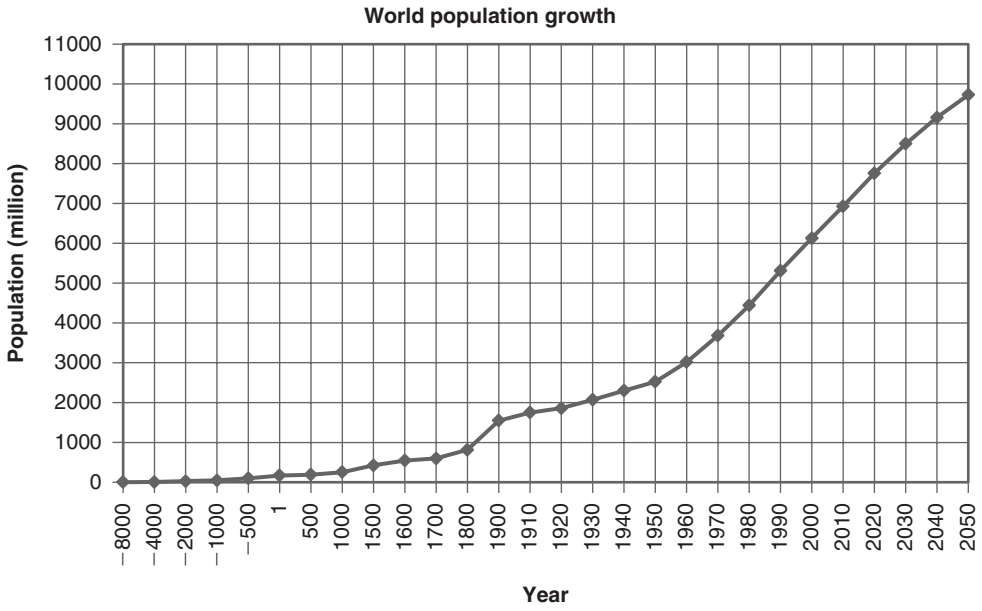

FIGURE 5-1 The growth of population and, in particular, the extraordinary change of the past 200 years.

and 2000, adding 3 billion people in only 40 years. By 2010, almost 1 billion people were added in just 10 years' time, so that world population in 2010 was 6.9 billion (United Nations Population Division, 2009); Figure 5-1). The global population projection until 2050 shows that every 10 years 1 billion people will be added in this planet (United Nations Population Division, 2015b).

The majority of this population expansion has taken place in the low- and middle-income regions of Asia, Africa, Latin America, and Oceania (**FIGURE 5-2**), which accounted for 84% of the world's population in 2010, compared with 71% in 1950. The share of world population in these regions is expected to continue increasing, reaching 88% in the middle of the twenty-first century (United Nations Population Division, 2015b).

The encouraging news is that the rate at which the world's population is growing has declined continuously since about 1960 (**FIGURE 5-3**), although the absolute *number* of people added in each decade has continued to increase. After 2000, that number was projected to decline. Population growth rates are declining in most LMICs, albeit at an uneven pace; that is, some countries and regions are experiencing much more rapid change than others. China is a particularly prominent example: Its growth rate was 2.1% in 1960, increased to 2.6% in 1965, but then steadily dropped to less than 1% by 1995 and is expected to reach zero growth by 2030.The United Nations estimates that world population in the middle of the twenty-first century will total between 8 billion and 11 billion people. By that time, the growth rate will be significantly less than 1% but will not yet have achieved the no-growth stable situation.

It is important to note that population projections involve complex statistical procedures with variable uncertainty, dependent on the stability of the mortality and fertility trend lines. This is particularly true as the projection period becomes longer. In hindsight, actual changes can vary significantly from the projections if mortality and fertility trends do not match expectations. For example, the UN projection made in 2008 estimated that the world population growth rate would decrease faster, reaching 0.34 in 2050. However, the updated projection in 2015 shows that the decline in world population growth will be relatively slower than earlier estimates and will reach only 0.57 by the year 2050 (Figure 5-3). This outcome reflects the combined effects of lower than expected fertility reduction and greater than expected mortality reduction, particularly in Africa. Fertility reduction was slower than expected due to lack of proper implementation of family planning programs, and mortality reduction was faster than expected due to better control of the HIV/AIDS epidemic in affected countries (May et al., 2014).

Because of reduced fertility and increased life expectancy, the proportion of the population consisting of people older than 65 years will increase over time from 8% in 2010 to 16% in 2050, while the proportion attributable to children younger than age 15 will decrease from 26.7% in 2010 to 21.3% in 2050 (United Nations Population Division, 2015b).

The Demographic Transition

What explains the historic experience of low initial population growth, followed by an explosive increase and finally by a steady decline in growth? The classic theory of demographic transition proposed by Notestein (1953) and others postulated that all societies initially start off with high fertility and high mortality levels. At some point in societal development, mortality rates fall due to public health advances, while fertility rates remain high. This combination results in explosive population growth, with birth rates far exceeding death rates, until at some point birth rates also start to decline and a new equilibrium is reached at low fertility and low mortality levels.

Until fairly recently, the classic theory of demographic transition held sway, and all societies were supposed to go through it in a lock-step manner. In the early to mid-1970s, however, an international team of researchers participated in the Princeton University European Fertility Project and carefully examined historical fertility declines in Europe. They came to a somewhat surprising conclusion: The process of demographic transition is quite varied and does not always follow the path suggested by classic theory (Coale & Watkins, 1986). Under that scenario, a certain level of socioeconomic development was required for the initial mortality decline, which was followed, at some later point, by fertility decline. Researchers in the European Fertility Project, however, found that mortality decline took place in different societies at different levels of development and that there was no magic threshold of mortality above which fertility decline would not take place.

The current consensus about the demographic transition is that there is no specific sequence in which fertility and mortality decline. They can decline together, or one can decline before the other. Furthermore, no specific thresholds of development are required for either process to start. Moreover, the intervals between a high-fertility and high-mortality regime and a subsequent low-fertility and low-mortality regime

are also not fixed and can vary considerably. The experience of the LMICs has borne out this new consensus. Demographic transitions have taken place at different rates in different places and with different sequences. A common thread, however, is that the transition has often been considerably more rapid than those seen in the European or North American historical record.

Population growth rates and fertility and mortality for different parts of the world since the mid-twentieth century to the mid-twenty-first century are shown in **TABLE 5-1**, and for the specific cases of Bangladesh and Kenya, in **EXHIBIT 5-1**. Growth rates are given as the percent change in population per year for the 5 years subsequent to the specified date. When a population stops changing in size, it becomes *stationary* and its growth rate is zero. The total fertility rate (TFR) is the number of children a woman would bear, on average, if they lived to the end of the reproductive period under the childbearing pattern of a particular year—for example, if they had, at age 15, the birth rate of 15-year-olds in 1970; at age 16, the birth rate of 16-year-olds in 1970; and so on. Life expectancy at birth is the average number of years people would live if their entire life were spent under the age-specific mortality conditions of a particular year—for example, if they experienced the infant mortality of 1970, the death rate at age 1 of 1970, and so on. The numbers resulting from these examples would be the 1970 TFR and the 1970 life expectancy. A TFR of approximately 2.1 is usually referred to as *replacement-level* fertility. If, over the long run, women have that number of children on average, the population will become stationary, neither growing

Note: Growth rate (% per year), total fertility rate, and life expectancy are for the subsequent 5-year period (e.g., 1950–1955). Life expectancy is for both sexes combined. All estimates are from the medium variant projections.

Data from United Nations, Department of Economics and Social Affairs, Population Division. (2015). *World population prospects: The 2015 revision, volume I: Comprehensive tables (ST/ESA/SER.A/379).* Accessed on November 10, 2016 from https://esa.un.org/unpd/wpp/publications/Files/WPP2015_Volume-I_Comprehensive-Tables.pdf

nor declining. Women will be contributing to the next generation one child for themselves and one for their partner, and a bit more for girls who were born but did not survive to reproduce.

As shown in Table 5-1, life expectancy rose continuously over the latter half of the twentieth century. The exceptions (not shown) occurred in the countries of Africa hardest hit by AIDS, where, by 2000, this disease had wiped out much, if not all, earlier gains (see Exhibit 5-1 for the specific case of Kenya). According to the United Nations, nine countries had adult HIV prevalence of 10% or more in 2009: Swaziland,

Botswana, Lesotho, Zimbabwe, South Africa, Namibia, Zambia, Malawi, and Mozambique (UNAIDS Fact Sheets, 2009). The U.S. Census Bureau (2004) estimated that, on average, life expectancy in 2010 will be significantly less in these countries than it would have been in the absence of AIDS. Much of the increase in every country in life expectancy is due to improvements in infant and child survival; by contrast, the HIV-related declines are primarily the result of increased adult mortality. However, the latest WHO (2016) estimate shows that African countries have overcome the setbacks posed by AIDS epidemic and that life expectancy dramatically improved between 2000 and 2015. With increasing access to antiretroviral treatment (ART), the number of AIDS-related deaths declined by 39% between 2005 and 2013 in sub-Saharan Africa, increasing life expectancy in that area by 10 years (Kharsany & Karim, 2016).

Total fertility rate had declined by 1970 in all parts of the world, with the exception of Africa. That decline was, in low- and middle-income regions, overwhelmed by increases in life expectancy, so that these

EXHIBIT 5-1 Demographic Change in Kenya and Bangladesh

Kenya (population = 46 million) and Bangladesh (population = 161 million) will be used as case studies to illustrate demographic change in this chapter for a number of reasons. There are both similarities and differences in their experiences.

First, similar to Bangladesh, Kenya experienced high population growth rates that were the result of continuing high fertility during a period when mortality was declining quite sharply. Thus, in the period 1950–1955, life expectancy was 40.5 years for males and 44.2 years for females. By 1980–1985, almost 16.5 years had been added to life expectancy for both males and females in Kenya, raising life expectancy there to 57 years for males and 60.7 years for females. In comparison, although life expectancy also rose sharply during the same period for Bangladesh, the increase was notably less than in Kenya (10 years for males and 14 years for females). Because Bangladesh started from a lower base in 1980–1985, life expectancy in Bangladesh was actually significantly (almost 10 years) lower than that in Kenya (male = 48.9 years; female = 50.2 years). As a result of the sharp decline in mortality coupled with continuing high fertility rates (during that period, the total fertility rate in Kenya exceeded 7 births per woman), population growth rates in Kenya increased from 2.77% per year in 1950–1955 to 3.78% per year in 1980–1985. Similarly, for Bangladesh, due to the sharp drop in mortality and the continued high fertility (TFR remained between 6 and 7 births per woman), there was also a sharp increase in population growth rates, from 2.11% in 1950–1955 to 2.61% in 1980–1985.

Second, as was the case in Bangladesh, a successful family planning program in Kenya managed to bring about a fertility decline despite relatively little improvement in socioeconomic indicators (Toroitich-Ruto, 2001). Fertility dropped sharply over the next 15 years, from 7.22 births per woman in 1980–1985 to 5.07 births per woman in 1995–2000. Fertility subsequently appears to have declined slowly; it was approximately estimated at 4.96 births per woman in 2005–2010 and 4.54 births per woman in 2010–2015. Both the initial sharp decline and the subsequent slower decline in total fertility rates are similar to the experience of Bangladesh, although TFR in Bangladesh remained at a significantly lower level—approximately 3.3 births per woman in 1995–2000—and subsequently dropped very slowly to an estimated 2.36 births per woman in 2005–2010 and 2.2 births per woman in 2010–2015.

Kenya, like other countries severely affected by AIDS, saw its life expectancy fall in the latter part of the twentieth century, from 57 to 51 years for males and from 62 to 52.3 years for females in 2000. Since then, the situation in Kenya has improved due to a significantly faster than expected morality decline resulting from more effective control of HIV in the post-2008 period. Additional gains of 4 to 5 years in life expectancies have been observed in both males and females for Kenya. However, unlike mortality reductions, fertility rates in Kenya declined much less than expected as per the 2008 projections. Instead of declining from 4.9 births per woman in 2010 to 2.39 births per woman in 2050, TFR will decline to only a projected 2.85 births per woman in 2050 as per 2015 projections. Thus, the annual population growth rate in Kenya was predicted to be 1.27% in 2050 by the 2008 projections and is now 1.69% according to the 2015 projections.

In the case of Bangladesh, since 2008, mortality reductions have been slightly greater than expected (an additional 2 years of life expectancy is projected through 2050) and fertility reductions have also been greater than expected, thus overriding the mortality decline. TFR, instead of declining from 2.36 births per woman in 2010 to 1.85 births per woman in 2050, is now expected to decline to a projected 1.67 births per woman in 2050. Thus, the predicted growth rate in 2050 for Bangladesh was 0.26% as per the 2008 projections and is now 0.18% according to the 2015 projections.

In conclusion, Kenya experienced significantly lower than expected declines in population growth rates in the post-2008 period due to a combination of higher than expected mortality decline along with significantly lower than expected fertility decline. Bangladesh, by contrast, experienced basically a flat picture, with a slightly higher than expected fertility decline matching the slightly higher than expected mortality decline.

regions' growth rates—and their population growth—increased. Fertility continued to fall, however, and at sufficient rates to counteract the continuing increased in life expectancy. This fertility transition is serving to bring growth rates down in all low- and middle-income regions today. HIV/AIDS may be contributing to recent declines in fertility in the parts of the world hardest hit by this disease; a mounting body of evidence indicates that infected women have reduced fecundity (Lewis, Ronsmans, Ezeh, & Gregson, 2004; United Nations Population Division, 2002). The changes in population growth rates, total fertility rates, and life expectancy are illustrated in Exhibit 5-1, which provides information for Bangladesh and Kenya from 1950 to 2050 using the medium-variant UN population estimates (United Nations Population Division, 2015b).

To understand the different types of fertility transitions that have taken place, we need an understanding of the determinants of fertility and fertility change in different contexts. An extensive body of literature has examined the impact of socioeconomic factors on desired family size (Bankole & Westoff, 1995; Bulatao & Lee, 1983; Rutstein, 1998). Much of this discussion centers on the costs and benefits of children and the notion that couples desire additional children as long as the benefits are greater than the costs. These benefits and costs are, in turn, determined by a range of factors, some of which are *structural* (e.g., wages, rates of return on investments, opportunity costs), and some of which are attitudinal (i.e., changes in values and expectations). Improvements in the educational status of women, for example, are thought to decrease desired family size because such trends increase the potential wages that women can earn and, therefore, raise the opportunity costs of childbearing. Education may, in addition, lead to attitudinal change about quantity–quality tradeoffs in numbers of children—for example, having fewer children so that greater investment in the education of each child is feasible.

Implicit in this theoretical framework is the idea that couples weigh a variety of alternatives, with childbearing being just one of the possible behavioral choices available. Other structural factors affecting fertility rates include trends such as increasing landlessness, which decreases the benefits of the labor provided by children and thereby tends to reduce family sizes. More recent research emphasizes attitudinal

change as affecting fertility rate. It posits that values and expectations can change as a result of outside influences. Thus, exposure to messages in which small families are treated as a marker for modernity may motivate couples to reduce their desired family sizes even in the absence of any changes in the structural costs and benefits of children.

Although this chapter focuses on LMICs, in almost none of which has fertility declined to replacement level, it is worth noting that high-income countries, especially those in Europe, are concerned about their very low fertility rates and population declines. For Europe as a whole, TFR fell to less than 1.9 births per woman before 1980 and has continued to decline. It is expected that the entire continent will have a negative growth rate for 2000–2020 (United Nations Population Division, 2009). Understanding which factors maintain below-replacement fertility and which factors cause it to increase is an important issue for high-income countries.

How Do People Control Their Fertility?

In addition to considering *why* people control their fertility, we need to understand *how* people actually do so. It is useful first to consider the *proximate determinants* that lead to variation in fertility in the absence of deliberate family planning (Bongaarts, 1978, 1983; Menken & Kuhn, 1996; Sheps & Menken, 1973). These proximate determinants can be divided into those that affect the *reproductive span* and those that influence the *intervals between successive births* within that span. As shown in **FIGURE 5-4**, the *effective reproductive span* exists within boundaries set by both the *biological span* and the *social reproductive span.* The biological span is the time during which a woman is capable of childbearing because she has the biological capacity to ovulate and to carry a pregnancy to a live birth. It is usually marked by menarche and menopause, but first ovulation may occur well after menarche and last ovulation precedes menopause.

In no society, however, do women devote their full biological span to reproduction. Were they to do so, according to Bongaarts (1978), women who survive to sterility would bear more than 15 children on average. This figure is well beyond the maximum ever recorded for any population.

Every society has social controls on initiation and cessation of sexual activity. We will refer to entry into sexual activity as *marriage* and cessation as *marriage dissolution*. We use these terms as social markers rather than as representing legal ceremonies and arrangements of the state. Specifically, marriage dissolution can occur through breakup of the relationship or through widowhood. The social reproductive span is, therefore, the interval between initiation and cessation of sexual activity. The effective reproductive span is the overlap of the biological and the social spans. It begins with the later of menarche and marriage and ends with the earliest of sterility, death, and cessation of sexual activity. In many societies, the effective reproductive span is interrupted by time between successive unions or by temporary separation of spouses.

Within the effective reproductive span, the pace of childbearing is determined by the lengths of the successive intervals between births (B1, B2, and so on in Figure 5-4). We will first discuss birth intervals in the

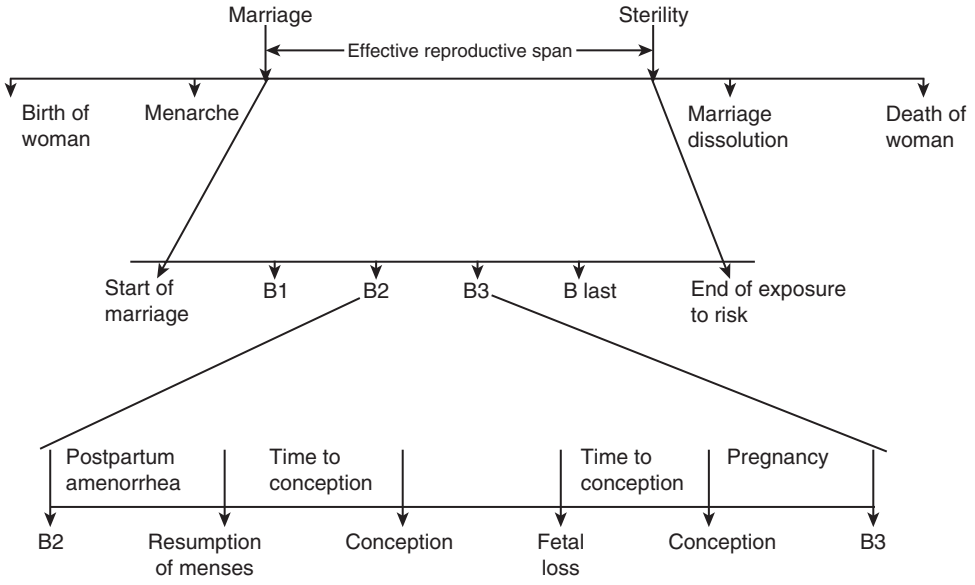

FIGURE 5-4 Reproductive span and birth intervals.

absence of deliberate family planning. The birth interval may be divided into several segments:

- The postpartum period after a birth until both ovulation and sexual relations resume
- The time to conception
- Additional time due to fetal loss through spontaneous abortion
- The pregnancy leading to the next live birth

Fertility in the Absence of Contraception and Induced Abortion

The postpartum period ends when both ovulation and intercourse have resumed. It is largely determined by the duration and intensity of breastfeeding and by postpartum taboos against intercourse by a nursing mother. Women who do not breastfeed usually menstruate for the first time approximately two months after giving birth (Salber, Feinleib, & Macmahon, 1965). Frequent, intense breastfeeding, however, can postpone average time of ovulation to more than 20 months (Wood, Lai, Johnson, Campbell, & Maslar, 1985). Some populations, particularly in sub-Saharan Africa, have traditionally had taboos against intercourse that can lengthen the postpartum period beyond the resumption of ovulation, but these practices are rare outside this region and their observance is believed to be decreasing.

Breastfeeding not only provides the child with nourishment (see the *Nutrition* chapter), but also, depending on the pattern of suckling, can postpone the return of ovulation for many months. It exerts this effect through a maternal response to suckling that suppresses the secretion of gonadotropins. The classic studies of McNeilly (1996) and his colleagues showed that "if the frequency of suckling is maintained above five times a day and the duration is maintained above 65 minutes a day, amenorrhea will often be the consequence." Others have found that night feeds are particularly important in maintaining amenorrhea (Jones, 1988). Women who fully breastfeed their infants and are amenorrheic are highly unlikely to conceive in the first six months after a birth. Indeed, one multinational study estimated that fewer than 2% would do so (Labbok et al., 1997). In addition, demographic studies suggest that the duration of lactational amenorrhea increases with the age of the woman (Wood, 1994). The effects of breastfeeding patterns are so important that they are the major factor in explaining differences in fertility among populations in which no family planning is practiced.

The time to conception depends on the monthly probability of conception in the absence of birth control and can vary among populations, by age, and according to the frequency and pattern of intercourse. The monthly probability of conception, known as *fecundability*, is extremely difficult to measure. Estimates of this probability differ in part because of the methods used to determine whether a conception has occurred. If early fetal loss occurs before the woman is aware she is pregnant, then the estimates of conception are biased downward. According to Wood (1994), the best study of early fetal loss was conducted by Wilcox and associates (1988), who followed a group of women ages 20 to 35 and collected blood and urine samples from them regularly. There were 198 pregnancies detected by assays of these samples; 43 pregnancies, or approximately 22%, were lost before the woman realized she was pregnant and before clinical diagnosis was made (Wilcox et al., 1988; Wood, 1994).

More traditionally, fecundability has been measured by accepting a woman's report of her pregnancy. This measure of *apparent* fecundability has yielded rates that range from approximately 0.10 to 0.30 for relatively young women (Menken, 1975; Wood, 1994). The waiting time to conception is, on average, the inverse of fecundability; for younger women, this time is 3 to 10 months on average. In many cases, fecundability has been estimated from reported waiting times to conception using a variety of mathematical models (some of which are summarized by Wood, 1994).

Fecundability depends in part on a couple's frequency and pattern of intercourse, which determines the likelihood that coitus will occur during the woman's fertile period. Both those couples wishing to conceive a wanted child and those couples hoping to avoid pregnancy without the use of hormonal or barrier contraceptives depend on knowledge of the woman's cycle to time their sexual activity, thereby changing their probability of conception. Whether ovulation is discerned by changes in cervical mucus or basal body temperature, conception is most likely to occur when intercourse takes place shortly before ovulation (Colombo & Masarotto, 2000).

Fecundability declines with the age of the woman, although increasing evidence indicates that this decline does not take place until the late thirties, on average, if patterns of intercourse remain unchanged. Decline with age of the man is quite slow.

Lactation has a fertility-reducing effect even after a woman has resumed menstruation and ovulation (Wood, 1994). Apparently, continued suckling beyond ovulation reduces fecundability through a response that interferes with the functioning of the corpus luteum. Although fertilization can occur, the corpus luteum may not produce sufficient progesterone to enable the pregnancy to continue (McNeilly, 1996).

Infection with HIV also affects fertility. Notably, it reduces conception rates beginning in the earliest asymptomatic stages of infection (Gray et al., 1998; Ross et al., 2004; United Nations Population Division, 2002).

Spontaneous abortion occurs frequently; the estimated rate, as already described, depends on how early the pregnancy is detected. From the time conceptions are recognizable by virtue of late menses, approximately 24% end in spontaneous abortion (French & Bierman, 1962). Even higher proportions of fertilized ova do not lead to live births. Wilcox and associates (1988), in the study cited earlier in which urine specimens were collected so that early pregnancy could be detected, found that 31% of the pregnancies ended in fetal loss. Rates of spontaneous abortion increase with the age of the woman (Nybo Andersen, Hansen, Andersen, & Davey Smith, 2004; Wood, 1994) and, more slowly, with the age of the man (Nybo Andersen et al., 2004; Slama et al., 2003). The time added to the birth interval by a recognized fetal loss is the sum of the time from pregnancy to the next ovulation (usually estimated to be slightly more than 3 months, on average, as the vast majority of spontaneous abortions occur very early in pregnancy) plus the time to the next conception. There is little evidence that rates of spontaneous abortion vary to any great extent among populations.

Gestation leading to a live birth does not vary much, usually lasting between 35 and 40 weeks, with few differences noted between population groups (Wood, 1994, p. 207). In some populations with outstanding care of premature infants or increasing maternal risks, gestation may be somewhat shorter on average. In the United States, the percentage of live births reported as preterm (fewer than 37 weeks' gestation) increased from 9.4% in 1981 to 12.1% in 2002 (a jump of 29%) and subsequently declined to 9.6% in 2015 (March of Dimes, 2016; Martin et al., 2003). In 2010, the highest rates of preterm births occurred in Southeastern Asia (13.5%), South Asia (13.3%), Africa (12.3%), and North America (12.0%), with Northern Europe (5%) having the lowest rate (Blencowe et al., 2016).

A cross-cutting issue that affects fertility rates is that of infertility and sterility. Especially in parts of Africa, infertility and early sterility are major factors affecting fertility. This effect may take the form of absolute sterility that causes the effective reproductive span to end early, or decreased fecundability or increased risk of spontaneous abortion (Larsen, 2000). In most cases, however, the concern is with early sterility, much of which is believed to be due to sexually transmitted infections.

Thus, the main reasons that populations not practicing family planning vary in terms of their fertility rates are differences in the effective reproductive span and the duration of the postpartum amenorrheic period, with variations in time to conception and infertility playing lesser roles.

Deliberate Control of Fertility

People can deliberately reduce their fertility in three ways: (1) by reducing the effective reproductive span through postponement of marriage or interrupted marriage or by sterilization that ends reproductive capacity early; (2) by using contraception, which increases the time to conception; and (3) by induced abortion, which increases the time added to the birth interval by ensuring that pregnancies do not lead to a live birth. Family planning programs can both promote the motivation to reduce fertility and provide the means to do so. Many governments encourage or enforce later marriage explicitly through changes in the legal age of marriage and implicitly through programs that foster female education. Family planning programs have traditionally focused on education regarding methods of fertility control, motivation to reduce the number of wanted children, and provision of family planning methods themselves. Such methods include promotion of breastfeeding, both for the health of the infant and to prolong the postpartum period; contraception, which is intended to prolong the time to conception; and, except where there is opposition for religious reasons, abortion, which increases the time added to the birth interval.

Although specific family planning methods are discussed in greater detail in the section on family planning programs later in this chapter, it seems appropriate to consider two important general issues here. First, why do populations in which the desired number of children is low still have high proportions of unintended births? Second, why is reliance on abortion an inefficient approach to family planning?

Contraception, even when highly effective, may not prevent all unintended pregnancies. A simple calculation makes this problem clear. Suppose a woman is using a highly effective method (0.5% failure)—one that reduces her probability of conceiving to about 1 in 200 per month. She begins using this method at age 30 and wants no more children before she reaches menopause at age 45. We can calculate the probability that she has no pregnancy in each of 13 lunar months over the next 15 years, or a total of 195 lunar months. The probability of succeeding (not getting pregnant) is 0.995 each month. The probability of not getting

pregnant in 195 months is 0.995^{195}, which equals 0.38. In other words, this woman has only a 38% chance of avoiding pregnancy for 15 years. Among women like her, 62% will have at least one unintended pregnancy in that time period. For this reason, even women who are very serious users of contraception are at high risk of unintended pregnancy. Family planning program and health planners need to be aware of this high risk when they are developing their programs.

In a population that relies primarily on induced abortion to reduce fertility, if a woman becomes pregnant unintentionally, she may choose to have an abortion. Approximately three months after the abortion, she again begins ovulating and is capable of conceiving. Suppose her time to conception averages 10 months. Then 13 months after the first abortion, she is again pregnant and must have another abortion if she is not to have an unwanted birth. Another 13 months later, an abortion is again performed, and so on. Preventing a birth for 15 years may, therefore, require 15 abortions.

Given this pattern, it is not surprising that many women in Eastern European countries who relied primarily on abortion for birth control reported numbers of abortions in the double digits. Women in the former Soviet Union, for example, are believed to have had six or more abortions, on average, over the course of their lifetime (David, 1992). While abortion rates in Eastern Europe have declined sharply in the last decade or so with increased access to modern contraception services, they remain among the highest in the world (42 women undergoing abortions per 1,000 women of childbearing age; 105 abortions for every 100 births) (Alan Guttmacher Institute, 2009a, 2016). Abortion, is, however, extremely effective as a backup to effective contraception. A woman who has an abortion and subsequently uses extremely effective contraception is unlikely to have more than one or two unintended pregnancies—but our previous analysis shows that she may, indeed, have these one or two.

For these reasons, it is not surprising that sterilization—the one method that has a failure rate near zero—is so widely selected by women and couples who want no additional children. In the United States in 2002, sterilization of the woman or of the man was the model method used by women older than age 30 (Mosher, Martinez, Chandra, Abma, & Willson, 2004). Reliance on the sterilization method in LMICs has declined over time. Approximately 26% of married women relied on sterilization to prevent additional births (22% of wives, and an additional 4% of their husbands had been sterilized) in 2002, but the rates declined to 12.8% female sterilization and 1.3% male sterilization in 2012 (Population Reference Bureau, 2002; Ross, Keesbury, & Hardee, 2015).

The Effect on Fertility of the Proximate Determinants: Bongaarts' Indices

Bongaarts (1978) developed a set of indices to measure the effects on fertility of some proximate determinants. These indices are based on the assumption that there is some maximum potential fertility, *TF*, for women. This figure is usually estimated to be slightly more than 15 children.

Ci	The **index of postpartum infecundity** varies from 0 to 1. It represents the proportion of potential fertility, *TF*, remaining when the average postpartum period of the population of interest is taken into account. Therefore, $Ci = 1$ if the population does not breastfeed at all. The fertility-reducing effect of postpartum infecundity is $(1 - Ci)$.
CA	The **index of abortion** is the proportion of *TF*, after postpartum infecundity is first taken into account, remaining when the effect of induced abortion in reducing live births is taken into account. Spontaneous abortions are included in the original estimate of *TF*, because they are treated as a purely biological occurrence. Few countries have sufficient information available on abortion to make reasonable estimates of *CA*, so it usually must be disregarded in application.
CC	The **index of contraception** is the proportion of *TF*, after the effects of postpartum infecundity and induced abortion are taken into account, remaining after contraceptive use is considered.
Cm	The **index of marriage** is the proportion of *TF*, after the first three factors are considered, remaining when the particular marriage or sexual union pattern is taken into account.

Reproduced from United Nations (1994). Programme of action of the 1994 International Conference on Population and Development. Paper presented at the (A /CONF.171/13), http://www.un.org/popin/icpd/conference/offeng/poa.html

Thus, in the Bongaarts decomposition of the total fertility rate,

$$TFR = TF \leftrightarrow Ci \leftrightarrow CA \leftrightarrow CC \leftrightarrow Cm$$

Both *CC* and *Cm* contain adjustments for infertility and sterility. In the first index, the adjustment takes into account infertility and sterility and assumes no use of contraception by infertile and sterile couples. In the second index, a weighting factor is present, in that nonmarriage has a greater effect on fertility reduction when the woman is young (e.g., the effect of nonmarriage is much greater for a 25-year-old woman than for a 42-year-old woman).

TABLE 5-2 presents these indices, except for *CA*, which is assumed to be 1 because of the lack of data, for a number of populations around 1970 and for several historical populations (Bongaarts & Potter, 1983). The major impact of breastfeeding can be seen through the values of the index *Ci* in countries whose populations used little contraception during the period in question. All of the South and East Asian countries, as well as Kenya, have indices that do not exceed 0.67; thus,

TABLE 5-2 Estimates of Total Fertility Rate and Bongaarts' Proximate Determinants Indices*

EXHIBIT 5-2 Proximate Determinants of Fertility in Kenya

The fertility rate in Kenya was estimated to be approximately 8.20 births per woman in 1978. This high fertility was due to the combination of very high rates of marriage for women of reproductive age (*Cm* = 0.91) and essentially no fertility control within marriage (C+ = 0.96). Fertility could, however, have been much higher except for prolonged amenorrhea, which is related to the long breastfeeding practiced in this country (*Cf* = 0.64). Total fertility, at 8.20 births per woman, was slightly more than half (0.56) of what it would have been if women had not breastfed at all (TFR = 14.7) (Toroitich-Ruto, 2001).

The focus of the Kenyan Family Planning Program has been to increase fertility control within marriage by increasing the use of contraception by married women. This emphasis paid off at least initially, resulting in sharp declines in TFR between 1978 and 1989 (from 8.20 births per woman to 6.60 births per woman). Estimates of Bongaarts' proximate determinants of fertility for Kenya in 1989 compared to 1978 support the notion that this sharp decline in TFR was essentially due to a rise in contraceptive prevalence rates. Bongaarts' estimates show a significantly lower index of contraception (*CC*) of approximately 0.80 in 1989 compared to 0.96 in 1978, reflecting the rapid rise in contraceptive prevalence over a period of 12 years (33% in 1989 versus 7% in 1978); a relatively unchanged index for marriage (*Cm* = 0.86 in 1989 versus 0.91 in 1978), reflecting the continuing high rates of marriage; and a relatively unchanged index of postpartum infecundity (0.66 in 1989 versus 0.64 in 1978), reflecting continued long breastfeeding durations (Toroitich-Ruto, 2001).

Total fertility rates continued to decline relatively rapidly until 1993 (TFR = 5.4 births per woman). Subsequently, fertility decline stalled. In 2014 (the most recent data available), TFR in Kenya was 3.9 births per woman, with contraceptive prevalence rates having risen to 58%, up from 33% in 1989 (Macro International, 2014).

their potential fertility is reduced by at least one-third by long postpartum periods. In fact, the long breastfeeding periods employed in Bangladesh and Indonesia reduced these countries' fertility rates to only about half of their potential. In Europe, the demographic transition to low levels of fertility was caused, to a great extent, by very late marriage and a relatively high degree of nonmarriage. The index of marriage is far lower, on average, for high-income countries around 1970 than for LMICs. Two historical populations shown, however, had indices of marriage less than 0.45, indicating that nonmarriage reduced their potential fertility by at least 55%. By 1970, fertility in all the developed countries shown was reduced by contraceptive use to no more than 30% of its potential level.

Thus, in high-income countries, breastfeeding has little effect on fertility, but nonmarriage and use of contraception reduce the TFR to relatively low levels. In the 1970s, contraceptive use had little impact on fertility in LMICs included in Table 5-2; lower fertility was achieved in some of these countries through long-term breastfeeding (**EXHIBIT 5-2** provides information on the example of Kenya). Populations that had very high TFRs achieved these rates through a combination of high indices of marriage and breastfeeding and little or no contraception.

Stover's Revision of Bongaarts' Indices

The indices of the effects of the proximate determinants on fertility have been revised a number of times by Bongaarts and others to take advantage of more recent detailed and reliable data and to substitute more realistic assumptions. Stover (1998), for example, dropped the original indices of marriage and contraceptive use; he also attempted to treat infertility and sterility more directly and to deal with sexual activity rather than using the proxy of marriage or stable sexual union incorporated in the earlier version of the indices (Stover, 1998). He includes, instead, three new indices:

Cx	The **index of sexual activity** depends on the reported proportion of women in the population who are sexually active. Its interpretation is, therefore, the proportion of potential fertility remaining after celibacy is taken into account.
Cf	The **index of infecundity** reflects the effect on fertility of infecundity among sexually active women, and is simply $1 - f$, where f is the proportion who report that they believe themselves to be infecund.
Cu	The **index of contraceptive** use reflects actual contraceptive use by women who believe themselves to be fecund and who are not experiencing postpartum amenorrhea.

Thus, the fertility-reducing effect of the proximate determinants is given by

$$Cx \leftrightarrow Ci \leftrightarrow CA \leftrightarrow Cu \leftrightarrow Cf$$

where the index of abortion (CA) is rarely estimated and Ci is the index of postpartum infecundity as previously defined by Bongaarts.

These results show that the two main factors producing lower fertility in Latin America are relatively low participation in sexual activity and relatively high contraceptive use (**TABLE 5-3**). By contrast, in most countries of Africa, there is much higher participation in sexual activity and lower use of contraception. Fertility would be even higher were it not for the effects of postpartum infecundity, which reduces fertility by at least 40% in the countries represented here. What is striking is the documentation of the rather large impact on overall fertility (approximately 20%) in

some countries due to infertility among sexually active women.

Family Planning Programs

A fundamental rationale for family planning programs is to reduce unintended fertility because of its negative health and welfare consequences and because control of fertility has been recognized as a human right of women and couples. Over the last 50 years, societal changes have included reduced infant mortality, increased urbanization, improved education for women, increased economic opportunities, and the dissemination and adoption of modern ideas about small families. The response by couples in LMICs has been accelerated change in expectations about both the number and the timing of births (Bongaarts, 1983; Freedman, 1987).

In 1997, 155 countries had programs that subsidized the cost of family planning services (Gelbard, Haub, & Kent, 1999). However, in part due to the lack of available, accessible, and effective contraception, the gap between observed and desired fertility grew, leading in turn to an increase in unintended fertility (Bankole & Westoff, 1995; Bulatao, 1998). Out of 213 million pregnancies in 2012, 85 million women become pregnant unintentionally (Sedgh, Singh, & Hussain, 2014). Due to concerted family planning efforts in the last three decades to increase access to contraceptive services (worldwide, such access increased from approximately 10% in the early 1960s to 59% in 2000 and 63.6% in 2015), many more women are now able to avoid unintentional pregnancies (United Nations Population Division, 2015a; WHO, 2005). For example, in Kenya, 35.5% of women expressing a desire to control their fertility were not able to meet this need in 1989. By 2003, this figure had decreased to 24.5% and by 2014 to 17.5% (**EXHIBIT 5-3**).

Unintended Fertility

A number of definitional issues complicate the process of estimating unintended fertility and its distribution. In general, data on unintended fertility come from representative population surveys in which women who are pregnant at the time of the survey or who have had at least one birth in the five years prior to the survey are asked whether each of those births (including the outcome of the current pregnancy) was intended, *mistimed* because it came too early but was still within the desired number of births, or *unwanted* in that no more children were desired. Unfortunately, usage of these terms is not completely consistent; some authors include mistimed births as part of their estimates of unwanted births, while others count only those births that exceed the desired family size as unwanted (Brown & Eisenberg, 1995). The major weakness of this approach is that women may be reluctant to classify specific births as unwanted, leading to artificially low estimates of unwanted births.

Measurement of fertility intentions has been criticized because it relies exclusively on mothers' intentions and not the intentions of other family members—most importantly, fathers—to gauge unintended fertility.

EXHIBIT 5-3 Desired Family Size and Unmet Need for Contraception in Kenya

One rationale for family planning programs is that couples who want to have fewer children may be unable to do so either because they lack knowledge of the means of fertility control or because they lack access to those means, owing to an absence of supplies or services.

In the case of Kenya, even in the earliest surveys carried out, a high proportion of married women reported that they wanted no more children. At that time, the mean ideal number of children was reported to be 4.4, and 45.5% of women reported they did not want to have another child. The desired TFR (wanted fertility) was 4.5 births per woman, while the actual TFR was 6.7 births per woman. Thus, there was a big gap between desired fertility and actual fertility despite the inception in late 1970s of a nationwide family planning program. Among the barriers to achieving this low desired fertility were (1) the economic costs of access to services, including the cost of transportation, and supplies; (2) the social costs, including travel by women whose mobility was traditionally constrained; (3) the psychic costs of contraceptive use in a society that offered little social or familial support for low fertility; and (4) the health costs of side effects, whether subjective or objective, from contraceptive use.

These barriers have been overcome to the extent that in 2015, 58% of married women of reproductive age were current contraceptive users, compared to 43% in 2003 and 33% in 1989. Also, actual TFR in Kenya declined from 6.7 births per woman in 1989 to 4.9 births per woman in 2003 and then to 3.9 births per woman in 2014. However, wanted fertility did not remain at the 1989 level: It fell to 3.6 births per woman in 2003 and 3.0 births per woman in 2014. The unmet need for contraception among women at risk of pregnancy decreased from 35.5% in 1989 to 24.5% in 2003 and 17.5% in 2014.

It has been argued that the intentions of the mother, especially in many LMICs, may not accurately reflect the desirability of a birth. Evidence suggests that intergenerational differences in family size goals (i.e., preferences of grandparents versus parents) may be more pronounced than interspousal differences (Caldwell, 1986; Mason & Taj, 1987). Ultimately, the justification for relying on the stated preferences of the mother in determining desired family size and unintended or unwanted births stems from the fact that the mother is the person most responsible for the birth and child care (Tsui et al., 1997).

Demographic and Health Surveys (DHS) have been conducted since 1984 in approximately 75 LMICs (https://dhsprogram.com/). This research is intended to provide comparable information on a variety of subjects related to health and fertility issues. DHS calculates, for each survey, both the total fertility rate (the number of children a woman would bear were she to live her reproductive life under the fertility conditions just prior to the survey) and the unwanted total fertility rate (the number of those children who would be unwanted) (Westoff, 2001). A birth is counted as unwanted only when the mother states she wanted no more children at the time of the pregnancy.

The results of DHS surveys conducted over the period 2010–2015 in 35 countries are shown in **TABLE 5-4**. On average, 17.7% of total fertility was unwanted, with the percentage varying considerably by region. The association between fertility level and proportion of unwanted births has been reversed in the last decade. Previously the regions with the lowest and highest fertility rates (Eastern Europe and sub-Saharan Africa, respectively) had the lowest

Data from Macro International Inc., 2010–2015, MEASURE DHS STAT compiler. Accessed on November 10, 2016 from http://www.measuredhs.com

proportions of unwanted births (the mean percentages were 8% for Eastern Europe and 16% for sub-Saharan Africa). Now the low-fertility region (Latin America and Caribbean) with average TFR of 2.72 births per woman has a 26.6% rate of unwanted births compared to a 14.8% rate of unwanted births in sub-Saharan countries with average TFR of 5.16 births per woman. This change is possibly due to faster decline of desired fertility than actual fertility in low-fertility regions, while in high-fertility countries both desired and actual fertilities decreased in the same pace. Variations in this regard are also evident by countries within and between regions. Some countries with high total fertility rates had low proportions of unwanted births (e.g., Niger), whereas Uganda has high proportion of unwanted births despite a relatively high TFR. The highest percentages of unwanted births (one-fourth or more) were found in countries with TFRs between 2.5 and 5.5 births per woman. Finally, in low-fertility countries where the TFR is less than 4 births per woman, a substantial proportion of those births remain unwanted (Macro International, 2015).

Note that this and earlier evidence suggest that increases in contraception prevalence rates do not necessarily cause a decline in the proportion of unwanted births and, in fact, may initially be associated with an increase in the proportion of unwanted births (Tsui et al., 1997). This scenario can happen if desired fertility rates drop faster than the compensating rises in contraceptive prevalence rates, and if the use of methods of fertility control is so effective that unintended births rarely occur. Thus, when couples have very high fertility desires, it is difficult to exceed those desires, so nearly all children are wanted. As desired fertility falls, use and effective use of contraception and abortion may not increase quickly enough to avoid unwanted births. Finally, at low levels of fertility, women want so few children that there remain many years after the last wanted child during which an unwanted pregnancy and birth can, and frequently do, occur. The differences by education within a country can, in part, be explained by this phenomenon: More-educated women within a society frequently are earlier adopters of contraception and, because they desire few children, a higher proportion of their children are unwanted.

With regard to mistimed births, DHS data from selected countries around 2005 (2002–2010) suggest that approximately 16% of births in LMICs were mistimed—that is, they came too early (Bradley, Croft, & Rutstein, 2011). Highest proportion of mistimed births is reported from Latin America (29%), followed by Africa (20%), Asia (15%), the Middle East (11.5%), and Europe (10%) (Bradley et al., 2011). There is no clear association between contraceptive prevalence and the proportion of mistimed births. Thus, even in a region such as sub-Saharan Africa, where contraceptive use rate is low, considerable mistimed fertility is still observed. Contraceptive failures contributed only 29% of total mistimed births, while 71% of such births resulted from lack of contraceptive use (Bradley et al., 2011). This finding suggests that there is a need for contraception to delay first births and control spacing of subsequent births even when there may be little demand for contraception to control the number of births (Bankole & Westoff, 1995; Rafalimanana & Westoff, 2001).

Consequences of Unintended Pregnancies and Births

Aside from helping individual couples fulfill their desires and expectations, why should we care about unintended pregnancies and births and, moreover, try to reduce them? A compelling public health reason is their negative consequences. Unintended pregnancies increase the lifetime risk of maternal mortality simply by increasing the number of pregnancies (Alan Guttmacher Institute, 2009a; Koenig, Fauveau, Chowdhury, Chakraborty, & Khan, 1988). Unintended pregnancies can lead to unsafe abortion, poor infant health, and lower investment in the child.

Abortion

In many cases, unintended pregnancies are terminated by abortion, which was the outcome for an estimated 25% of all pregnancies in 2010–2014 (Alan Guttmacher Institute, 2016). Most abortions, especially those in LMICs, continue to be conducted illegally under unhygienic conditions and pose significant health risks to the mother.

The legal status of abortion and, consequently, access to safe abortion services is highly variable. Roughly 26% of women of childbearing age (15 to 44 years) in 66 countries currently live in countries where abortion is highly restrictive (Center for Reproductive Rights, 2013). Women in LMICs (except for China and India) are much more likely to live under restrictive abortion laws than women in high-income countries. As of 2013, out of 199 countries, only 61 countries allowed abortion without any restriction; in contrast, in 66 countries, abortion remained illegal even in the face of incest or rape (Center for Reproductive Rights, 2013). There have been some positive

changes in access to legal abortion since 1995, with more than 30 new countries broadening the grounds under which abortion can be performed, and only a few counties tightening legal restrictions (Center for Reproductive Rights, 2014; Reed, Koblinsky, & Mosley, 2000).

Despite these differences in legal access, there is little difference in the likelihood of having an abortion. Thus, in 2010–2014, the abortion rate was 34 per 1,000 women of childbearing age (15 to 44 years) in Africa, where abortion is fairly restrictive, compared to 30 per 1,000 women in Europe, where it is very accessible (Alan Guttmacher Institute, 2016). As a result, women in LMICs (excluding China) are more likely to have illegal abortions, and their abortion mortality rate is many times higher than that for women in high-income countries. Compared to the rate of 0.6 death per 100,000 abortions in the United States, the global abortion rate is 220 deaths per 100,000 procedures; it is a staggering 460 deaths per 100,000 abortions in Africa (Alan Guttmacher Institute, 2016).

Sedgh et al. (2016) estimated that approximately 56 million abortions were performed worldwide yearly between 2010 and 2014, which is about 4 million higher than the annual estimates of 52 million in the 2005–2009 period (Sedgh et al., 2016). Of these 56 million abortions, 34 million were legal abortions and 22 million were unsafe (illegal) procedures (WHO, 2017). The proportion of abortions that are unsafe decreased from 49% in 2008 to 39% in 2010–2014, while the overall rate of abortion has decreased from 40 abortions per 1,000 women in 1990–1994 to 35 abortions per 1,000 women in 2010–2014 (Sedgh et al., 2016). Overall, the decrease in the worldwide abortion rate was largely due to reductions in safe abortions, most likely associated with increases in contraceptive use in the high-income world. Most strikingly, in Eastern Europe, which had the highest abortion rates in 1995, abortion rates declined dramatically—from 90 per 1,000 women in 1995 to 44 per 1,000 women in 2003 and to 42 per 1,000 women in 2010—coincident with a substantial increase in contraceptive use. Western Europe continues to have the lowest abortion rate, which has not changed since 1995 (12 per 1,000 women) (Sedgh et al., 2012).

Even where abortion is legal, access is very limited, there are poor systems of referral, and very often services are of poor quality. For example, despite the fact that manual vacuum extraction is much safer, the most frequently used method for abortion in most countries is dilatation and curettage, which has significant associated morbidity. In recent years, some encouraging signs indicate that use of manual vacuum extraction and medications to end unwanted pregnancies is increasing (Alan Guttmacher Institute, 2009a).

The World Health Organization estimates that approximately 21.2 million unsafe abortions (i.e., those not attended by a trained health professional) were performed in 2008, resulting in nearly 46,800 deaths of women in LMICs. Globally, unsafe abortion accounts for 8% of maternal deaths (Say et al., 2014). Case fatality rates (i.e., deaths per 100,000 unsafe abortion procedures) vary tremendously by region, with the world average being 220 deaths per 100,000 unsafe abortions and ranging from 4 deaths per 100,000 unsafe abortions in the high-income world to 470 deaths per 100,000 unsafe abortions in sub-Saharan Africa (WHO, 2011). It is worth noting that case fatality rates for unsafe abortions are many times higher than the rates for safe abortions, again with significant regional differences—ranging from 10 times higher in the high-income world to 1,000 times higher in sub-Saharan Africa.

Another abortion-related issue is the recent rise in the male-to-female sex ratio at birth in Southeast Asia. Data from a number of countries, including China and Korea, show that the sex ratio at birth in these areas is unusually high compared with the expected ratio of 1.06 male birth to each female birth, and is steadily increasing. Rising sex ratios at birth suggest that selective abortion of female fetuses may be increasing (Arnold, Kishor, & Roy, 2002; Larsen, Chung, & Das Gupta, 1998; Westley, 1995). This practice is embedded in the context of strong societal preferences for male children and declining family size desires, which increase the incentives to have both the desired family composition and the desired number of children (Hesketh, Lu, & Xing, 2011).

In recent decades, the broader availability of modern technology has provided the means to actualize these preferences. There are basically three ways of determining the sex of a fetus: chorionic villus sampling, amniocentesis, and ultrasound. Ultrasound is the safest and cheapest method, but works reliably only 5 to 6 months into the pregnancy (i.e., the end of the second trimester). This technology is widely available in rural areas in India, China, and other parts of East Asia. Despite strong legal sanctions against sex-selective abortion, the availability of relatively cheap ultrasound technology has promoted this practice, leading to deleterious consequences for women who undergo late-term, riskier abortions and possibly for children due to the increasing sex imbalance in the population.

Consequences of Unintended Births for Infant Health

Data on the consequences of unintended births for infant health are available for the period before 1990. They show that these births were concentrated in demographically high-risk categories (**TABLES 5-5**–**5-7**); that is, the proportion of unintended births was much higher among young mothers and older mothers, among higher-parity mothers, and following a short birth interval (National Research Council, 1989). Why these demographic characteristics are associated with higher risks for infant health is discussed in greater detail in the next section. Notably, unwanted births have higher mortality even when the pregnancy fits into an otherwise demographically low-risk category (e.g., mothers age 24 to 29; parity of 2 to 4).

Human Capital Investments

In addition to deleterious health consequences for the mother and the index child, unintended births have spillover and long-term cumulative effects by reducing human capital investments (i.e., allocation of

resources for education and health) in the family as a whole. A number of studies in LMICs have shown that older children, especially girls, suffer disproportionately in terms of lower educational attainment and health status as family size increases—the latter being a proxy for unwanted births (Bledsoe & Cohen, 1993; Desai, 1995; Frenzen & Hogan, 1982; Lloyd, 1994).

Cross-sectional associations between large family sizes and lower health and educational attainments need to be interpreted cautiously, given that parents who choose to have large families may also choose to invest differently in different children (Knodel, Chamratrithirong, & Debavalya, 1987). Nevertheless, some evidence, from a family planning quasi-experiment in which villages were assigned different levels of family planning services, suggests that part of the relationship between large family sizes and low human capital investments is causal (Foster & Roy, 1996).

Unmet Need for Contraception

A primary objective of family planning programs has been to reduce unintended births by addressing "the unmet need for contraception." This unmet need is conventionally estimated from representative population-based surveys of currently married women as the sum of the number of currently pregnant women who report that their pregnancy is unintended and the number of currently nonpregnant women who are not using contraception and would not like to have any more children or, at least, none in the next two years (Bankole & Westoff, 1995). On the basis of this definition, the unmet need for contraception (**TABLE 5-8**)

Data from Macro International Inc., 2010–2015, MEASURE DHS STAT compiler. Accessed on November 10, 2016 from http://www.measuredhs.com

is estimated to be 20% or less for married women in countries with high contraceptive prevalence rates (e.g., 55% or higher) and ranges up to 30% (Uganda) of women in countries with lower contraceptive prevalence rates.

The definition of "unmet need for contraception" has been criticized as an underestimate of actual need because it excludes both currently married women who are not pregnant and who are using inappropriate (because of health consequences or side effects) methods of contraception and sexually active women who are not currently married and who do not wish to become pregnant, at least in the next two years (Bongaarts, 1991; Dixon-Mueller & Germain, 1992; Pritchett, 1994a, 1994b). An additional criticism revolves around the issue of ineffective contraception. Large numbers of women currently use traditional methods, which have much higher failure rates than available modern contraceptives. Current estimates of unmet need do not include women who are using traditional (i.e., ineffective) contraceptive methods.

More recent estimates (2007) consider unmarried as well as married women. They show that for all LMICs, approximately 112.4 million women have an unmet need for contraception (108 million married and 4.2 million unmarried). These numbers translate into 14% of married women versus 7.7% of unmarried women having an unmet need for contraception. Women age 15 to 24 have significantly higher unmet need than 25- to 49-year-old women (Sedgh, Hussain, Bankole, & Singh, 2007). More than half of the total unmet need for contraception is attributed to the need to space births, and the other half to the need to limit births (Ross & Winfrey, 2002). The total number of women whose needs are unmet results from the combination of upward pressure due to population growth and downward pressure due to the success of family planning programs (Ross & Winfrey, 2002).

Family planning programs have played an important role in reducing the unmet need for contraception by making contraceptive options both physically accessible and financially affordable. Since the late 1950s, when the first national family planning programs in LMICs were established, there has been a significant increase in the prevalence of contraceptive use. This increase has played an important role in the significant reduction in fertility that has taken place especially over the last three decades in these regions, where the average number of births per couple declined from more than 6 to fewer than 3 in the latter half of the twentieth century.

Program success in improving contraceptive prevalence rates has, however, been somewhat uneven. It has depended on a number of factors, including a receptive social and family environment that accepts fertility control as legitimate behavior, a favorable political and bureaucratic climate, a management structure that pays close attention to both quality and quantity of services, and reliable sources of funding. Furthermore, those programs that have succeeded have invested considerable resources in evaluation, research, and monitoring of their services, and have had the flexibility to adapt to local conditions (Bongaarts, 1997; Bongaarts & Watkins, 1996; Bulatao, 1993, 1998; Freedman, 1987).

A long-standing debate has focused on the relative merits of "demand-side" versus "supply-side" interventions to reduce the unmet need for contraception (Bongaarts, 1997; Pritchett, 1994a, 1994b). Demand-side proponents argue that improvements in women's socioeconomic status are an essential and necessary prerequisite to the success of family planning programs. Thus, educated women with higher status, compared to their less-educated and lower-status peers, are more likely to know about contraception and to seek it out to actualize their latent fertility desires. Supply-side proponents, in contrast, posit that family planning programs, when properly managed, can increase access to and availability of contraception, even in the absence of changes in the socioeconomic status of women. Thus, they can lead to increased contraceptive prevalence rates and initiation of fertility decline.

The experience of many countries shows that the onset of fertility decline[1] is not dependent on any particular threshold in socioeconomic factors such as levels of urbanization, female education, or infant mortality. In fact, fertility decline appears to have started in a wide range of LMICs at quite varied levels of socioeconomic status. Bangladesh is frequently cited as the best example of improved contraceptive prevalence rates and dramatic fertility decline in the absence of socioeconomic improvements but in the presence of a well-run, sharply focused family planning program (Cleland, Phillips, Amin, & Kamal, 1994), although the absence of socioeconomic change has recently come under question (Caldwell, Barkat, Caldwell, Pieris, & Caldwell, 1999; Menken, Khan, & Williams, 1999). While there appears to be no magic

1 The onset of fertility decline is usually dated from an initial decline of at least 0.7 point in total fertility over a five-year period, following the practice employed by Bulatao and Elwan (1985).

threshold of socioeconomic development for initiation of fertility decline, the decline occurs more rapidly in countries with greater levels of socioeconomic development (Bongaarts & Watkins, 1996).

The demand-side versus supply-side debate is basically a false dichotomy. Neither development nor family planning programs are a necessary prerequisite, nor is either sufficient to induce fertility decline on its own (Ross & Mauldin, 1996). Rather, these factors work in a complementary fashion, with the time scales of their respective impacts being very different. On the one hand, investments in improving women's status and educational attainment certainly have an important impact in reducing unmet need, but it is a long-term impact. On the other hand, family planning programs can increase access to contraception in the short run, thereby enhancing knowledge about its use and availability and addressing many of the negative myths about particular methods of contraception. Appropriately crafted and focused media campaigns, when implemented as part of family planning programs, can also help legitimize contraception as an acceptable and desirable form of behavior. Moreover, it is important to note that access to the means to limit fertility in and of itself helps improve the status of women. Family planning programs work synergistically with improvements in socioeconomic status and are most effective when they are directed at an informed, educated, empowered client base (Freedman, 1987).

In summary, Bongaarts (1997) estimates that approximately 40% of the fertility decline in the last three decades of the twentieth century in LMICs (from a TFR of 6 to 3 births per woman) can be attributed to family planning programs, and approximately 60% to changes in socioeconomic status, particularly for women.

The Challenges Facing Family Planning

Despite significant family planning program success in reducing financial and logistic constraints to contraceptive access, the unmet need for contraception remains high in many countries. Studies by Bongaarts and Bruce (1995) and Casterline and associates (1996) reported that the major barriers to use of contraception appear to be lack of knowledge about contraception availability and use, concerns about the deleterious health consequences of contraception, and opposition from family and community to contraception use.

Given that physical access and financial constraints are not considered to be significant barriers to the use of contraception, the major challenges for family planning revolve around improving the quality of services, particularly in the areas of information exchange and method choice; integration with reproductive health services other than contraception; and last, but not least, financial sustainability.

Information Exchange

In upgrading the quality of family planning services, the major area of concern is information exchange between providers and clients. The fragmentary evidence that exists suggests that inadequate information is often provided about the proper use of contraceptives, alternatives in the event of non-optimal use, contraceptive side effects, and the appropriateness of the chosen method for women who have particular health problems (Winikoff, Elias, & Beattie, 1994). For example, quite a few women who are using oral birth control pills do not know that they can make up for a missed day by taking two pills the next day. Similarly, not enough women know that birth control pills should not be used if a woman is a smoker or has a heart condition (Trottier, Potter, Taylor, & Glover, 1994).

In general, far fewer than 50% of women have meaningful knowledge about contraceptive methods (Bongaarts & Bruce, 1995). This lack of specific knowledge often leads to exaggerated notions of the health risks of contraception (Casterline et al., 1996). It is worth reiterating that contraception is, by and large, very safe, especially when compared to the health risks deriving from an unplanned pregnancy. Ross and Frankenberg (1993) have estimated that the mortality risk of an unplanned, unwanted pregnancy is 20 times the risk of any modern contraceptive method and 10 times the risk of a properly performed abortion (Ross & Frankenberg, 1993). Although the last two decades have witnessed great success in social marketing, whereby most women have become aware of the benefits of small families and the existence and availability of contraception, much more needs to be done to educate women about method choice and associated health risks and benefits.

Although concern about information exchange in family planning programs is long-standing, progress in addressing this problem has been uneven. An issue that comes up repeatedly is whether there is a quality–quantity tradeoff. Program managers voice a common complaint that they have their hands full just providing physical access to contraceptives. Many feel they do not have the luxury of providing extensive information about contraception because of the time-intensive nature of this type of activity.

In reality, there is little contradiction or tradeoff between paying attention to quality issues and achieving quantity targets for numbers of users. The two are integrally linked in several ways. First, the key steps needed to improve quality—such as attention to logistics, adequate supervision, motivation of workers at every level, real feedback to managers and supervisors, and accountability for supplies and money—are exactly the same steps needed to improve quantity. Second, family planning services are inseparable from information provision. In fact, provision of information is one of the key services that a family planning program can offer. Third, attention to quality will improve efficiency and will allow the addition of new users to family planning services without new costs (Tsui et al., 1997).

Contraceptive Use and Method Choice

Modern contraceptive methods are now so widely available in LMICs that approximately 46% of all couples outside of China and approximately 62% of all couples in high-income countries in which the woman is of reproductive age use such methods (Population Reference Bureau, 2016). In 2003, the estimated number of contraceptive users in LMICs was 506 million. This number had grown to 600 million by 2008 and to 645 million by 2012 (Darroch & Singh, 2013). By 2030, the number of global users of contraceptives is expected to be approximately 800 million (United Nations Population Division, 2015a). This rapid growth rate is a result of population increases and a concomitant rise in contraceptive prevalence in LMICs, from 61% in 2000 to 64% in 2015, due to declines in desired fertility.

TABLE 5-9 shows the change in worldwide distribution of contraceptive use according to method from 2002 to 2015. Note that the global contraceptive use rate increased by only 3% between 2000 and 2015. The increase is almost uniform across the regions except Africa, where a 7% increase has been experienced (from 26% to 33%); this rate remains the lowest on a regional basis in the world. These findings support the notion that once the contraceptive use rate reaches 60% in any country, there is little scope for further increase.

In addition to demonstrating the great variation in use, these data are remarkable in that they show, for much of the world, a high proportion of those couples using contraception are using sterilization—the one method that has almost zero risk of failure. Note that the average rate of contraception use for LMICs in Asia (67.8%) is heavily influenced by the very high rate of contraceptive prevalence in China (83.4%). Without China, the average for all LMICs would drop from 61% to 54% (Population Reference Bureau, 2016). More recent data show that there is a consistent decline in permanent method use across the regions with increase in condom and pill use.

Another modern contraceptive that has not yet reached the mainstream is emergency contraception. A recent study in LMICs shows that nearly 20% of women age 15 to 49 years had heard about this method and approximately 2% of sexually active women had ever used it (United Nations, 1994), although wide variations exist among countries (Palermo, Bleck, & Westley, 2014). Another important observation is that there is no strong correlation between TFR and contraceptive use rate in many high-income countries. For example, Japan has one of the lowest TFR in the world (1.4 births per woman), but a modest contraceptive use rate of 56%, of which 80% involves use of condoms. Japanese couples rely on other fertility control measures that reduce exposure to risk of pregnancy, perhaps including more effective use of controlled abstinence (Moriki, Hayashi, & Matsukura, 2015); in Japan, the average age at marriage is 26.3 years for women and the average age at first birth is 27.5 years (Anonymous, 1996).

It is much more difficult to judge how much *choice* of method women in LMICs have, and how their array of choices has changed in recent years. With the exception of sub-Saharan Africa, where contraceptive prevalence rates are low, significant progress in overall method availability occurred in most countries between 1982 and 1994 (Ross & Mauldin, 1996). In all 22 countries (with the exception of Nigeria) where DHS surveys were conducted between 1990 and 1993, at least half of all women had heard of at least one modern contraceptive method; in 13 of these countries, more than 90% of women knew of at least one contraceptive method (Curtis & Neitzel, 1996).

TABLE 5-10 shows historical data on contraceptive method mix and alternative projections for contraceptive choices in 2015 in LMICs (Bongaarts & Johansson, 2002). Although the two projection methodologies resulted in varying estimates for specific methods, female sterilization appeared likely to remain the most popular method of choice in 2015, followed by intrauterine devices (IUDs) and pills. When the estimated method mix was compared with actual data collected between 1998 and 2012 from LMICs, the earlier projections were found to have largely overestimated the use of sterilization and IUDs (Ross et al., 2015). Conversely, injectable methods

TABLE 5-9 Contraception Use Pattern in 2000 and 2015: Percentage of Married Couples[a] in Which Women Are of Reproductive Age, by Region

(2015). *Trends in contraceptive use worldwide 2015 (ST/ESA/SER.A/349)*. Retrieved from http://www.un.org/en/development/desa/population/publications/pdf/family/trendsContraceptiveUse2015Report.pdf

TABLE 5-10 Estimates of Method Distribution in 1980 and 1993 and Alternative Projections for 2015, Low- and Middle-Income Countries

	Actual	Actual	Futures Group Projection	New Procedure Projection	Estimated
Method	**1980**	**1993**	**2015**	**2015**	**1998–2012***
Female sterilization	24	39	26	37	12.8
Male sterilization	13	8	3	5	1.3
Pill	13	11	22	17	22.3
Injectable/Implants	0	4	6	5	18.0
Intrauterine device	32	26	18	20	12.9
Vaginal methods	0	0.3	0.6	0.4	—
Condom	5	4	10	9	10.7
Traditional methods	12	9	14	7	22.1
Total	100	100	100	100	100

The figures for 1993 are proportions of total contraceptive use. An estimated 21% of married couples used female sterilization. As the total number of married couples using contraceptive methods was 55%, this translates into (21/55 = 39%) of total contraceptive use.
Modified from Population Council, Bongaarts, J., & Johannsson, E. (2002). Future trends in contraceptive prevalence and method mix in the developing world. *Studies in Family Planning, 33*(1), pp. 24–36.
*Estimates for 1998–2012 are taken from Ross, J., Keesbury, J., & Hardee, K. (2015). Trends in the contraceptive method mix in low- and middle-income countries: Analysis using a new "average deviation" measure. *Global Health: Science and Practice*, *3*(1), 34–55.

were used by a significant share of the population (18.0%), and—perhaps surprisingly—use of traditional methods also increased more than projected. An issue of considerable concern is that despite evidence of a spreading HIV epidemic in LMICs, condom use remains low in all estimates.

Largely due to a lack of funding and the long lead time required for new methods to gain acceptance, there has been relatively little innovation in contraceptive technology in the last 30 years. Thus, in an era of increasing expectations for contraception, the menu of choices has not expanded greatly. Given the AIDS pandemic, new contraceptive methods that are of high priority are vaginal microbicides, which protect women from STIs, in combination with spermicides, which provide contraceptive protection (Bongaarts & Johansson, 2002; Harrison & Rosenfield, 1996; Tsui et al., 1997).

In some situations, knowledge and use of existing technology have not been widely disseminated. One example is emergency contraception—that is, the prevention of pregnancy through the use of contraceptive methods after unprotected sex—for which appropriate technologies (e.g., a combination of oral contraceptive pills, progestin-only pills, and the copper-T IUD) have long been available but are not used by many women (e.g., victims of coercive sex) who could benefit from them (International Planned Parenthood Foundation, 1995; Trussell, Ellertson, & Stewart, 1996). Although this treatment was discovered in 1966, it was not until 1995 that the International Consortium for Emergency Contraception (ICEC, 2010) was formed to promote and mainstream emergency contraception worldwide. However, progestin-only preparations, commonly known as the "morning-after pill," are now available commercially in most countries as a dedicated emergency contraception product under many names worldwide (Trusell & Cleland, 2010).

Political, Social, and Financial Constraints

Although high unmet need is in part a function of specific management deficiencies in family planning programs, it is important to recognize that broader political and societal constraints also play a role.

Kenney (1993) has identified policies in a variety of countries that retard access to safe contraception:

- Health and safety regulations that restrict choice of methods or providers (e.g., the failure to approve oral contraceptives for use in Japan for more than nine years; a committee finally recommended their approval after the male impotence–relieving drug Viagra received endorsement within six months (Goldberg, 1999)
- Taxes and barriers to trade that affect importation of contraceptives
- Regulation of advertising (usually due to concerns about modesty and privacy)
- Restrictions on private-sector involvement in family planning

In addition, law and policies in many countries restrict or forbid access to abortion (Kenney, 1993).

In any discussion of family planning programs and their performance, the issue of financial sustainability is key. Family planning expenditures in LMICs as a whole are estimated to be approximately $14 billion annually, or roughly $1–2 per person per year in 2014 (High-Impact Practices in Family Planning [HIP], 2014). In the last two decades, most of this expense has been paid for by national governments (50%) and individual households (20%), with international donor assistance accounting for only 30% of the total ($4.2 billion). In the coming decades, rising demand for contraception and increasing budget constraints will require that programs either mobilize more public resources or increase the cost of family planning services to the individual, so that more users can be accommodated (Bulatao, 1998).

The Broader Effects of Family Planning Programs

Even before the 1994 International Conference on Population and Development in Cairo, concerns were expressed, both by women's groups and by policy makers, about the effects of family planning programs on the lives of individual women. Family planning programs have been criticized as exclusively concerned with reducing population growth. Studies in recent years have broadened research to include consideration of the effects of programs on the quality of life for women. In particular, the Women's Studies Project found that family planning programs provided the following benefits to women:

- "Most women and men are convinced that practicing family planning and having smaller families provide health and economic benefits."
- Family planning offers freedom from fear of unplanned pregnancy and can improve sexual life, partner relations, and family well-being.
- Where jobs are available, family planning users are more likely than non-users to take advantage of work opportunities.
- "Family planning helps women meet their practical needs and is necessary, but not sufficient, to help them meet their strategic needs" (Women's Studies Project, 1999).

The Women's Studies Project also found costs to women from such programs:

- "Contraceptive side effects—real or perceived—are a serious concern for many women, more so than providers realize.
- When partners or others are opposed, practicing family planning can increase women's vulnerability.
- When women have smaller families, they may lose the security of traditional roles and face new and sometimes difficult challenges, including the burden of multiple responsibilities at home and work" (Women's Studies Project, 1999).

In addition, the Women's Studies Project found that the exclusion of men from most family planning programs affected the ability of women to take advantage of their services, because men play a dominant role in family planning decisions in many regions.

Most family planning programs have emphasized only the positive benefits of family planning; they are now being urged to pay attention to at least some of these broader considerations.

A Broader Definition of Family Planning and Reproductive Health Programs

As discussed earlier, the 1994 ICPD brought about an international reevaluation of the conceptualization of family planning programs. These programs are now viewed as falling under the larger rubric of more general reproductive health services and interventions, some of which are directly health related, whereas others are related indirectly. It is useful, however, to first consider conventional family planning programs.

Organization and Structure of Family Planning Programs

While nearly all LMICs have established an infrastructure to deliver family planning services, their organization varies markedly. One example, Bangladesh, is discussed in **EXHIBIT 5-4**.

EXHIBIT 5-4 The Bangladesh Family Planning Program

Family planning in Bangladesh can be traced to the private Family Planning Association created in 1953, before Bangladesh achieved its independence from Pakistan. By 1960, Pakistan had begun public-sector programs, which Bangladesh continued after becoming a nation in 1971. The overall program has grown and changed over the years, but throughout there has been high-level political support and considerable funding from external donors. The Family Planning Association program has emphasized provision of services, outreach activities at the village level, and mass communication through a variety of media.

Within the early 1960s public-sector programs, family planning services were offered in government health clinics as part of regular health services. A system of using village aides to provide education was established but abandoned after only 18 months for a variety of reasons, including poor training of the aides, complaints that their services were directed only to family planning and not to other health problems, inadequate resources, and poor supervision. It was followed by renewed efforts run by a new Family Planning Board independent of the Ministry of Health.

Bangladesh's family planning efforts in the late 1960s met with little success, primarily because of poor-quality services provided by a program that had been instituted on a large scale, with little pilot testing and poor organization. The program emphasized use of the intrauterine device (IUD), which was met with resistance by many concerned about side effects and problems with its use. It did not help that the program was seen by many as having been imposed on Bangladesh, then East Pakistan, by a government whose political support was declining.

In the aftermath of the country's war for independence, although the health and social sectors of the government were particularly negatively affected, it was felt that family planning was urgently needed. A large and complex program was established. A separate Population Wing was created within the Ministry of Health and Population to run the program. Thus, health and family planning services were separated. At the local level, the primary healthcare staffs were predominantly male. In a society where little interaction is permitted between women and men who are not members of their families, male workers cannot provide maternal and child health services except for immunizations. This staffing was a legacy of early programs to combat smallpox, tuberculosis, and malaria; it was ill suited to the new focus. By contrast, local family planning workers were women, although their supervisors were men. These female workers went directly to households and offered family planning counseling and free supplies. They spent some time focusing on maternal and child health, although they were not well trained for this purpose.

Over the years, the Bangladeshi Family Planning program has continued to be revised, restructured, and expanded. In all cases, the elements of strong political support, strong financial support, and extensive administrative support have remained (Cleland et al., 1994; Streatfield & Kamal, 2013).

Cleland, J., Phillips, J. F., Amin, S., & Kamal, G. M. (1994). *The determinants of reproductive change in Bangladesh*. Washington, DC: World Bank.

According to Tsui, Wasserheit, and Haaga (1997), successful performance in the family planning realm is influenced by a focused commitment to achieving program objectives and access to adequate resources. At the national level, strong leadership, clearly formulated policies, explicit goals and objectives, and a clear agenda for meeting those goals can all contribute to the success of programs. In some countries, political commitment is evidenced by placing the family planning program under a national supervisory council or by establishing a separate ministry.

Programs also need ways of assessing progress toward meeting their objectives. Indicators such as contraceptive prevalence, proportion of unwanted births, maternal morbidity and mortality, pregnancy complications and their management, and actual fertility levels all provide information that, over time, can permit program evaluation. Therefore, one element of successful programs is the definition of result measures to be used and establishment of mechanisms for collecting the needed information. Caution is in order, however. For example, goals that are defined in terms of targets, such as the number of acceptors of particular methods in a given time, may lead workers to exert pressure on clients and reduce their options.

Family planning service programs have tended to focus on a narrow set of goals—reducing unwanted fertility by providing access to the means of fertility control. Several models have been used for the design of programs. In the vertical model, family planning administration and service delivery are carried out by staff for whom this is their single function. In a second model, a separate family planning administration unit is established, but field staff at each level of the healthcare system can deliver a variety of linked services. In practice, the linkage between family planning and maternal and child health services has been the most common. Under the new broader definition of reproductive health, it is expected that other types of services will be offered, so that the ways in which they

are linked, both administratively and in provision of care, will have to be addressed.

No matter which model is followed, the program design involves decisions about which services will be offered and at which level of the healthcare system. Tsui, Wasserheit, and Haaga (1997) have illustrated the various possibilities.[2] The levels of healthcare system that they suggest can deliver interventions for prevention and management of unintended pregnancies are summarized here:

Community

- Information, education, and communication programs
- Community-based distribution
- Social marketing of condoms and oral pills

Health Post

- Counseling/screening for contraception
- Counseling and referral for menstrual regulation or abortion
- Provision of injectable contraceptives
- IUD insertions
- Counseling and treatment of contraceptive side effects

Health Center

- Menstrual regulation/manual vacuum aspiration abortion
- Performing surgical contraception on set days
- Post-abortion counseling and contraception
- Counseling and treatment of contraceptive side effects

District Hospital

- Surgical contraception
- Abortions through 20 weeks, where indicated
- Post-abortion counseling and contraception

These authors' report concludes that the breadth and scope of the services to be delivered present formidable challenges in terms of design, execution, administration, and evaluation. Even if these challenges are met, a program can falter if adequate resources are not allocated to meet its needs for trained staff, equipment, and supplies. Additional demands will be placed on whatever system is in place if services related more generally to reproductive health are provided.

Research on design and implementation can help improve family planning and reproductive health programs. **EXHIBITS 5-5** and **5-6** describe the approach taken by Bangladesh in this regard.

Additional Reproductive Health Care Services

Some reproductive health services are closely linked to contraception; it is likely that, without much added expense, they can be integrated into conventional family planning programs relatively easily. These services may include pregnancy tests, Pap smears, and screening for sexually transmitted infections. STI screening has been carried out, in many cases, only in the context of separate programs to treat such infections. That type of intervention misses the general population of women who may not realize that they are infected or understand that they may pass their infection to their unborn or nursing children.

HIV/AIDS deserves special mention. In 1999, the United Nations convened a conference to assess the progress made on this front since the 1994 ICPD. Attendees concluded that the earlier conference had greatly underestimated the effects of HIV/AIDS on the populations of LMICs and called for specific programs and targets to reduce the spread of infection ("Conference Adopts Plan on Limiting Population," 1999). Directly related to the family planning realm is their call for greater access to methods such as female and male condoms that can reduce or prevent transmission of the virus. This and other approaches to preventing the spread of HIV/AIDS are discussed in the *Infectious Diseases* chapter.

Other desirable reproductive health interventions remain within the health realm but will require significant changes in staffing and significantly more financial resources to implement. These services include emergency obstetrics, general women's health services, abortion services where they are not already available, infertility services, and greatly expanded testing and counseling for HIV/AIDS. Some infertility services are already provided within the context of programs to reduce STIs, as these diseases are a major cause of infertility and premature sterility (Tsui et al., 1997). The others, however, are generally lacking. Without considerable expansion of the financial base for family planning and for the expanded reproductive health program, it is unlikely that these services can be provided in many LMICs.

EXHIBIT 5-5 Research to Improve the Family Planning Program in Bangladesh

How well do various types of family planning programs work? Few experiments in applied research have been conducted to determine whether a particular design is more effective in reaching the objectives of the program. The International Centre for Diarrhoeal Disease Research, Bangladesh (ICDDR,B) has carried out just these kinds of operations research experiments, which have served to improve the ways in which services are delivered within the Bangladeshi family planning program.

An early effort, in 1975, was intended to test the hypothesis that there was latent demand for family planning. ICDDR,B maintains a field station in Matlab, approximately 40 kilometers from the capital, Dhaka. A family planning program was introduced in roughly half of the area in which the center provided services, while people living in the remainder of the area had access only to standard government or private services. Local women, mostly illiterate widows, were hired to visit households approximately every 90 days to offer oral contraception to women. Later, condoms were added to the offerings. The hypothesis was that couples wanted to reduce their fertility, but would do so if only they were supplied with the necessary means. Initial acceptance was good; prevalence of use rose in the early stage of the program to almost 20% from its near-zero level prior to the program. Nevertheless, within less than nine months, it had dropped, so that the program area prevalence was only 6 percentage points higher than in the comparison area.

Lessons learned: This type of demand-oriented program is inadequate in a situation where women and couples have little social support for contraceptive use. Rather, a system that addresses the non-economic costs of use—whether social, psychological, or based on health concerns—is essential. In addition, problems arose in complying with a daily pill regimen, and condoms were not popular. Analysis of the experiment through interviews with people in the community also demonstrated the importance of the characteristics of the family planning worker. Women who had little status in the community and who were older than reproductive age themselves did not have sufficient credibility to help others withstand the social costs of use. Improving access was simply not enough.

A subsequent experiment begun in 1978 tested better follow-up for users, an expanded set of method choices, employment of better-educated and younger women, and new management strategies. These steps were undertaken to ensure that women received regular visits and that problems were addressed rapidly. A new dual leadership system was introduced, which included both technical (paramedical) and administrative supervision. The interval between visits was reduced to 14 days. Within a year, nearly one-third of women in the study area were contraceptive users, while there was little change in the comparison area. Increases in contraceptive use continued so that by 1990, nearly 60% of women in the targeted area were users, compared to only 25% in the comparison area. Clearly, taking advantage of latent demand for contraception required that the program address the social costs of contraceptive use. It also demonstrated the value of providing service in the home.

In 1983, a new experiment was begun outside of Matlab, to see if the lessons learned there could be applied within the government family planning program and without injection of major additional resources or changes in administration. This pilot project was carried out in two areas. Because of the success of this Extension Project, the government changed the national program to increase the number of female village workers, train them to provide injectable contraception within the home, and upgrade management to provide better support, both technical and supervisory, for local workers. In fact, one of the main lessons learned from these experiments was that careful supervision and support of workers were critical factors for success. Another lesson emphasized the importance of designing a program for local cultural circumstances—in this case, providing basic services in the home.

Since these experiments were conducted, other projects have tested variations of the Extension Project model to see how much it can be altered and still achieve the objectives of increased use of family planning and reduced fertility. Since the International Conference on Population and Development, the Extension Project (later renamed as the Operations Research Project) has initiated studies examining how the family planning program can be expanded to provide a wide array of reproductive and other health services under what is termed the Essential Services Package (Cleland et al., 1994).

Cleland, J., Phillips, J. F., Amin, S., & Kamal, G. M. (1994). *The determinants of reproductive change in Bangladesh*. Washington, DC: World Bank.

Reproductive Health Services Beyond Direct Health Care

Reproductive health interventions that go beyond the healthcare realm, while clearly valuable, are not linked in any obvious way to conventional family planning services. The ICPD's Cairo agenda focused on improving the status of women. It called for interventions such as income-generating activities for women and female education that improve the overall status of women as well as for sex education for youth, both male and female, to increase responsible sexual

EXHIBIT 5-6 Strategies Used by the Bangladesh Family Planning and Reproductive Health Programs

According to Cleland et al. (1994), at least four sets of strategies have been implemented:

1. Strategies to improve the coverage and quality of services:
   - Clinics, located within 5 miles of most couples, now provide free clinical contraception (IUDs, injectables, and implants) and treatment of side effects.
   - Sterilization is offered without charge at all subdistrict hospitals and is carried out by well-trained personnel.
   - Related health services for children and women are provided either in the home or in clinics.
   - Community-based distribution of low-cost nonclinical contraceptives (condoms and oral pills) is provided through pharmacies and is well publicized through various media.
2. Strategies to improve awareness and motivation:
   - Mass media are used to provide extensive relevant information; family planning and reproductive health are openly discussed in public media.
   - Focused programs (for example, with religious leaders) are carried out to build awareness and consensus.
3. Strategies to foster village-based and household services:
   - Outreach involves female workers who deliver services in the home. These services are now provided by both the government and nongovernmental organizations.
   - This strategy has been questioned in recent years by critics who say the time is past when women should be provided with services that encourage continued seclusion. They argue that the demand for family planning and reproductive health services is now so great that women will travel outside their homes to obtain these services and that this type of modernization is to be encouraged. In addition, issues of cost of maintaining the large cadre of home visitors is encouraging experimentation with less costly alternatives.
4. Strategies to foster community development and demand generation:
   - These strategies have not been carried out within the family planning program itself, but rather are directed toward improving the status of women. They include micro-credit and other programs sponsored by local organizations, such as Grameen Bank and the Bangladesh Rural Advancement Committee, and government strategies to increase education of girls. In fact, education of women has increased substantially in recent years. In many parts of Bangladesh, nearly all children—male and female—receive at least several years of primary schooling.

As a final note, the Bangladesh effort is characterized by the use of research to help determine the design of programs. Ongoing studies at the International Centre for Diarrhoeal Disease Research, Bangladesh are addressing how the new Essential Services Package (which includes services related to reproductive health, child survival, and curative care) can best be implemented within the existing fixed service provision sites, how to meet the health needs of adolescents, how to improve prevention and management of reproductive tract and sexually transmitted infections, and how to provide essential obstetric care (Cleland et al., 1994).

behavior. The 1999 follow-up conference reiterated and intensified these calls ("Conference Adopts Plan on Limiting Population," 1999).

Others have called for programs that decrease violence against women. Violence in women's intimate relationships can lead to death through homicide or through driving the woman to suicide. A less drastic outcome is loss of control by women over their sexuality and, therefore, their sexual health.

Another kind of violence against women is female genital mutilation, a practice that has been reported in more than 40 LMICs and has followed immigrants from these areas to high-income countries (Tsui et al., 1997). It is estimated that more than 200 million women have been affected globally by female genital mutilation and approximately 3 million girls are at risk for female genital cutting every year (UNICEF, 2016). Although any type of genital cutting carries a risk of infection, the implications of genital cutting for long-term reproductive health differ according to the severity of cutting, conditions of delivery, and sociodemographic factors. It is generally accepted that women who have undergone the most severe type of cutting, which includes removal of external genitalia and infibulation (stitching or narrowing of the vaginal opening), have an increased likelihood of delivery complications or obstetric morbidity (Slanger, Snow, & Okonofua, 2002). Even death may occur from excessive bleeding and infection resulting from use of unsterile equipment for performing the procedure by quacks. In some

countries, evidence suggests that a growing proportion of these procedures are being carried out by medical personnel (Yoder, Abderrahim, & Zhuzhuni, 2004).

Can These Goals Be Achieved? All parts of this new "beyond family planning" mandate are worthwhile. Nevertheless, it remains unclear how this expansion, in the absence of clearly designated additional funds to finance it, will affect the ability of family planning programs to reach their objective of promoting safe contraception (Cleland et al., 1994; Finkle & Ness, 1985). In addition, concerns have been raised that the expansion from family planning programs to reproductive health programs without additional funds will not only dilute what traditional family planning does reasonably well, but also fail to provide significant improvements in other areas (Bulatao, 1998; Mukaire, Kalikwani, Maggwa, & Kisubi, 1997; Twahir, Maggwa, & Askew, 1996). **EXHIBIT 5-7** discusses these issues in the context of Bangladesh.

In fact, the new agenda comes in an era when many high-income countries are reducing their

EXHIBIT 5-7 Challenges and Constraints for Family Planning and Fertility Reduction in Bangladesh

In the early 1990s, following the rapid decline in Bangladesh fertility from a TFR of 6.3 births per woman in 1975 to 3.4 births per woman in 1994, much optimism was voiced that fertility would continue to decline and that replacement-level fertility would be reached by 2005. However, fertility in Bangladesh plateaued at a TFR of approximately 3 children per woman from 1994 until 2005. Although this became a source of major concern, fertility once again started falling since 2005 and reached 2.3 births per woman (near replacement level) in 2015.

The initial dramatic fall in fertility took place within the context of relatively insignificant overt improvements in socioeconomic development, and was largely attributed to "supply-side initiatives"—that is, the impact of an intensive family planning program.

Various hypotheses have been put forth to explain the lack of progress in diminishing fertility in the 1995–2005 decade. Advocates of conventional family planning programs suggest that this trend may have been due to the change of focus (in the mid-1990s, following the expansion of the family planning agenda to include broad-based reproductive health services—see Exhibit 5-4) from household distribution of contraceptives by a vertical cadre of family planning workers to clinic-based family planning and reproductive health services provided by a unified integrated health and family planning service. They argue that this change (1) reduced the motivation of the family planning workers, who now had an expanded set of health-related duties that they were ill prepared to fulfill, and (2) made contraceptive provision just one of many government-sponsored healthcare activities, none of which had adequate resources committed to their fulfillment. Moreover, they question the optimistic view that family planning was so well established that women in rural Bangladesh no longer had social constraints vis-à-vis seeking family planning and reproductive health services outside the home.

Those who favor clinic-based services have pointed out that contraception prevalence rates have continued to rise in Bangladesh since 1995. They note that the change of method mix from predominantly oral contraceptives to more long-term contraceptive methods with lower failure rates required clinic-based initiatives.

Demand-side advocates argue that the exclusive focus on fine-tuning family planning programs to bring about fertility reduction is misplaced. They contend that further reductions in fertility will require broad-based initiatives to improve socioeconomic development (with a particular focus on improving women's status), which will help to reduce the benefits of additional children and increase their costs. They point to continued desired fertility of 2.3 children per woman—still higher than the replacement level, with quite significant regional variations that can be correlated with differences in women's education and employment, as well as continued preference for sons.

Due to the lack of progress in achieving further fertility declines, in 2006 the government of Bangladesh switched back from clinic-based services to household distribution. The current situation with regard to TFR is that it has declined from 3.0 births per woman in 2005 to 2.3 births per woman in 2015. The reasons behind this slow but steady decline continue to be debated.

In addition to the continuation of traditional supply-side initiatives such as household distribution of contraception, a highly successful social marketing program promoting contraceptive distribution and sales has been established all over the country. Bangladesh Demographic and Health Survey 2014 (BDHS) reports that 43.5% of the oral pill users and 62.0% of condom users relied on social marketing brands bought from commercial outlets (BDHS, 2016).

On the demand side, it is also important to note that in the 2005–2015 period, significant improvements occurred in female education, employment, and economic growth (Bangladesh has averaged 6% growth in its gross domestic product over the last decade). All of these factors can be said to increase the opportunity costs of childbearing and childrearing, leading to lower levels of desired fertility among Bangladeshi families.

The debate about demand-side versus supply-side policy initiatives as the best approach to fertility reduction continues. Most researchers and policy makers believe that both kinds of initiatives are important, but there is growing appreciation that the final stretch of fertility decline to replacement levels may be a long, hard battle all over the world.

aid contributions. International experts estimate $14 billion is needed annually to sustain coverage for existing users and to achieve the 2020 family planning goal of reaching 120 million additional contraceptive users in the poorest 69 countries (Singh & Darroch, 2012). In-country funding to purchase commodities and supplies has increased dramatically to sustain such programs in many countries (proportion of total FP expenditure)—from nothing in 2006 to 89% in 2012 in Paraguay; from 73% in 2009 to 99% in 2012 in Bangladesh; and from 5% in 2011 to 21% in 2012 in Rwanda (HIP, 2014). In contrast, funding commitments for international programs have experienced an overall decline. The largest donor—the U.S. government—has significantly curtailed its funding of family planning programs, particularly in the Donald Trump administration (BBC, 2017). Commitments from other donors including the Bill and Melinda Gates Foundation, the Canadian government, and several European governments have increased but might be inadequate to replace the shortfall due to the U.S. pull-out (Wildman, 2017). Increasing the political will and raising the funding for these new programs and for maintaining existing effective ones is perhaps the greatest challenge for reproductive health in the twenty-first century.

Impact of Reproductive Patterns on the Health of Children

Over the last several decades, an impressive body of evidence has accumulated suggesting that certain kinds of reproductive patterns are injurious to infant and child health (**TABLE 5-11**). These risk factors are usually discussed as if they were completely independent. In reality, a number of problematic issues arise with this approach to deleterious reproductive patterns. For example, many of the risk factors are integrally linked with one another and their independent

TABLE 5-11 Mechanisms by Which Reproductive Patterns Affect Child Health

Reproductive Pattern	Mechanism Through Which Child Health Is Affected
Firstborn children	First-time mothers have a higher frequency of health problems during pregnancy and childbirth; parents have less experience with child care; poorer intrauterine growth
Higher-order children	Possible cumulative effect of earlier maternal reproductive injury—"maternal depletion" syndrome—leading to poorer intrauterine growth
Large families	Competition for limited resources, with some children, possibly disproportionately girls, losing out; possible spread of infection
Children born to very young mothers	Inadequate development of maternal reproductive system and incomplete maternal growth; young mothers less likely to know about and use prenatal and delivery care or provide good child care
Children born to older mothers	Greater risk of birth trauma; greater risk of genetic abnormalities
Short interbirth intervals	Inadequate maternal recovery time (maternal depletion); competition among similar-age siblings for limited family resources; early termination of breastfeeding; low birth weight; increased exposure to infection from children of similar ages
Unwantedness	Neglect (conscious or unconscious); child born into a stressful situation
Maternal death or illness (e.g., chronic infection such as AIDS)	Early termination of breastfeeding; no maternal care; disease may be passed to child
Contraceptive use	Hormonal contraception may interrupt breastfeeding

effects are difficult to disentangle. Thus, first births and young age of mothers are separately cited as risk factors, but young mothers usually are having their first birth. Similarly, children of high parity come from large families and are likely to have older mothers, yet all three factors are often referred to individually.

Parity and Child Health

First births are known to be more dangerous for the child than are subsequent births. The excess risk relative to births of order 2–4 is limited to the first year of life, however—particularly to the neonatal period (the first 28 days of life), when the odds ratio for mortality is 1.7. There appears to be no survival disadvantage after the child reaches his or her first birthday (Hobcraft, 1987; Hobcraft, McDonald, & Rutstein, 1985).

The excess risk for firstborn children varies considerably across countries. It is not clear whether this risk reflects inadequate physiologic adjustment of first-time mothers to pregnancy (leading to lower intrauterine growth, shorter gestation, lower birth weight, a higher probability of birth trauma, higher risks of pregnancy-induced hypertension, higher prevalence of placental malaria in malaria-endemic areas, and so on) or whether it arises because of the lack of experience of first-time mothers in care seeking and care taking. The latter factor is, of course, amenable to policy prescriptions that encourage first-time mothers to seek prenatal and postnatal care (Haaga, 1989; National Research Council, 1989).

Higher-order births may suffer due to poor maternal health as a result of cumulative exposure to previous pregnancies (Hobcraft et al., 1985; Pebley & Stupp, 1987). Mothers may experience inadequate recovery of their energy stores after earlier pregnancies (maternal depletion hypothesis) or the long-term cumulative effects of prior delivery-related injuries. Thus, higher-order children (parity of 5 or greater) may be at greater risk of poor intrauterine growth, greater trauma during birth, and, more generally, poorer health than lower-parity (orders 2–4) children. Although these mechanisms are plausible, the empirical evidence supporting them is inconsistent and suggests that little additional risk can be attributed to higher-order births, once short birth intervals are taken into account (Gubhaju, 1986; Hobcraft et al., 1985; National Research Council, 1989).

In addition to physiologic deficiencies, higher-order children may suffer deleterious consequences of competition for limited family resources. In particular, they may get proportionately less food and less attention from their parents. This negative consequence of large families may not be limited solely to higher-order births. If family resources are limited and there is no preference for specific children, all children may suffer as a result of large family sizes. Some evidence suggests that certain children (particularly higher-order girls, and especially those with older sisters) suffer disproportionately from the impact of large family size in specific social settings (Muhuri & Menken, 1997).

Maternal Age

Hobcraft (1987) found that children born to teenage mothers had significantly higher risks of dying than children born to mothers age 25 to 34 years (Hobcraft et al., 1985). This excess mortality risk was 1.2 for the neonatal period, 1.4 for the post-neonatal period, 1.6 for toddlers, and 1.3 for children age 2 to 5 years. Nevertheless, considerable variability was observed among countries in terms of the excess mortality risk for children born to young mothers.

Plausible explanations reflecting both physiological and social causes have been offered for the health disadvantage experienced by children born to young mothers. Perhaps these children are disadvantaged because maternal reproductive systems are inadequately developed (Aitken & Walls, 1986) or because young mothers lack experience and knowledge about prenatal and postnatal care (Geronimus, 1987). Unfortunately, little solid empirical evidence from LMICs is available to prove (or disprove) any of these hypotheses. It has been difficult to study possible competition between fetal growth and maternal development as a factor underlying the excessive mortality of children born to young mothers in LMICs. Due to lack of reliable data on gynecologic age (i.e., age since menarche—a particularly important concern because of delayed age at menarche in LMICs [Foster, Menken, Chowdhury, & Trussell, 1986]) or chronological age of mothers younger than 20, Haaga (1989) concluded that there was only weak evidence for this proposed mechanism. Studies that have addressed social causes (i.e., poor knowledge and use of prenatal care) have used socioeconomic status as a crude proxy for use of prenatal care services. In multivariate analyses, this measure fails to help explain the high risk that accrues to infants and children born to young mothers.

Children born to older mothers may suffer because of poorer maternal health due to age-related declines in physiologic function and a higher risk of genetic abnormalities (Hansen, 1986). Little proof exists that this is a major risk factor in LMICs, however.

Short Birth Intervals

Short birth intervals, both prior and subsequent to the birth of a child, are probably the most consistent reproductive pattern identified as a risk factor for

excess child mortality. Hobcraft (1987) reports that the excess mortality risk of children born less than 24 months after the preceding birth compared to those born 24 months or more after the preceding birth is 1.8 in the first year of life, 1.3 for toddlers (ages 1 to 2 years), and 1.3 for children ages 2 to 5 years. In terms of subsequent birth intervals, on average, across 34 countries, children whose birth was followed by a subsequent birth within less than 24 months had 2.2 times the risk of dying of those children for whom the subsequent birth interval was longer (Hobcraft, 1987). As is the case for other demographic risk factors, considerable variation exists between countries in terms of risks related to short birth intervals.

A number of plausible explanations have been put forth for the relationship between short prior and subsequent birth intervals (less than 24 months) and a child's risk of poor health and increased mortality. First, due to maternal depletion (resulting from inadequate recovery time from the nutritional burdens of breastfeeding and prior pregnancy [Merchant & Martorell, 1987]), children born after a short birth interval may suffer poorer intrauterine growth, and possibly have a higher risk of preterm birth. To date, little empirical evidence has been collected that supports this mechanism (Ferraz, Gray, Fleming, & Maia, 1988; National Research Council, 1989; Pebley & DaVanzo, 1988; Winikoff & Sullivan, 1987).

Second, children born before a short birth interval may suffer from premature cessation of breastfeeding (which has been shown to be an important correlate of child survival in LMICs [Palloni & Millman, 1986]), as the mother shifts her attention to the more recent arrival. Given that studies that have controlled for the length of breastfeeding still show an association between short subsequent birth interval and high infant mortality (Pebley & Stupp, 1987), premature termination of breastfeeding does not entirely explain this effect.

Third, children born in close proximity to each other may suffer from competition for limited family resources of time and food. The evidence for this type of competition is unclear and sometimes contradictory (DaVanzo, Butz, & Habicht, 1983; Palloni, 1985).

Fourth, close birth spacing may increase the likelihood of transmission of infectious diseases such as diarrhea and measles, due to overcrowding and presence of children of similar ages (Aaby, Bukh, Lisse, & Smits, 1984).

Finally, despite adequate controls for observable confounding factors in multivariate analyses, part of the relationship between short birth intervals (either preceding or following the index birth) and increased child mortality may be due to unobserved factors such as short gestational length or parental characteristics. Babies born before or after very short birth intervals are known to be at high risk for short gestational durations, which independently have been shown to increase child mortality dramatically (Miller, 1989; Pebley & Stupp, 1987).

In terms of unobserved parental characteristics, it is possible that women who are likely to have short birth intervals are inherently at higher risk for poorer child health outcomes than their peers who have longer birth intervals. This would lead to a spurious inference that short birth intervals are causally related to higher child mortality (Pebley & Stupp, 1987; Potter, 1988; Rosenzweig & Schultz, 1983).

Unwanted Pregnancy and Birth

As discussed previously, unwanted children have much higher risks of morbidity and mortality. They may suffer from both conscious and unconscious neglect, due to smaller allocations of food, less parental time and attention, and less access to health care. In countries with a strong son preference (South and Southeast Asia), significant evidence points to higher mortality among female children relative to their male siblings (Das Gupta, 1987; D'Souza & Chen, 1980; Muhuri & Menken, 1997). Moreover, the recent rise in sex-selective abortion in China and Southeast Asia (which has led to a disproportionately high male-to-female sex ratio at birth) is evidence of the high risk of mortality for unwanted female fetuses (Larsen et al., 1998; Tsui et al., 1997). The pattern of gender discrimination is complex and nuanced, however, and may vary by societal setting (Muhuri & Menken, 1997).

Maternal Health

Maternal morbidity and mortality can have profoundly negative effects on child health, leading to high rates of morbidity and mortality. Population-based studies in South and Southeast Asia suggest that more than half of all perinatal deaths (i.e., deaths in the first week of a child's life) are associated with poor maternal health and pregnancy and delivery-related complications (Fauveau, Koenig, Chakraborty, & Chowdhury, 1988; Kusiako, Ronsmans, & Van der Paal, 2000; National Statistics Office [Philippines] & Macro International, 1994). These deleterious consequences may result from a combination of direct delivery-related consequences, such as premature labor, prolonged or obstructed labor, and abnormal fetal position (Kusiako et al., 2000); physiologic processes, such as cessation of breastfeeding following maternal morbidity and mortality

as well as maternal fetal transmission of a variety of infectious agents, including HIV, toxoplasmosis, cytomegalovirus (CMV), rubella, hepatitis B virus, herpes simplex, syphilis, malaria, and tuberculosis; and emotional impacts and lower levels of caregiving (National Research Council, 1989; Overall, 1987; Turner, Miller, & Moses, 1989; Weinbreck et al., 1988). This is particularly a major concern in sub-Saharan Africa, where significant numbers of mothers are infected with HIV and other STIs (National Research Council, 1989; Turner et al., 1989; Weinbreck et al., 1988).

Methodological Concerns

The previously mentioned mechanisms by which specific reproductive patterns affect infant and child health are certainly plausible and suggestive. Nevertheless, it is important to reiterate that the empirical evidence—in terms of the appropriateness of both data and statistical methods—supporting such mechanisms is variable and needs to be interpreted cautiously. Women have some control over their choices of reproductive patterns (i.e., whether to have children early or late, whether to have shorter or longer birth intervals, whether to have high parity births). Therefore, unobservable factors that are associated with both reproductive patterns and child health may be operating, and reverse causality may influence the results observed. As a consequence, our estimates of the impact of specific reproductive patterns on the risk of poor infant and child health may be overstated.

For example, if women who choose to be young mothers are prone to behavior patterns that devalue prenatal and postnatal care, delaying childbirth for these women will not produce the salutary effects that the earlier discussion suggests. Similarly, unobserved selection biases may operate such that a significant proportion of women who choose to have children at older ages, have higher-parity births, and have closely spaced births, are intrinsically in better health—most likely because of their higher socioeconomic status. If that is the case, then reducing higher-parity births, increasing interbirth intervals, and reducing births to older women (older than age 35) will not result in the degree of improvement that the current studies suggest.

With regard to reverse causality, one example is the often-cited relationship between the mortality of an index child and a short subsequent birth interval. The inference is that a child is at a higher risk of death if the next-younger sibling arrives after only a short interval, presumably because the pregnancy and the arrival of a newborn cause early cessation of breastfeeding for the older child and a shift of other maternal resources to the younger child. In reality, it is quite possible that the subsequent birth interval is short because the index child died, or was ill and weaned earlier because of his or her existing health problems. Thus, the direction of causation is not from the short subsequent birth interval to the death of the preceding child, but rather in the reverse direction—from the death of the preceding child to a short subsequent birth interval. Although in principle statistical methods can deal with this kind of potential bidirectionality (Rosenzweig & Schultz, 1983; Schultz, 1984), in practice relatively few published studies have employed such sophisticated methods of analysis.

In summary, because of the various methodological concerns, we should be careful not to overinterpret the evidence linking specific reproductive patterns and poor child health.

Summary of the Impact of Reproductive Patterns on Child Mortality

Despite these caveats about over-interpretation and overestimation, it is instructive to consider the impact of specific deleterious reproductive patterns on infant and child mortality. The National Research Council (1989) has simulated the impact of various reproductive patterns on child mortality rates using data from 18 LMICs reported by Hobcraft (1987). The simulations in **TABLE 5-12** refer to death rates that would be observed in individual families with particular reproductive patterns; they assume the mortality risks associated with the specific reproductive pattern are causative.

Table 5-12 shows that children of parity 2 and greater are at much higher risk of mortality if they are born to teenage mothers than if their mothers are ages 20 to 34 years. Moreover, both teenage and nonteenage mothers can significantly reduce the risks of child mortality by adopting better spacing patterns (i.e., birth intervals of 24 months or more). The best-case scenario for children of parity 2 and greater is for those born to mothers between the ages of 20 and 34, whose older sibling has survived, and whose birth interval is 24 months or more. Only 67 of 1,000 such children fail to reach their second birthday. This is less than half the mortality risk of their peers born to teenage mothers and whose birth intervals are less than 24 months. In the latter situation, 165 of 1,000 such children die before age 2 years.

Other simulations show the deleterious consequences of increasing family size and birth intervals on the probability of a child surviving to his or her fifth birthday. These calculations were carried out under low, moderate, and high baseline child mortality rates

TABLE 5-12 Estimated Risk of Dying (Deaths per 1,000 Births) Prior to Their Second Birthday for Second- and Higher-Order Births to Women with Different Reproductive Patterns

Age of Mother	Better Spacing Pattern	Poor Spacing Pattern
Teenage mothers	92	165
Mothers ages 20–34	67	120

Note: Better spacing pattern: Birth intervals both preceding and subsequent to this birth were 24 months or greater and the older sibling survived. Poor spacing pattern: Birth intervals both preceding and subsequent to this birth were less than 24 months and the older sibling survived.
Data from the National Research Council. (1989). *Contraception and reproduction: Health consequences for women and children in the developing world.* Washington, DC: National Academy Press; Hobcraft, J. N. (1987). Does family planning save lives? Paper presented at the International Conference on Better Health for Women and Children Through Family Planning, Nairobi, Kenya.

(to take into account variations in overall mortality among populations). The baseline child mortality rates represent the probability of a child surviving to his or her fifth birthday for children who have the lowest risk profile—that is, parity 2–3, preceding and subsequent birth intervals of 24 months or more, and the older sibling survived. Thus, in a population with a baseline child mortality rate of 150/1,000, out of 1,000 births of children who were parity 2–3, had long preceding and subsequent birth intervals (24 months or more), and whose older sibling survived, 150 would die before their fifth birthday.

Mortality rates for specific combinations of parities below and above the baseline, of short and long intervals, and of survival of older sibling were estimated by Hobcraft (1987). He then simulated the average number of children per 1,000 births who would die before their fifth birthday. Here we discuss only those cases where the older sibling survived. In terms of family size, small families were much better off than large families. Regardless of the baseline mortality rates or the closeness of birth spacing, the larger the family size, the higher the child mortality rates. In all cases, four-child families experienced fewer than half the deaths per 1,000 births of nine-child families. Similarly, families with long spacing experienced half or less the mortality per 1,000 births of families with consistently short spacing. Clearly, the most beneficial scenario for children is that of well-spaced births and small overall family sizes.

Impact of Reproductive Patterns on the Health of Women

Pregnancy is one of the major health risks for women in LMICs. Nearly 303,000 women die worldwide each year due to pregnancy-related causes, and the vast majority (99%) of these deaths occur in LMICs (WHO, 2015b). Although these numbers are alarming, it is important to recognize that 210 million pregnancies and approximately 140 million births occur annually in the world (Graham et al., 2016); thus, by and large, reproduction is relatively safe for women.

Maternal mortality risks are a fraction of infant mortality risks. For example, Bangladesh has still high infant and maternal mortality risks, but the latter is roughly a 1/20th of the former. The maternal mortality ratio is approximately 176 deaths per 100,000 births, while the infant mortality rate (which has fallen considerably in the last decade) is approximately 38 deaths per 1,000 births (Macro International, 2015; WHO, 2015b). Similarly, for Kenya, the maternal morality ratio, 510 deaths per 100,000 births, is roughly one-eighth of the infant mortality rate, approximately 39 deaths per 1,000 births (Macro International, 2015; WHO, 2015b).

Definitions

In any discussion of maternal mortality, a number of potentially confusing definitional issues arise. The first is the definition of a maternal death. A maternal death is usually defined as the death of a woman while pregnant or up to 42 days post delivery from any cause (except accidents). There has been some discussion as to whether this definition is overly restrictive (i.e., leading to an undercount of maternal deaths) and should be expanded to include female deaths up to 90 days post delivery. In reality, data from a number of well-conducted population-based studies using different post-delivery durations show that the majority of maternal deaths occur within 42 days post delivery, with approximately 40% occurring within 24 to 48 hours of delivery. Furthermore, extending the definition to up to 90 days would result in only a marginal increase (6%) in the number of deaths classified as related to maternal causes (Egypt Ministry of Health, 1994; Fauveau et al., 1988).

The second issue is the measure of maternal mortality risk that should be used in comparing and contrasting the situations in different populations both geographically and across time. Maternal mortality risks are conventionally described using three measures. It is important to understand and to think of these measures separately, because they are conceptually distinct.

The first measure is the *maternal mortality ratio*, which is defined as the ratio of the number of maternal deaths to the number of pregnancies. It is an indicator of the risk of death that a woman faces for each pregnancy she undergoes. Although conceptually the denominator for such a risk measure should include all pregnancies, operationally, because of the difficulty of counting miscarriages and induced abortions, the denominator used is live births.

The second measure is the *maternal mortality rate*, which is defined as the number of maternal deaths divided by the number of women of reproductive age (i.e., between ages 15 and 49). This composite measure is the product of the maternal mortality ratio (number of maternal deaths per births) and the birth rate in the reproductive age group (number of births for women between ages 15 and 49). The maternal mortality can be changed by altering the frequency of pregnancies or births in the population without changing the risk of maternal death per pregnancy/birth. Although the maternal mortality ratio and the maternal mortality rate are conceptually distinct, they are often confused in the public health literature, with rates referring to ratios, and vice versa. In this book, these two measures are carefully distinguished.

The third measure is the *lifetime risk of maternal mortality*. Also a composite measure, it not only takes into account the maternal mortality risk per pregnancy, but also factors in the cumulative exposure to pregnancy that an individual woman experiences. The average cumulative exposure to pregnancy is usually taken to be the total fertility rate for the population. It is an estimate of the number of births a woman in a particular society would have over her lifetime if she were to adhere to the current age-specific fertility rates in that population.

The lifetime maternal mortality risk for a woman in one of the LMICs in 2005 was estimated to be 1/75 (Population Reference Bureau, 2008; United Nations Population Fund [UNFPA], 2004, 2009). This estimate can be interpreted as follows: A woman in the LMICs who (1) has the same total number of pregnancies over her lifetime as the current fertility norm (estimated to be 2.7 births) and (2) experiences at each pregnancy the same independent risk of maternal death as the current maternal mortality ratio (approximately 500 maternal deaths per 100,000 births) would have 1 chance in 75 of dying from pregnancy-related causes. This lifetime risk captures both the risk of dying per pregnancy and the cumulative effect of exposure to multiple pregnancies.

Maternal Mortality Risks

A major constraint with respect to investigating the magnitude of maternal mortality risks and its determinants is the lack of available and reliable population-based data. Even in LMICs, many of which have high maternal mortality rates and ratios, maternal deaths are relatively rare. For example, in sub-Saharan Africa and South Asia, where maternal mortality ratios of 800 maternal deaths per 100,000 live births have been reported, one would need very large sample sizes to obtain reasonable estimates of maternal mortality risks and their accompanying determinants. A sample of 10,000 births (a very large sample by any standards) would be expected to yield only 80 maternal deaths. In contrast, infant mortality rates in these settings are typically 15 times as large, and the same sample would yield 1,050 infant deaths.

To date, relatively few large-scale population-based studies of maternal mortality have been conducted in LMICs. The major investigations were carried out in Bangladesh (Alauddin, 1986; Chen, Gesche, Ahmed, Chowdhury, & Mosley, 1974; Fauveau et al., 1988; Koenig et al., 1988; National Institute of Population Research and Training [NIPORT], 2003), Ethiopia (Kwast, Rochat, & Kidane-Mariam, 1986), Egypt (Egypt Ministry of Health, 1994; Fortney et al., 1985), and Jamaica (Walker, Ashley, McCaw, & Bernard, 1985). Estimates for other countries are derived from model-based assumptions and, therefore, are not as precise.

Huge disparities in maternal mortality are observed among various regions of the world. The disparity between LMICs and high-income countries is much greater for maternal mortality (20 times higher risk of maternal death per pregnancy in 2015) than for infant mortality (10 times higher risk of infant death per pregnancy). Lifetime risks of maternal mortality vary from 1/41 in African countries to 1/4,900 in in high-income countries (**TABLE 5-13**).

Table 5-13 shows the estimates of total number of pregnancies per woman (TFR), maternal mortality ratio (MMR), individual risk of dying per pregnancy (lifetime risk), and total number of maternal deaths in different regions of the world in 2005 and 2015. Although global maternal mortality was almost halved in 2015 relative to the 2005 maternal mortality, all the estimates are still much higher in LMICs than

TABLE 5-13 Total Fertility Rate, Maternal Mortality Ratios, and Lifetime Risks of Maternal Death by Region of the World, 2005 and 2015

					Maternal Deaths			
Region	Total Fertility Rate (births per woman)		Maternal Mortality Ratio (deaths per 100,000 live births)		Lifetime Risk		Deaths per Year	
	2005	2015	2005	2015	2005	2015	2005	2015
World total	2.6	2.5	400	216	1 in 92	1 in 180	536,000	303,000
High-income countries	1.7	1.7	9	12	1 in 7,300	1 in 4,900	960	1,700
Low- and middle-income countries	2.7	2.6	450	238	1 in 75	1 in 150	533,000	302,000
Africa	4.8	4.7	820	495	1 in 26	1 in 42	276,000	204,000
Asia	2.3	2.1	330	119	1 in 120	1 in 370	241,000	90,000
Latin America and Caribbean	2.3	2.1	130	67	1 in 290	1 in 670	15,000	7,300

Accessed on November 8, 2016 from http://www.prb.org/Publications/Datasheets/2015/2015-world-population-data-sheet.aspx; Trends in maternal mortality: 1990 to 2015: estimates by WHO, UNICEF, UNFPA, World Bank Group and the United Nations Population Division. Accessed on November 8, 2016 from http://www.who.int/reproductivehealth/publications/monitoring/maternal-mortality-2015/en/

in high-income countries. Even so, it is the risk of dying per pregnancy that accounts for the vast majority of the difference in lifetime risk of maternal mortality. Total fertility rates in LMICs were, on average, 1½ times as high as in the high-income countries (2.6 births per woman versus 1.7 births per woman). Maternal mortality ratios were still 20 times as high (238 maternal deaths per 100,000 births in LMICs versus 12 maternal deaths per 100,000 births in high-income countries), although they were about 50 times higher in 2005. Only one country (Sierra Leone) in 2015 had an MMR of more than 1,000 deaths per 100,000 live births, compared to 14 countries—Afghanistan, Angola, Burundi, Cameroon, Chad, Democratic Republic of the Congo, Guinea-Bissau, Liberia, Malawi, Niger, Nigeria, Rwanda, Sierra Leone, and Somalia—in 2005. However, still 19 countries had MMRs of more than 500 deaths per 100,000 live births; all of these countries were in sub-Saharan Africa: Burundi, Cameroon, Central African Republic, Chad, Cote d'Ivoire, Democratic Republic of the Congo, Eritrea, Gambia, Guinea, Guinea-Bissau, Kenya, Liberia, Malawi, Mali, Mauritania, Nigeria, Sierra Leone, Somalia, and South Sudan (WHO, 2015b).

Direct and Indirect Causes of Maternal Mortality and Morbidity

What are the sources of the mortality risk per pregnancy? The causes of maternal mortality are conventionally divided into direct causes—those that occur only during pregnancy and the immediate post-delivery period—and indirect causes—those derived from conditions that precede, but are aggravated by, pregnancy, such as anemia, diabetes, malaria, tuberculosis, cardiac disease, hepatitis, and increasingly AIDS (Ronsmans et al., 2006; WHO, 2005).

In LMICs, direct causes account for 73.0% of maternal mortality and include, in approximate order of importance, hemorrhage (27.1%), hypertensive disorders of pregnancy (eclampsia—14%), sepsis (10.7%), complications of unsafe abortion (7.9%), and embolism and other direct causes (1.8%) (Filippi, Chou, Ronsmans, Graham, & Say, 2016). Obstructed labor and complications due to delivery, each of which accounts for 2.8% or maternal deaths, are included in the "other causes" group (Filippi et al., 2016). The vast majority of these maternal deaths can be attributed to just three causes: hemorrhage, eclampsia, and sepsis.

Attribution of cause of death is complicated by the fact that in most cases unsafe abortion and obstructed or prolonged labor eventually cause death via the proximate causes of hemorrhage or sepsis.

There is variation in the order of importance of these causes in different studies from different parts of the world (Jamison, Mosley, Measham, & Bobadilla, 1993), partly due to real differences in the availability and use of obstetric care and partly due to differences in the quality of reporting. Thus, in countries that have poor access to obstetric care facilities, a relatively large proportion of deaths are attributed to hemorrhage, sepsis, and abortion. Differential reporting—particularly reluctance to attribute maternal deaths to abortion in countries where it is illegal—also artifactually inflates the proportion of deaths attributed to hemorrhage and sepsis. For example, Jamison and associates (1993) estimated that, for the period 1980–1985, these two causes were responsible for 56% of maternal deaths in Indonesia, 40% of such deaths in Egypt, and 18% of maternal deaths in the United States.

The remaining 27% of maternal deaths can be attributed to illnesses aggravated by pregnancy (Jamison et al., 1993; WHO, 1993b). For example, anemia hampers a woman's abilities to resist infection and to survive hemorrhage; it may increase the likelihood of her dying in childbirth by a factor of 4 (Chi, Agoestina, & Harbin, 1981). Hepatitis can cause hemorrhage or liver failure in pregnant women (Kwast & Stevens, 1987). Latent infections such as tuberculosis, malaria, or STIs can also be activated or exacerbated during pregnancy and cause potentially severe complications for both mother and child (Jamison et al., 1993).

In keeping with the high rates of maternal mortality in LMICs, there are also high rates of maternal morbidity in these countries. An estimated 30 to 50 morbidities (temporary and chronic) occur for every maternal death (Safe Motherhood Initiative, 2010). Between 30% and 40% of the approximately 180 million women who are pregnant annually in the world, or roughly 54 million women, report some kind of pregnancy-related morbidity (Koblinsky, Campbell, & Harlow, 1993; WHO, 1993b). Of these women, 10 to 15 million each year develop relatively long-term disabilities deriving from complications from obstetric fistula or prolapse, uterine scarring, severe anemia, pelvic inflammatory disease, reproductive tract infections, or infertility (Filippi et al., 2006; Ronsmans et al., 2006; Tsui et al., 1997).

These figures demonstrate significant variability from one country to another (Tsui et al., 1997). For example, Guatemalan women report one in five pregnancies as being complicated (Bailey, Szászdi, & Schieber, 1994), women in West Java report one in three pregnancies as being complicated (Alisjahbana et al., 1995), and two out of three pregnancies in Ghana had some complications (De Graft-Johnson, 1994). This variability in rates stems at least in part from differences in study design and data quality. To date, relatively few population-based surveys have been carried out. Moreover, maternal morbidity data are often based on self-reported symptoms—a data collection technique that has been shown to have relatively low reliability and validity (Stewart & Festin, 1995). A few data sets with reliable information have come from the United States and Canada (Koblinsky et al., 1993; WHO, 1994) and from specific validation studies (Stewart & Festin, 1995). These data show that, on an annual basis, 12% to 15% of women who are pregnant suffer life-threatening obstetric complications, equivalent to approximately 20 million women in LMICs (assuming approximately 150 million women giving birth annually). In contrast to the evidence on acute pregnancy-related morbidity, little is known about the long-term chronic morbidity sequelae of pregnancy-related complications, which may significantly affect women's lives.

Specific Causes of Pregnancy-Related Morbidity and Mortality

This section focuses on some of the more prominent causes of pregnancy-related morbidity and mortality in LMICs.

Obstructed and Prolonged Labor

Obstructed or prolonged labor leads to approximately 8,500 maternal deaths annually, with high proportions of the survivors developing obstetric fistulas and their newborns often experiencing long-term sequelae of anoxia and even death (Kusiako et al., 2000; Say et al., 2014). Predictive risk factors for this outcome are not particularly reliable (Fortney, 1995; Maine, 1991). Monitoring during labor using a partograph is the only effective way to detect such problems (Mathai, 2009).

Obstetric Fistula and Genital Prolapse

Both obstetric fistulas and genital prolapse have severe consequences for pregnant women. As a consequence, they represent a major global health problem.

An obstetric fistula is a passage or channel from the vaginal wall to either the rectum (recto-vaginal fistula) or the bladder (vesico-vaginal fistula). It is usually a result of a tear in the vaginal wall during complicated labor. Risk factors for obstetric fistulas include being a young mother, a stunted mother, or a mother who

has complicated labor and delivers in a nonhospital setting with the help of traditional birth attendants (Lawson, 1992; Tahzib, 1983, 1985). Population-level estimates of obstetric fistulas are difficult to find, but a recent meta-analysis reports that the population-based pooled prevalence of obstetric fistula is 0.29 case per 1,000 women of reproductive age in all regions, with the highest prevalence in sub-Saharan Africa (1.60 cases per 1,000 women) and South Asia (1.20 cases per 1,000 women) (Adler, Ronsmans, Calvert, & Filippi, 2013). The prevalence of obstetric fistula is estimated to be 1.69 per 1,000 ever-married women in Bangladesh (Waiz et al., 2003).

The consequences of fistulas are quite severe, especially for young primipara women. The baby is often stillborn, and the mother is incontinent of urine and/or feces. This condition is a source of enormous personal discomfort, whose consequences are exacerbated by social stigma. In many cases, it leads to divorce and social ostracism—these women are often barred from food preparation or even participating in prayer, due to lack of personal hygiene (Reed et al., 2000).

Genital prolapse occurs when the vagina and uterus descend below their normal positions. This condition is usually a result of damage to supporting muscles and ligaments during childbirth and is most often associated with high parity. It is particularly uncomfortable for women who are squatting, which is the normal position for doing many chores in LMICs. It can also lead to chronic backache, urinary problems, and pain during sexual intercourse. Subsequent pregnancies have a higher probability of fetal loss and further maternal morbidity.

Although good estimates are difficult to obtain, some reliable population studies suggest that 2% to 20% women younger than age 45 suffer from genital prolapse worldwide (Kuncharapu, Majeroni, & Johnson, 2010). The Giza study (Younis et al., 1993), which clinically validated reported prolapse, found that one-third of women suffered from genital prolapse and also documented a relationship between genital prolapse and risk of reproductive tract infections.

Anemia

Approximately 50% of pregnant women around the world are estimated to be anemic (i.e., to have hemoglobin levels less than 11 g/dL). Dietary iron deficiency is the primary cause of this condition, followed by malaria, other parasitic diseases (schistosomiasis, hookworm), folate deficiency, AIDS, and sickle cell disease (Tsui et al., 1997). In addition to its well-documented effects on pregnancy outcomes—prematurity, stillbirths, and spontaneous abortions (Levin, Pollitt, Galloway, & McGuire, 1993)—anemia, even at fairly mild levels, has been implicated as directly contributing to maternal deaths (Harrison & Rossiter, 1985; United Nations, 1991). In addition, some evidence suggests that anemia predisposes women to higher risks of complications during pregnancy, including urinary tract infections, pyelonephritis, and preeclampsia (Kitay & Harbort, 1975). Anemia is also associated with reduced productivity and quality of life for women (Bothwell & Charlton, 1981).

Data on the effectiveness of iron supplementation in reducing the prevalence of iron-deficiency anemia are not encouraging (Sloan, Jordan, & Winikoff, 1992). While a significant part of the failure to reduce anemia is due to inadequate efforts to provide iron supplementation, even in situations where properly conducted supplementation trials have been conducted, these programs do not appear to be very effective in reducing anemia levels (Sood et al., 1975). The relatively poor outcomes may reflect inadequacies of strategies that focus just on pregnant women. Long-term success probably will require the use of a multipronged strategy including iron supplementation schemes, efforts to raise household income, and efforts to reduce workload during pregnancy (Tsui et al., 1997).

Pregnancy-Related Hypertension

Both eclampsia and preeclampsia are significant causes of maternal morbidity. Unfortunately, these conditions are difficult to predict and prevent, although routine prenatal blood pressure measurements and urinalysis for proteinuria in the first prenatal visit continue to be recommended for this purpose (Rooney, 1992; Stone et al., 1994). Women with moderate hypertension and proteinuria require appropriate follow-up. Treatment options and their effectiveness vary, so no definitive conclusions or recommendations can be made. As a general rule, a combination of bed rest, antihypertensive agents, and anticonvulsant medications (especially magnesium sulfate for frank convulsions) may provide some relief (Eclampsia Trial Collaborative Group, 1995; Rooney, 1992).

Consequences of Pregnancy and Delivery Complications for Infants

Pregnancy- and delivery-related complications have important health consequences not only for mothers but also for infants, particularly stillbirths (intrauterine

fetal death after 28 weeks' gestation) and neonatal deaths (death of live-born babies in the neonatal period—that is, the first 28 days following birth/delivery), especially in the early neonatal period (i.e., the first 7 days of birth/delivery) (Kusiako et al., 2000; WHO, 2006; Zupan, 2005). Each year, 2.5 million stillbirths and 5.9 million under-5 child deaths occur globally, resulting in total 8.4 million deaths from the 28th week of pregnancy to 5 years of age among the children. Out of the 5.9 million under-5 child deaths (not including stillbirths), 2.7 million (45%) occur during the neonatal period (Liu et al., 2016). Notably, the proportion of under-5 child deaths that occur during the neonatal period has been increasing over time, due to the fact that the decline in neonatal deaths has been slower than the decline in post-neonatal and 1- to 4-year-old child deaths globally. Developing countries account for more than 99% of both stillbirths and neonatal deaths (Blencowe et al., 2016; Liu et al., 2015). Of the 2.8 million neonatal deaths, 73% (2.02 million deaths) occur in the first 7 days of life (Oza, Cousens, & Lawn, 2014).

In LMICs, neonatal mortality declined from 40 deaths per 1,000 live births in 1990 to 21 deaths per 1,000 live births in 2015. These countries have five times the neonatal mortality rate of high-income countries. The highest neonatal mortality rates are found in South Asia and sub-Saharan Africa (30 and 29 neonatal deaths per 1,000 live births, respectively), and the lowest rates in East Asia and Pacific (9 neonatal deaths per 1,000 live births) (You, Hug, Ejdemyr, & Beise, 2015). Early neonatal mortality rates (ENMR—deaths in the first 7 days of life) declined from 23 per 1,000 live births in 2000 to 14.7 per 1,000 live births in 2015 (Oza et al., 2014; WHO, 2006). The global rate of stillbirth in 2015 was 18.4 per 1,000 births, with the highest rate found in sub-Saharan Africa (28.7 per 1,000 births) and the lowest rate in high-income countries (3.4 per 1,000 births) (Blencowe et al., 2016). The early neonatal death rate in 2013 was 14.7 per 1,000 live births globally, with the ENMR ranging from 22.7 per 1,000 livebirths in sub-Saharan Africa to 2.6 per 1,000 live births in high-income countries (Oza et al., 2014). Most neonatal deaths occur in Asia and Africa, where most children are born (Liu et al., 2016). Within Asia, the most strongly affected region is South Asia (e.g., Afghanistan, Bangladesh, India, Nepal, and Pakistan), which accounts for more than 39% of global neonatal deaths (Liu et al., 2016).

In 2015, a total of 5.9 million under-5 child deaths occurred globally (not including stillbirths), of which 2.7 million deaths occurred in the neonatal period (first 28 days of life), 1.8 million deaths occurred between 29 days and 1 year of age, and 1.4 million deaths occurred between 1 and 5 years of age. The number of infant deaths (death between birth and 1 year of age) was 4.5 million (Liu et al., 2016). Thus, neonatal deaths accounted for approximately 60% (2.7 million/4.5 million) of all infant deaths and 45% (2.7 million/5.9 million) of all under-5 child deaths on a worldwide basis. As infant mortality rates drop, the proportion of infant deaths attributed to the neonatal period actually increases, because post-neonatal deaths (those after the first 28 days of life, which are most sensitive to environmental contamination and amenable to public health interventions) are the first to decrease (Black, Morris, & Bryce, 2003; Hill & Choi, 2006; WHO, 2006; Zupan, 2005).

Of the estimated 2.6 million stillbirths and 2.7 million neonatal deaths worldwide, the vast majority are associated with maternal health problems during pregnancy (e.g., preterm birth, maternal infections, and severe malformations) and around delivery (e.g., intrapartum complications or trauma during birth, infections such as tetanus). The contribution of each of these factors varies with the level of neonatal mortality. In areas where neonatal mortality is high, birth trauma and infections play larger roles; in contrast, in areas where neonatal mortality is low, preterm birth and severe malformations predominate (Beck et al., 2010; Fauveau, Wojtyniak, Mostafa, Sarder, & Chakraborty, 1990; Hill & Choi, 2006; Zupan, 2005). Most of the adverse outcomes leading to stillbirth and neonatal death are due to poor antenatal care (e.g., non-immunization against tetanus, poor prevention of HIV and other STIs) inadequately treated maternal conditions such as eclampsia, complications of labor and delivery, poor-quality neonatal care, and harmful traditional practices such as discarding the colostrum, nonsterile umbilical cord cutting, and failure to keep babies warm. Roughly half of the 2.6 million stillbirths are due to delivery complications and could largely be prevented by skilled care during delivery and in the first 24 hours post delivery (de Bernis et al., 2016).

One of the most important risk factors for neonatal mortality is low birth weight (LBW), with babies weighing less than 2,500 grams having 20 to 30 times the mortality risk of babies of normal weight. In addition to increasing the risk of neonatal mortality, low birth weight is associated with a substantial burden of long-term disability (e.g., impaired immune function and greater susceptibility to infection, long-term undernourishment and decreased muscle strength throughout the child's life, inhibited cognitive development, higher incidence of diabetes and heart disease, cerebral palsy, seizures, and severe learning disorders) for babies who survive (Jamison et al., 1993; Tsui et al.,

1997; UNICEF & WHO, 2004; WHO, 2006; Zupan, 2005). Women who have inadequate nutritional status (including short stature, poor prepregnancy weight, inadequate weight gain during pregnancy, and anemia) or infections during pregnancy are more likely to have LBW babies (UNICEF & WHO, 2004; WHO, 1993b; Zupan, 2005).

When assessing outcomes for LBW babies, it is necessary to distinguish between those who are born preterm (less than 37 weeks' gestation) but appropriate for their gestational age and those who are full term and inappropriately small for their gestational age due to intrauterine growth retardation (IUGR). Considering gestational age at birth and birth weight, babies can be classified into four groups:

1. Full term and appropriate weight for gestational age (AGA)
2. Full term and small for gestational age (SGA)
3. Preterm and AGA
4. Preterm and SGA

In LMICs, the majority of LBW babies are full term but suffer from IUGR (Group 2). In contrast, in the high-income world, most LBW babies are preterm and AGA (Group 3).

The risk of neonatal mortality substantially varies across these groups. In a recent study reported that compared term and AGA babies, term and SGA babies were at lowest risk of neonatal mortality (relative risk [RR]: 2.44; 95% confidence interval [CI]: 1.67–3.57), preterm and AGA babies were at higher risk of neonatal mortality (RR: 8.05; 95% CI: 3.88–16.72), and preterm and SGA babies had highest risk of neonatal mortality (RR: 15.42; 95% CI: 9.11–26.12) (Katz, Lee, Kozuki, & Black, 2015). In 2013, out of approximately 138 million babies born worldwide, 16%—22 million—were LBW; 96% of these infants were born in developing countries (UNICEF, 2013). The level of LBW in LMICs was more than double that in high-income countries (16.5% versus 7%), with the highest rates being found in South Asia (27%). Of 18 million LBW babies born in 2010 in LMICs, 59% (10.6 million) were term-SGA, 16% (2.9 million) were preterm-SGA, and 25% (4.5 million) were preterm-AGA (Lee et al., 2013).

Preterm birth is a major risk factor for neonatal mortality and morbidity, accounting for 35% of neonatal mortality other than those deaths related to congenital malformations (Liu et al., 2015). It is estimated that 11.1% of all births worldwide in 2010 were preterm, which translates into a total of 14.9 million preterm births (Blencowe et al., 2013). In light of the earlier discussion of LBW and IUGR, it is important to note that most preterm babies are, in fact, appropriately developed for their gestational age and have LBW (i.e., weigh less than 2,500 g) because of premature delivery. In 2010, the majority of these births occurred in Asia (53%), followed by Africa (20%), the Caribbean (11.2%), Latin America (8.4%), and Oceania (7.4%), with only 8.6% taking place in Europe and North America (Blencowe et al., 2012). A variety of factors are associated with preterm birth, including medical conditions of the mother or the fetus, genetics, environmental exposures, infertility treatments, behavioral and socioeconomic factors, and iatrogenic interventions (Goldenberg, Culhane, Iams, & Romero, 2008).

High-Risk Pregnancies

For the sake of simplicity, the calculations of lifetime risk presented earlier assumed that the risk of maternal death per pregnancy is the same across all women and across successive pregnancies within each woman. The reality is somewhat more complicated, with some types of pregnancies being riskier than others. Higher-risk conditions include pregnancies of first-time mothers, mothers with multiple previous pregnancies (five or more pregnancies), very young and older mothers, women already in poor health, and pregnancies that are terminated by unsafe abortions (National Research Council, 1989; Tsui et al., 1997). **TABLE 5-14** summarizes the hypothesized mechanisms by which different reproductive patterns affect maternal health.

First pregnancies have a higher risk of maternal mortality than subsequent pregnancies (up to five) both in high-income countries and in LMICs (Filippi et al., 2016). Population-based data from Bangladesh (Koenig et al., 1988), Ethiopia (Kwast et al., 1986), and the Gambia (Greenwood et al., 1987) suggest that first pregnancies may be as much as three times riskier than later pregnancies.

The impact of young maternal age on maternal mortality is more difficult to evaluate, because relatively few studies have disaggregated the confounding effects of young maternal age and first pregnancy. Among those that have controlled for confounding factors appropriately, the largest study to date looked at maternal mortality among 14,631 first births in rural Bangladesh (Koenig et al., 1988); it showed no age effect. Other smaller studies from the same area (Chen et al., 1974), Indonesia (Chi et al., 1981), and Jamaica (Walker et al., 1985) have shown a higher mortality risk for mothers younger than age 20 compared to mothers age 20 to 24. A more recent large study shows that the mortality risk pattern is similar

TABLE 5-14 Mechanisms by Which Reproductive Patterns Affect Maternal Health

Reproductive Pattern	Mechanism Through Which Maternal Health Is Affected
Number of pregnancies	Each pregnancy carries a risk of morbidity and mortality
High-Risk Pregnancies	
First-time mothers	Higher risk than pregnancies 2–4 for obstructed labor, pregnancy-induced hypertension, and other obstetric complications due to initial adaptation to pregnancy
Higher-order pregnancies	Higher risk for hemorrhage and uterine rupture, due to the cumulative toll of previous pregnancies and reproductive injuries
Pregnancy at very young maternal ages	Higher risk due to physiologically immature reproductive systems and reduced propensity for timely care seeking
Pregnancy at older maternal ages	Body in poorer condition for pregnancy and childbirth
Short interbirth intervals	Inadequate time to rebuild nutritional stores and regain energy levels
Unwanted pregnancies ending in unsafe abortions	Unsafe abortions increase exposure to injury, infection, hemorrhage, and death
Pregnancies for women already in poor health	Aggravated health condition

in all regions, with the lowest risk being in 20- to 24-year-old women. A "J" shaped curve, with markedly higher risk after age 30, is evident in all regions (Blanc, Winfrey, & Ross, 2013). A further problem that makes interpretation of data difficult is that maternal age younger than 20 is not disaggregated into single years of age; in fact, the highest risk may be for young mothers in the 15- to 17-year-old age group (Harrison & Rossiter, 1985).

The major causes of morbidity and mortality for young primigravida women include a high risk of pregnancy-induced hypertension (WHO, 1988), a high frequency of obstructed labor due to the pelvis being too small for the child's head to pass (Aitken & Walls, 1986), and a high incidence of placental malaria (McGregor, Wilson, & Billewicz, 1983).

A number of studies have shown that women with four or more pregnancies have 1.5 to 3 times the risk of maternal death as women of parities 2 and 3. In general, for any given parity, older women—particularly those beyond age 35—have higher risks of maternal death (Chi et al., 1981; Koenig et al., 1988; Walker et al., 1985). A major cause of maternal morbidity and mortality for older multiparous women is the higher risk of malpresentation (in which the fetus assumes a position other than the usual head-first delivery, as in a breech or transverse lie presentation). Malpresentation of the fetus may occur due to the flaccidity of the uterine wall from repeated stretching from successive pregnancies. It can lead to uterine rupture, hemorrhage associated with rupture, or infections resulting from unsuccessful attempts to deal with malpresentation. Another major cause of morbidity and mortality in older multiparous women is hemorrhage due to placental abnormalities such as placenta previa (where the placenta overlies the cervical opening of the uterus) and placenta abruptio (where the placenta separates prematurely from the uterus prior to delivery of the baby) (Faundes, Fanjul, Henriquez, Mora, & Tognola, 1974).

There has been much talk about the possibility of a maternal depletion syndrome whereby multiple short birth intervals result in women not having enough time to recover their energy and nutritional levels between pregnancies, which in turn may lead to higher risks of maternal mortality (Jelliffe, 1976; Winikoff, 1983). As yet, no convincing evidence validating this hypothesis has been

presented (Koenig et al., 1988; National Research Council, 1989; Ronsmans & Campbell, 1998). This could be due to the fact that intrinsically healthier women (in this case, women of higher socioeconomic status) may be more likely to have multiple short birth intervals, whereas less healthy women may take longer between subsequent births (Duffy & Menken, 1998).

Pregnancy is more dangerous for women who are already in poor health. It increases the likelihood that a woman will die if she has certain preexisting conditions, such as malaria, hepatitis, anemia, sickle cell disease, or rheumatic heart disease (Koblinsky et al., 1993; Morrow, Smetana, Sai, & Edgcomb, 1968; National Research Council, 1989; Tsui et al., 1997; WHO, 1993b).

Finally, unsafe abortions are a significant cause of maternal death in countries where abortion is not legal and regulated. Kwast, Rochat, and Kidane-Mariam (1986) reported that the primary cause of maternal mortality in Addis Ababa, Ethiopia, especially among primigravida, unmarried women, is complications from illegal abortions. In Bangladesh, abortion-related deaths declined dramatically from 18% in the 1980s to 5% in 2001, and then to only 1% in 2010 (Koenig et al., 1988; NIPORT, 2011). The major reason for this remarkable decline is wide availability of menstrual regulation (MR) service, although abortion is not legally approved in Bangladesh (Benson, Andersen, & Samandari, 2011). More recent global data indicate that in LMICs, a woman dies from an unsafe abortion every 8 minutes (WHO, 2007b). Approximately one in every four women having an unsafe abortion develops significant medical complications, and unsafe abortion causes approximately 8% of all maternal deaths and 20% of the overall burden of maternal death and long-term sexual and reproductive ill health.

Mechanisms to Reduce Maternal Morbidity and Mortality in Low- and Middle-Income Countries

Although significant progress was made toward Millennium Development Goal 5, which required reduction of maternal mortality by 75% between 1990 and 2015, the target was not achieved at the end (UNICEF & WHO, 2015). The global maternal mortality ratio has been reduced by roughly half since 1990 (from 385 to 216 per 100,000 live births) and the rate of improvement has accelerated since 2000. Only 6 countries achieved MDG 5 (Maternal health) out of 75 countdown countries, while only 4 (Cambodia, Eritrea, Nepal, and Rwanda) achieved both MDG 4 (Child Health) and 5 (UNICEF & WHO, 2015). Bangladesh, for example, was able to reduce maternal mortality significantly during the MDG era, from 569 maternal deaths per 100,000 live births in 1990 to 196 maternal deaths per 100,000 live births in 2016 (NIPORT, icddr,b & MEASURE Evaluation). Although the MDG 5 target was not fully achieved (the target was 143 maternal deaths per 100,000 live births), the progress made in Bangladesh was remarkable. Kenya, however, did not perform well in terms of MDG 5. The MMR was reduced from 678 in 1990 to only 510 in 2015 against the MDG target of 170.

The reasons behind the significant decline in the MMR in Bangladesh is attributed to factors both within and outside the health sector. Improved access to and use of health facilities are the key contributors of MMR reduction, along with a decrease in the proportion of births associated with high risk of maternal mortality, a decline in the poverty rate, and significant improvements in female education (El Arifeen et al., 2014).

In addition to reducing the risk per pregnancy, a strategy focused on reducing teenage fertility in Bangladesh (which remains stubbornly high, despite the country's great success in lowering overall TFR to near replacement levels) will most likely lead to modest but significant reductions in MMR. Nevertheless, social/political constraints in Bangladesh continue to be a barrier in increasing the average age at marriage (*Dhaka Tribune*, 2017, p. 3).

Weak health systems, continued high fertility, lack of supportive polices, inadequate financial investment, and poor availability of data to monitor change were the major barriers to achieving MDG 5 in many LMICs, where 99% of maternal deaths occur, and particularly in sub-Saharan Africa (Koblinsky et al., 2006; Ronsmans et al., 2006; UNICEF & WHO, 2015; WHO, 2008a). Researchers have suggested that a multisectoral approach will be required to decrease the number of maternal deaths through reduced exposure to pregnancy (i.e., by reducing fertility), optimization of access to emergency obstetric care, and improvement of general health status and treatment of pregnancy- and childbirth-related complications (Bartlett et al., 2005; Campbell, Graham, & Lancet Maternal Survival Series Steering Group, 2006; Dogba & Fournier, 2009; Koblinsky et al., 2006; Paxton, Maine, Freedman, Fry, & Lobis, 2005; WHO, 2005, 2007a).

The major emphasis in the last few decades in LMICs in reducing maternal morbidity and mortality has been on decreasing the total number of

pregnancies per woman. As documented earlier, the total number of pregnancies per woman has fallen quite sharply in many of these countries; this drop has contributed significantly to the decrease in the lifetime risk of maternal mortality by reducing cumulative exposure. For example, assume a constant MMR of 750 maternal deaths per 100,000 live births. In Kenya, if the total fertility rate had remained at its 1975 level of 8.2 births per woman instead of dropping to the 2015 level of 3.9 births per woman, the lifetime risk of maternal mortality would have been 1/16 instead of 1/35. In addition to the significant drop in TFR, some fairly modest improvement in mortality risk per pregnancy has occurred; the 2015 MMR was 510 deaths per 100,000 births (WHO, 2015b). Taken together, these changes have led to a decrease in the lifetime maternal mortality risk to its current level of 1/51, with most of the improvement in lifetime risk coming from reduction of the overall number of births and, therefore, women's exposure to the risk of maternal mortality.

In addition to the reduction in the TFR in LMICs, some progress has been made in reducing the numbers of high-parity births (**TABLE 5-15**), births to older women (**TABLE 5-16**), and births following short intervals (i.e., less than 24 months). By 2000, however, as fertility continued to decline in most of these countries, the proportion of births to older women increased again due to postponement of births (United Nations Population Division, 2009). Access to safe abortion has also increased (Alan Guttmacher Institute, 2009a, 2009b; Tsui et al., 1997); unfortunately, the number of unsafe abortions remained more or less steady from 1995 to 2008 at approximately 20 million per year, with 98% of these procedures occurring in developing countries (Alan Guttmacher Institute, 2009a, 2009b; Sedgh et al., 2012; WHO, 2007b). An often-overlooked benefit of fertility-reduction initiatives is their impact on reducing the frequency of unsafe abortions by providing access to effective contraception

for those who want it (Alan Guttmacher Institute, 2009a, 2009b; Bulatao, 1998; National Research Council, 1989; WHO, 2007b).

Despite these positive efforts, a significant burden of maternal mortality persists in LMICs. Two reasons explain why this condition remains in spite of the increase in the proportion of pregnancies that are in the demographically low-risk category (i.e., parity 2–4 among mothers age 24 to 29 with birth intervals of 24 months or more). First, the absolute risk of maternal death is still very high in these settings, even in low-risk pregnancies. Second, some of the factors associated with the highest-risk pregnancies, such as first pregnancies, are unavoidable.

In this regard, it is worth considering the following scenario. Kenya—which has very high risks of maternal mortality per pregnancy—experiences little change in the mortality risk per pregnancy (now 510 maternal deaths per 100,000 live births), but fertility declines to replacement levels (i.e., each woman has just 2.1 births over her lifetime). Under these conditions, the lifetime risk of maternal mortality would still be 1/94—almost 52 times as high as the lifetime maternal mortality risk (1/4,900) of women in high-income countries (WHO, 2015b).

Even this scenario may be overly optimistic. Our calculation does not allow for any heterogeneity in maternal mortality risks across pregnancies. If first pregnancies are intrinsically more dangerous or if healthier women were the ones who had more pregnancies, simply reducing the number of births would not achieve the reduction in maternal mortality estimated previously.

Finally, a number of studies have shown that older women with more surviving sons have significantly lower mortality than their peers with fewer

sons (Rahman, 1999; Rahman, Foster, & Menken, 1992). This research suggests that although increased numbers of pregnancies may expose a woman to considerable risk of morbidity and mortality, women in certain social settings (where family support is crucial) are actually better off when they are older if they have had higher fertility. These considerations lead to the conclusion that, to reduce maternal deaths to a significant extent in LMICs, an emphasis on reducing overall fertility levels and the frequency of high-risk pregnancies is unlikely to be sufficient. Instead, the emphasis must be on reducing the mortality risk for each and every pregnancy.

Obstetric Care

As pointed out earlier, the majority of maternal and perinatal mortality and morbidity stems from complications related to the delivery process, which are difficult to predict and avoid prenatally (Maine, 1991; National Statistics Office [Philippines] & Macro International, 1993; Ronsmans et al., 2006; Thaddeus & Maine, 1994; WHO, 2005). Perhaps the most important benefit of prenatal care is in sensitizing the mother to warning signs of obstetric emergencies and the need to seek appropriate obstetric care when they occur (Tsui et al., 1997).

It is instructive to review briefly what qualifies as the basic acceptable package of obstetric care. WHO uses the following eight criteria to assess the adequacy of obstetric care facilities (Campbell et al., 2006; Dogba & Fournier, 2009; Paxton et al., 2005; WHO, 1995):

1. The ability to treat infection, both orally and intravenously
2. The ability to provide intravenous labor-inducing agents such as oxytocin
3. The facilities for the medical treatment of shock, anemia, and hypertensive disorders of pregnancy (provision of parenteral anticonvulsants)
4. The ability to provide manual procedures for removal of the placenta, including vacuum extraction
5. The ability to carry out the removal of retained products of conception and ectopic pregnancy and provide safe abortion services
6. The ability to carry out assisted vaginal delivery and monitor labor
7. The ability to carry out caesarean section along with appropriate facilities for anesthesia
8. The ability to provide blood transfusions

Facilities that can carry out the first six interventions are called basic EmOC (Emergency Obstetric Care) centers; those that can carry out all eight interventions are termed complete EmOC centers (Campbell et al., 2006; Paxton et al., 2005).

The historical record in the United States and Europe (Hogberg, Wall, & Brostrom, 1986; Loudon, 1991) and the more recent experience of specific LMICs such as Sri Lanka show that the implementation of even limited parts of the essential obstetric care package can result in major declines in maternal mortality. The maternal mortality ratio in Sri Lanka dropped dramatically, from 555 maternal deaths per 100,000 births in the mid-1950s to 239 maternal deaths in the 1960s and again to 95 maternal deaths in 1980 (WHO, 2005). These gains were largely due to the expansion of health centers appropriately equipped for essential obstetric care and the increase in births attended by trained personnel.

A 2008 report focusing on maternal health interventions in 68 countries that experience 97% of maternal and child deaths worldwide suggested that several interventions have been proven to improve maternal survival (Bhutta et al., 2008; Bryce et al., 2008; United Nations Children's Fund, 2008). Under the circumstances when complications are not predictable, skilled care at delivery is the key to reduce maternal mortality. For example, a package of healthcare services consisting of skilled care by doctors, nurses, and midwives during pregnancy and childbirth, including family planning and emergency medical services, and costing less than $1.50 per person, can reduce an estimated 80% of maternal mortality. Increased access to hospital and midwifery care, improved quality of care, and control of infectious diseases have been successfully combined to significantly lower maternal mortality in several low-and middle-income countries, including Bangladesh, Nepal, Thailand, Malaysia, Sri Lanka, Egypt, Honduras, and some states of India (WHO, 2005).

For a variety of reasons—including cultural taboos, lack of social mobility, lack of economic resources, lack of logistic resources, and lack of information—women in LMICs for the most part do not use appropriate obstetric care services, with the most vulnerable group in this regard being rural, less educated, and poorer women (Govindasamy, Stewart, Rutstein, Boerma, & Sommerfelt, 1993). In 1993, only 37% of births in LMICs took place in a health facility (WHO, 1993a). The remaining deliveries (some 55 to 60 million infants) were carried out with the help of traditional birth attendants, family members, or no assistance at all.

In this regard, it is interesting to note that prenatal care services are used significantly more than obstetric care services. In 39 of 43 countries covered by DHS surveys between 1985 and 1994, prenatal care coverage was significantly higher than the rates of delivery care from a trained provider (i.e., doctor, nurse, or midwife) (Macro International, 1994). These results need to be viewed with some caution, however, as prenatal care is self-reported and may include very low and episodic use of appropriate services.

There is considerable variation in the DHS-surveyed countries in use of both prenatal and maternal care services. South Asia (with the exception of Sri Lanka) has particularly low rates of use of prenatal care and maternal care services. More recent data show significant improvements in developing countries in terms of access to both antenatal and skilled care services during delivery, with the latter showing a greater increase in their utilization rate. Approximately 66% of pregnant women in LMICs currently receive at least one antenatal care visit, compared to at least four antenatal care visits for most women in high-income countries. Huge disparities in the distribution of antenatal care are apparent, however: In Ethiopia, for example, this figure is only 12%. Moreover, only 62% of pregnant women in LMICS currently receive assistance from skilled birth attendants during their deliveries. As in the case of antenatal care, large regional differences in access to these services exist, with utilization rates ranging from 34% in Eastern Africa to 93% in South America (Maternal Deaths, 2008; United Nations Children's Fund, 2008; WHO, 2008b).

Despite these improvements in access to skilled delivery care, there is currently a 50% deficit worldwide against the estimated demand for 700,000 midwives to ensure universal coverage with maternity care. More generally, there is a global shortage of 4.3 million health workers (WHO, 2008b).

Leaving aside the significant gaps in the availability of skilled maternal care/delivery services, even when such services are available they are not used to the degree they should be. The failure to use appropriate maternal/delivery care services can be viewed as resulting from a multipart process, which includes the following factors:

- Deficiencies in identifying life-threatening medical complications that would benefit from obstetric care services
- Constraints that prevent the use of obstetric services even when appropriate conditions for such use are identified (e.g., lack of financial resources, transportation difficulties, other logistic problems)
- Obstetric care facilities of such poor quality that they are ineffective in preventing obstetric complications and death, even when pregnant women come to such facilities (Thaddeus & Maine, 1994; Tsui et al., 1997)

Each of these problems is elaborated upon in the following subsections.

Identification of Serious Medical Complications That Will Benefit from Obstetric Care

It is important to reiterate that most women in LMICs deliver their babies at home, far away from even rudimentary obstetric care facilities, and assisted for the most part by family members and/or traditional birth attendants. The ability to recognize a potentially life-threatening complication (such as obstructed or prolonged labor, incipient hemorrhage, or other fetal distress), and the corresponding need for specialized obstetric care, depends on appropriate education and sensitization of both family members and traditional birth attendants, with the former being perhaps the more important constituency.

A number of cultural factors affect the recognition that obstetric complications can benefit from specific kinds of medical care. When a woman is bleeding, the need for obstetric intervention by trained medical personnel is better recognized. Other complications, however, are generally not viewed as benefiting from specialized obstetric care. In some cultures, complications are seen as determined by fate, with little that can be done to alter the course of events. In Indonesia, for example, malposition of the fetus is seen as the domain of traditional birth attendants, who deal with it with soothing massage whereby the pregnant woman maintains the inner calm considered necessary for correcting the baby's position (Ambaretnani, Hessler-Radelet, & Carlin, 1993). As a result, referral to obstetric care services is often significantly delayed. In other instances, due to concerns about privacy and modesty, the home is perceived as the more natural and fitting place for birth than any healthcare facility. For the Fulani and Hausa in Nigeria, pregnancy is seen as a shameful period with an unpredictable outcome; thus no preparations are made for referral for obstetric services (Public Opinion Polls, 1993; Tsui et al., 1997).

It is clear from these examples that cultural sensitivities need to be taken into account when constructing appropriate educational messages that emphasize the identification of particularly serious obstetric risks and the need to refer these women to health facilities with adequate obstetric care services. A purely technocratic approach, which focuses on modern systems of

logic and evidence, may not be very effective in bringing about changes in behavior. Much attention has been focused on training birth attendants, given that they are present in the majority of births in LMICs. Nevertheless, the evidence suggests that focusing on just training birth attendants leads to mixed results in terms of increased referrals for appropriate conditions. In urban/peri-urban areas, such training appears to be no impact, whereas there is some improvement in rural areas with low prevalence rates of use of maternal care services (Alisjahbana et al., 1995; Bailey, Dominik, Janowitz, & Araujo, 1991). The consensus from a number of sources is that husbands and possibly other family members (mothers-in-law, mothers, and sisters) are the key people who should be targeted, as they are the final decision makers with regard to whether the woman will go to a modern healthcare facility (Alisjahbana et al., 1995; Bailey et al., 1991; Center for Health Research Consultation and Education & MotherCare/John Snow, 1991; Howard-Grabman, Seoane, & Davenport, 1994).

Constraints Affecting Use of Obstetric Care Services Once Complications Are Identified

Several concerns affect the decision to use modern obstetric care services once a life-threatening complication is identified and the need for obstetric care is acknowledged. These issues include economic constraints (i.e., not being able to afford the costs of such care, including transportation costs), logistic constraints (taking time off to accompany the patient to often distant care facilities), and quality concerns (attitude and treatment of healthcare providers) (Sundari, 1992; Thaddeus & Maine, 1994).

The economic costs of care include not only the nominal costs charged by the healthcare facility for delivery-related services, but also transportation costs (which are not insignificant in many rural settings), costs of medications, and costs of housing. In many cultures, family members need to accompany the patient, which adds to transportation and housing costs. In addition to these direct costs, opportunity costs or lost wages for the patient and particularly family members who accompany the patient are key considerations. Relatively few population-based data have been gathered from which to estimate the various components of costs that are incurred for a maternal delivery in a healthcare facility, but some reports suggest that these costs may be a real barrier to the use of obstetric services. For example, data from three countries in Africa (Nigeria, Ghana, and Sierra Leone) show that there were declines in deliveries in seven referral sites from 1983 to 1989, paralleling increases in costs to patients for drugs and services (Prevention of Maternal Mortality Network, 1995). To date, the impact of user fees on the decision to seek out obstetric care for complicated cases (as opposed to normal deliveries) has not been adequately investigated. The existing evidence shows a mixed response to the imposition of user fees, with use of modern medical facilities for obstetric complications being reduced to different degrees in different countries (Ambaretnani et al., 1993; Prevention of Maternal Mortality Network, 1995).

Clearly, much more information needs to be collected to understand how demand and use of obstetric care services change with changes in costs of services. Special attention needs to be focused on obtaining data on the nonservice components of obstetric costs (i.e., travel costs, opportunity costs).

Aside from economic costs, transportation constraints are a major factor in the low use of maternal care services. In most LMICs, advanced obstetric care (including surgical services with appropriate transfusion capabilities) is available in only a few healthcare facilities, which are often located at a considerable distance from the patient. Transportation facilities are, for the most part, poorly developed and quite expensive. Thus, problems need to be anticipated in advance to allow for enough time for the patient to reach the care facility. The degree to which lack of transportation infrastructure is a major constraint on the use of modern obstetric services is not certain; the evidence on this issue is mixed. On the one hand, data from rural Bangladesh suggest that relatively modest investments in transportation can have a significant impact on use of obstetric services, leading to reductions in maternal mortality (Fauveau, Stewart, Khan, & Chakraborty, 1991; Maine, Akalin, Chakraborty, de Francisco, & Strong, 1996). On the other hand, three different experiments that aimed at ensuring transport did not by themselves increase the use of obstetric services (Alisjahbana et al., 1995; Poedje et al., 1993; Prevention of Maternal Mortality Network, 1995).

Transportation concerns assume the patient has to be brought to the care facility. A complementary approach, of course, is to bring the provider closer to the patient. Some limited success has been achieved with programs that place certified midwives in health posts closer to the pregnant patient population, but such staffing may be difficult to sustain logistically and financially (Fauveau et al., 1991; Tsui et al., 1997).

Finally, the perception of the welcoming nature of the referral site and its flexibility in accommodating accompanying family members are often ignored, but are particularly important constraints to

seeking modern obstetric care. Oftentimes, referral sites are perceived as impersonal and unfriendly and are passed over in favor of care from traditional birth attendants (Bailey et al., 1994; Eades, Brace, Osei, & LaGuardia, 1993).

Quality of the Obstetric Care in the Healthcare Facility

Relatively few systematic data on the quality of healthcare services in obstetric care facilities exist. The rare studies that have been conducted suggest that the majority of obstetric care facilities in LMICs fall far short of minimal acceptable standards of care. Important indicators of quality include waiting time from admission to treatment, trends in numbers and rates of maternal and perinatal deaths, and trends in case fatality rates for all complications including cesarean deliveries (O'Rourke, 1995; Prevention of Maternal Mortality Network, 1995).

Much of this problem can be traced to lack of adequate resources in terms of trained personnel (Dogba & Fournier, 2009), equipment, and bed capacity. For example, a UNICEF survey of three districts in India in 1993 found not only inadequate numbers of beds, but also huge disparities in bed allocation between different levels of the healthcare system. The majority of beds were allocated to referral sites, where a small minority of complicated births were managed. There were also major deficiencies in availability of essential drugs and appropriately trained surgical and anesthesia professionals.

In addition to supply constraints, major deficiencies in the management of services and in provider attitudes are often in evidence in obstetric facilities located in LMICs. Triage is not done systematically, such that very sick patients are often left waiting for much longer than medically desirable, while others with less severe problems are treated before them. Obstetric care is often provided in an ad hoc manner, with no consistent set of case management algorithms being followed. Nursing is often seriously below standard, and basic levels of hygiene are not adhered to, leading to considerable postoperative morbidity and mortality. There is also very little sensitivity to patient concerns, and little effort is expended in explaining complexities of care to patients, leading to widespread patient dissatisfaction (Dogba & Fournier, 2009).

In a nationally representative study of 718 maternal deaths in Egypt in 1992 (Egypt Ministry of Health, 1994), avoidable factors (i.e., those that could have been changed by either the health delivery system or the patient) were assessed by an expert panel. In approximately half of the cases, the primary avoidable factor identified was poor management and diagnoses by healthcare professionals. In the other half of cases, patient factors—particularly delay in seeking medical care or compliance with medical recommendations—were implicated as key issues in the mother's death. Notably, the health professionals most often cited for poor quality of care were not traditional birth attendants or general practitioners, but rather obstetricians with supposedly appropriate training. This sorry state of affairs is significantly related to the lack of consistent management guidelines for complicated obstetric cases.

Similar results have been reported from China (WHO, 1994), where a study of 1,173 maternal deaths in 1990 implicated deficiencies in the healthcare system as the major contributor (48%), followed by individual and family delays in using health care and transport problems. There appears to be a clear rural/urban divide in this situation, with rural areas having a much higher frequency of problems that are avoidable both from the point of view of the healthcare system and from the point of view of the patient.

Improvements in the quality of care require a number of initiatives to be undertaken simultaneously. Governments must appropriately fund healthcare referral facilities so that they have adequate supplies and equipment and are staffed by adequate numbers of appropriate specialists. There must be a clear chain of referral whereby trained birth attendants refer complicated obstetric cases to higher-level facilities, where specialist care is available. Efforts must be made to follow consistent management protocols that are clearly articulated, and both birth attendants and specialists must be trained to adhere to these protocols (Marshall & Buffington, 1991; Schieber, Mejia, Koritz, Gonsalez, & Kwast, 1995). In addition, a monitoring system must be established to provide regular audits of both process and outcome indicators such as waiting times and case fatalities, with the results being used in a continuous process of review and upgrading of the healthcare system (Egypt Ministry of Health, 1994).

If even some of these improvements in quality of care are made, they will not only improve outcomes for those women who reach the healthcare facility, but also increase the demand for such services by pregnant women (Dogba & Fournier, 2009; Mantz & Okong, 1994; O'Rourke, 1995).

Conclusion

This chapter has outlined the need for reproductive health and family planning to help individual women and men and larger populations reduce fertility and maintain reproductive health. Population growth rates are declining in much of the world because people are reducing their fertility. The primary factors effecting this reduction are early termination of the reproductive period through sterilization, use of contraception to reduce conception rates, and induced abortion. Because of increased desire for smaller families, both unwanted fertility and unmet needs for family planning and reproductive health services exist in most LMICs. To meet this challenge, improvements are needed in the quality of family planning services, especially in the areas of information exchange and method choice, interaction of reproductive health services and contraceptive provision, and financial sustainability.

Maternity care needs to be significantly expanded so that the adverse sequelae of pregnancy and childbearing can be reduced. While preventive services (including education of both men and women regarding health and sexuality, family planning, and prevention of STIs) need to be increased and targeted to those at greatest risk of adverse outcomes, special attention should be paid to increasing both physical and financial access to skilled birth attendants and high-quality emergency and non-emergency obstetric care.

At the societal level, programs need to be supported to improve the status of women, whether through improved access to education and employment or through changes in laws and culture to reduce violence and exposure to unwanted potentially high-risk births. Although this may be unfamiliar territory for public health professionals, the consequences for the health of women and children make it essential that this broader perspective become part of global health programs.

An overriding concern regarding continuing—let alone expanded—funding remains. Many high-income countries have reduced their aid contributions; many LMICs are experiencing financial and health crises. Part of the agenda for the future must be research to determine sustainable cost-effective programs that will address the reproductive health needs of the twenty-first century using public–private partnerships.

Discussion Questions

1. Using the proximate determinants framework (originally proposed by Bongaarts and subsequently revised by Stover), discuss the relative impacts of contraception, breastfeeding, abortion, sexual activity, and infecundity on total fertility rates in Latin America versus Africa. What are the policy implications of these findings? Similarly, explain why Japan, which has a relatively low contraceptive prevalence rate (56%), has such a low TFR (1.4).
2. Discuss fertility changes using the framework of wanted versus unwanted fertility and the forces that drive each of them. Why might unwanted fertility increase in tandem with increasing contraceptive prevalence? What are the policy approaches that stem from a consideration of this kind of framework?
3. The 1994 Cairo ICPD substantially enlarged the scope of family planning to include a broader conception of women's health and development. Discuss the pros and cons of this expansion in the context of limited financial and logistic resources, particularly in sub-Saharan Africa, with its very heavy HIV/AIDS burden.
4. Discuss the impact of the birth interval length, both prior and subsequent, on the health of children, taking into account methodological concerns about reverse causality. What are the implications for policy?
5. Consider the following statement: "Family planning has only a limited role to play in reducing the risk of maternal mortality." Do you agree with this statement? Elaborate on the policy implications of your analysis.
6. Discuss the reasons why, in the context of LMICs, despite initial dramatic success in lowering maternal mortality as per MDG goals, there has been a recent plateauing of these gains. What are the major constraints faced by countries and the policy implications that follow from this analysis?
7. Consider the following statement: "Specific health technological inputs are a necessary but not sufficient determinant of significant improvements in reproductive health." Using the examples of changes in women's status and sociopolitical resistance to raising age at marriage, discuss the validity of this proposition.

CHAPTER 6

Infectious Diseases

Aubree Gordon and Arthur L. Reingold

This chapter describes the epidemiologic features of the infectious diseases of greatest public health significance in low- and middle-income countries (LMICs) and details available strategies to prevent and control them. Because these diseases cannot be covered in depth in a single chapter, the emphasis here is on their unique epidemiologic features and the relevant technological challenges, resource limitations, and cultural barriers that have shaped current approaches to their prevention and control. Conceptually, these approaches include preventing exposure to the infectious agent; making otherwise susceptible individuals or populations immune to the infectious agent; treating infected individuals or populations to prevent illness and transmission of the agent to others; and improving the timeliness and appropriateness of care for symptomatic individuals so as to minimize morbidity and mortality and, in some instances, to reduce the likelihood of transmission to others. Examples of successful programs using one or more of these various conceptual approaches are discussed, as are the challenges and obstacles that confront LMICs and their partners as they seek to reduce the burden of disease caused by infectious agents.

Overview

Collectively, infectious diseases have undoubtedly been the single most important contributors to human morbidity and mortality throughout history. Over the past 150 years, the mortality attributable to them has declined substantially in high-income countries, and chronic diseases such as cardiovascular disease, cancer, stroke, chronic obstructive pulmonary disease, and diabetes mellitus have assumed prominence as the leading causes of death in these countries. Although uncertainty exists about the relative importance of various social, economic, environmental, and public health factors in this epidemiologic transition, most of the reductions in mortality attributable to infectious diseases clearly preceded any advances in clinical medicine and public health that plausibly could have had an impact on the infectious diseases of public health significance of the time (e.g., tuberculosis, rheumatic fever, scarlet fever, typhoid fever, and cholera). At present, only influenza and pneumonia rank among the top 10 causes of mortality in the United States (Heron, 2016).

The global burden of disease and the epidemiologic transition are discussed in detail elsewhere in this text (see the *Measures of Health and Disease in Populations* chapter). Although current projections suggest that acute infectious diseases will decrease substantially in their absolute and relative importance as causes of death and disability in LMICs in the decades to come, today they remain issues of great public health significance. Acute infectious diseases are, collectively, the leading cause of death among children, accounting for more than half of all child deaths in LMICs (see the *Measures of Health and Disease in Populations* chapter), as well as being important causes of morbidity and mortality in people at all stages of life. In many countries, the human immunodeficiency virus (HIV)/

acquired immunodeficiency syndrome (AIDS) pandemic initially reversed decades of progress in reducing mortality due to acute infectious diseases, with a resulting decrease in life expectancy (Lozano et al., 2013; UNAIDS, 2013). Further, it is now well accepted that chronic infection contributes in important—if poorly understood—ways to the pathogenesis of a number of chronic diseases, including cervical cancer (in which human papillomavirus [HPV] plays a role), hepatic cancer and cirrhosis (in which hepatitis B virus [HBV] and probably hepatitis C virus [HCV] play a role), gastric cancer and peptic ulcer disease (in which *Helicobacter pylori* plays a role), and possibly cardiovascular disease (in which *Chlamydia pneumoniae* and perhaps other infectious agents may play roles). Hepatic cancer and cirrhosis due to HBV were the first vaccine-preventable chronic diseases, and it is expected that widespread vaccination against HPV will reduce by two-thirds the number of cervical cancer cases worldwide and reduce the incidence of anal and oral cancers. Thus, for all the reasons just mentioned, infectious diseases and their prevention and control will remain of major public health importance for LMICs for the foreseeable future.

Underlying almost every infectious disease of public health importance in LMICs is the significant role played by poverty and its associated problems. For example, both obvious and more subtle forms of malnutrition and micronutrient deficiencies are associated with an increased risk of severe morbidity and mortality from a wide range of infectious diseases (see the *Nutrition* chapter, which highlights the association between infectious disease and malnutrition). At the same time, lack of education, poor access to clean drinking water, inability to dispose properly of human waste, household crowding, and lack of access to medical care—all manifestations of poverty—make substantial contributions to their incidence.

However, LMICs and the people living in them cannot be lumped together into a single group insofar as their risk of various infectious diseases is concerned. Important geographic differences exist in the incidence and public health significance of various infectious diseases, due to differences in climate, the distribution of insect vectors and intermediate hosts, and variations in other environmental, social, and cultural factors. In addition, all LMICs are not equally resource poor—they vary enormously in the resources that are available to provide clinical services (e.g., oral rehydration therapy), mount public health programs (e.g., vaccination programs), and reduce environmental sources of infection (e.g., provide clean drinking water and adequate sanitation or control vector populations). Also, all LMICs include within them culturally, economically, and sometimes geographically diverse subpopulations with very different needs and resources, particularly with regard to infectious diseases. Given the enormous diversity of LMICs and the infectious diseases that confront them, it will be possible in this chapter to discuss these diseases only selectively, using representative examples when appropriate.

Control of Infectious Diseases

The twentieth century saw an ever-increasing number of programs to prevent morbidity and mortality from specific infectious diseases in LMICs. Strategies that have been employed include various combinations of vector control (e.g., for malaria, dengue, yellow fever, and onchocerciasis [river blindness]); vaccination (e.g., for smallpox, measles, polio, neonatal tetanus, diphtheria, pertussis, tetanus, hepatitis B, meningococcal meningitis, and yellow fever); mass chemotherapy (e.g., for hookworm, onchocerciasis, dracunculiasis [Guinea worm]); improved sanitation and access to clean water (e.g., for diarrheal diseases); improved care seeking and caregiving (e.g., for diarrheal diseases and acute respiratory infections); and behavior change (e.g., for HIV and other sexually transmitted infections [STI]s, diarrheal diseases, and dracunculiasis), among others. The successful eradication of smallpox in the late 1970s through a combination of enhanced case finding, containment, and vaccination gave considerable impetus to attempts to control other infectious diseases (**EXHIBIT 6-1**).

As the world health community has established goals for reducing morbidity and mortality from other infectious diseases, a variety of terms describing different levels of control have come into use. Organizations such as the World Health Organization (WHO) and its governing body, the World Health Assembly (WHA), have been careful to define their prevention goals vis-à-vis various diseases; these are set forth in appropriate sections of this chapter. A useful set of definitions of such terms was put forward at the Dahlem workshop on the Eradication of Infectious Diseases (Dowdle & Hopkins, 1998):

- *Control:* Reduction of disease incidence, prevalence, morbidity or mortality to a locally acceptable level as a result of deliberate efforts; continued intervention measures are required to maintain the reduction.
- *Elimination of disease:* Reduction to zero of the incidence of a specified disease in a defined

EXHIBIT 6-1 Smallpox Eradication

Most individuals who work in the area of global health consider the eradication of smallpox to have been the single most important contribution of public health efforts in the twentieth century, and possibly the most significant accomplishment in the field of human health in recorded history. Although the ultimate eradication of smallpox through the use of vaccine was foreseen by Edward Jenner and President Thomas Jefferson at the beginning of the nineteenth century, it took more than 150 years for it to become a reality. Eradication of smallpox was possible because of several important features of the disease itself; technological advances in vaccine preparation and administration; development and application of a new approach to using the vaccine selectively rather than in mass campaigns; and a combination of international will and cooperation, strong leadership, and the focused effort of large numbers of health workers in multiple countries.

One feature of smallpox that made it a candidate for eradication was its relatively inefficient transmission from person to person. In addition, individuals with smallpox were generally bedridden before the appearance of the rash—the stage of the illness when person-to-person transmission was most likely to occur. Moreover, subclinical cases did not occur in unvaccinated individuals, and vaccinated individuals who developed mild smallpox did not efficiently transmit the virus. Smallpox was also characterized by a lack of a carrier state and the existence of a single serotype of the virus. Other notable features of the disease included a marked seasonal fluctuation in cases and the lack of a nonhuman reservoir for the virus in nature.

A key advance in vaccine development and delivery that was crucial to smallpox eradication was the development of a heat-stable, freeze-dried vaccine. In addition, two improved methods of delivering the vaccine were introduced—a bifurcated needle that was inexpensive, easy to use, and economical in its use of a small volume of vaccine, and jet injector guns that allowed a team to vaccinate more than 1,000 persons per hour.

Nevertheless, despite the availability of a heat-stable smallpox vaccine and the means of vaccinating large numbers of persons, mass vaccination campaigns intended to render entire populations immune to smallpox were unsuccessful in eliminating the disease, even in countries that achieved vaccine coverage in the range of 80% to 95%. Smallpox virus continued to circulate among the remaining unvaccinated individuals, who were extremely difficult to identify and vaccinate.

A delay in the arrival of sufficient vaccine to mount a mass campaign against smallpox in Nigeria in 1966 led to the development of an alternative approach to preventing the spread of smallpox in an area: Energetic case detection followed by isolation of all infected individuals and intense vaccination efforts focused on the area and population immediately surrounding a case. This approach, dubbed a surveillance containment strategy, proved to be remarkably successful in eradicating smallpox once imaginative and locally acceptable approaches to detecting all suspected cases, isolating individuals with smallpox, and vaccinating those around them were implemented. Surveillance containment ultimately replaced mass vaccination campaigns, and global efforts to complete eradication of smallpox relying on this approach gained momentum.

In 1967, as many as 10 to 15 million cases of smallpox occurred in 33 countries with endemic smallpox and 14 other countries with imported cases of smallpox. These countries, which had a total population of more than 1.2 billion persons at the time, included many of the poorest countries in the world and those presenting the greatest logistical barriers to mounting an effective eradication program. As a result of the efforts of dedicated public health workers in these countries and a small cadre of public health professionals from unaffected countries, the last person with smallpox not caused by a laboratory accident had onset of a rash on October 26, 1977, in Somalia. On December 9, 1979, the World Health Organization's Global Commission for the Certification of Smallpox Eradication concluded that "smallpox eradication has been achieved throughout the world," a conclusion accepted by the World Health Assembly in May 1980.

geographic area as a result of deliberate efforts; continued intervention measures are required.

- *Elimination of infection:* Reduction to zero of the incidence of infection caused by a specific agent in a defined geographic area as a result of deliberate efforts; continued measures to prevent reestablishment of transmission are required.
- *Eradication:* Permanent reduction to zero of the worldwide incidence of infection caused by a specific agent as a result of deliberate efforts; intervention measures are no longer needed.
- *Extinction:* The specific infectious agent no longer exists in nature or in the laboratory.

In the near term, extinction is possible only for smallpox, although concerns about its use as an agent of bioterrorism have prevented the long-awaited destruction of the last known stocks of the virus. Eradication of other diseases, such as polio, measles, rubella, and dracunculiasis, is considered theoretically possible using existing control methods and is being actively pursued. Unfortunately, for most of the infectious

TABLE 6-1 Levels of Control Considered Achievable for Selected Infectious Diseases in the Foreseeable Future Using Currently Available Methods

Extinction	Eradication	Elimination of Infection	Elimination of Disease	Control
Smallpox	Polio	Onchocerciasis	Rabies	Malaria
	Measles Rubella		Trachoma	Neonatal tetanus
	Dracunculiasis (Guinea worm)			Cholera
				Tuberculosis
				Schistosomiasis
				Diarrheal disease
				Acute respiratory infections
				Acquired immunodeficiency syndrome
				Sexually transmitted infections
				Leprosy

diseases responsible for the majority of morbidity and mortality in LMICs at the beginning of the twenty-first century, only their control is considered achievable in the foreseeable future (**TABLE 6-1**).

Childhood Vaccine-Preventable Diseases: The Expanded Program on Immunization

Overview

Based on the success of the vaccination program mounted to control and then eradicate smallpox, WHO and various partner agencies launched the Expanded Program on Immunization (EPI, or PEV in French) in 1974. At that time, it was estimated that fewer than 5% of infants and children in LMICs were receiving relatively inexpensive and highly effective vaccines, despite the fact that these vaccines had been licensed and available for a number of years. Many obstacles to vaccinating these children existed, including the lack of demand for vaccines on the part of the community; the small number of sources of vaccines of adequate quality; the lack of the infrastructure needed to purchase, store, and distribute vaccines, some of which were temperature sensitive; a deficiency in the number of trained personnel to administer vaccination programs; and insufficient funds to purchase vaccines and vaccination supplies and equipment. Further, most countries lacked health information and surveillance systems to assess the burden of disease caused by various vaccine-preventable diseases or to evaluate the impact of a vaccination program. Remarkable progress since 1974 in correcting these problems has led to the expected eradication through immunization of polio; dramatic reductions in morbidity and mortality from measles and neonatal tetanus worldwide; and likely, but more difficult to demonstrate, reductions of a similar magnitude in morbidity and mortality from diphtheria and pertussis.

For the first 20 years or so of its existence, the EPI focused on diseases for which safe, effective, and inexpensive vaccines were available and could be given

entirely during the first year of life. These included oral polio vaccine (OPV, a trivalent live vaccine against poliomyelitis); measles vaccine (a live vaccine); a three-component killed vaccine against diphtheria, pertussis, and tetanus (DPT); and bacillus Calmette-Guérin (BCG, a live vaccine against tuberculosis). Vaccination with tetanus toxoid (TT) was included for women of childbearing age to prevent neonatal tetanus in their newborn babies, even though the group being targeted for vaccination did not consist of infants in the first year of life. Subsequently, it was recommended that vaccine against yellow fever and Japanese B encephalitis be added in countries where these two diseases pose a threat. Vaccines against hepatitis B and *Haemophilus influenzae* b were then included after large quantities of these relatively inexpensive vaccines became available. Newer vaccines, including rubella vaccine, rotavirus vaccine, pneumococcal conjugate vaccine, and HPV vaccine, have also recently been added (**FIGURE 6-1**). (**TABLE 6-2** provides the current WHO recommendations concerning infant and childhood immunizations.) Hepatitis B, *H. influenzae* b, *Streptococcus pneumoniae,* HPV, yellow fever, and tuberculosis are discussed elsewhere in this chapter, so they will not be considered here.

Poliomyelitis

Etiologic Agent, Clinical Features, and Characteristics of the Currently Available Vaccines

Poliomyelitis (polio) may be caused by any of the three known serotypes (1, 2, and 3) of poliovirus. This virus is efficiently transmitted through the fecal–oral route. Ingestion of the virus leads to asymptomatic or mild, self-limited infection and shedding of the virus from the throat and gastrointestinal tract in the vast majority of exposed persons. However, an estimated 1 in 100 to 1 in 850 infected persons develops symptomatic

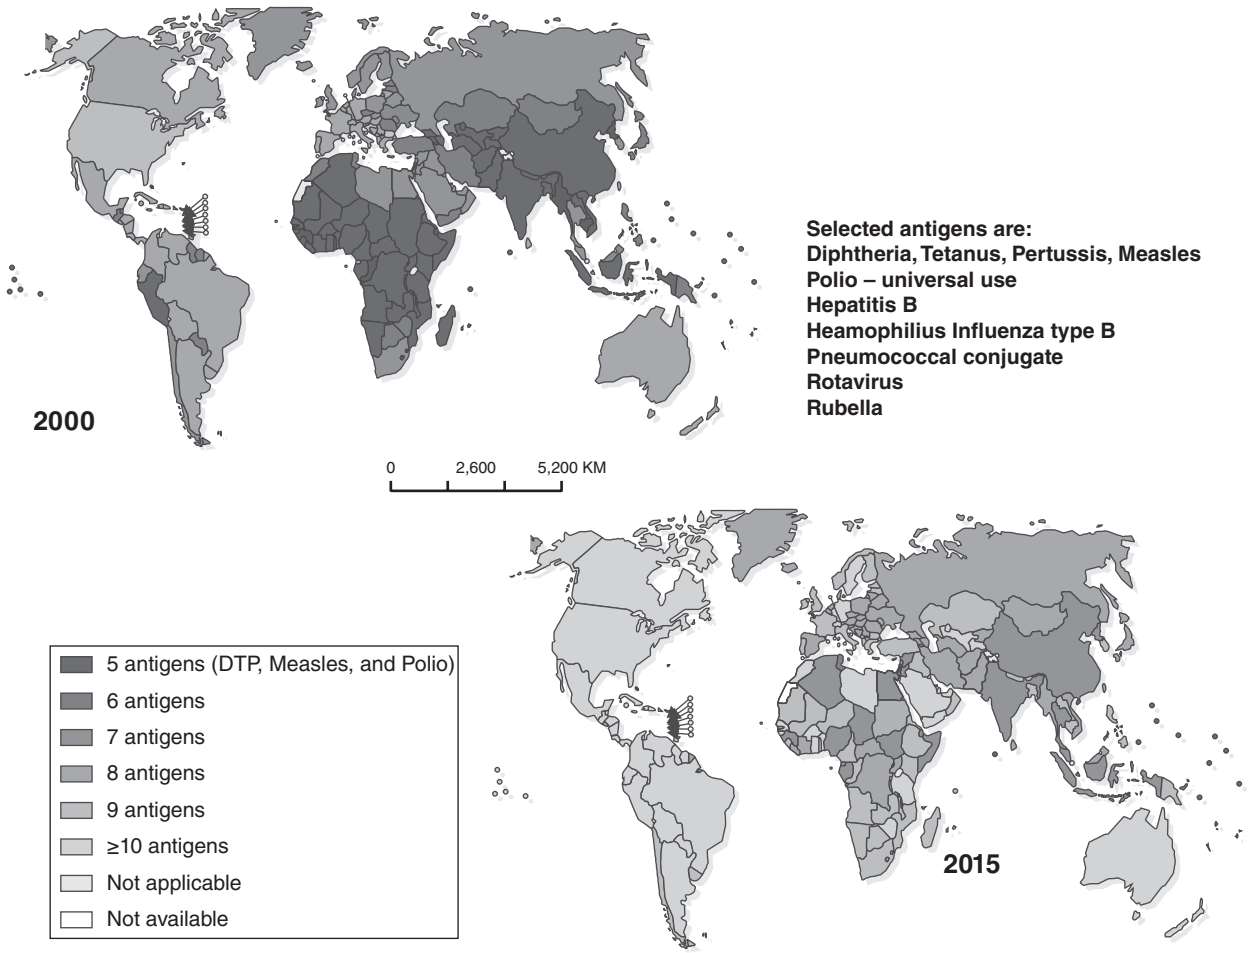

FIGURE 6-1 Number of vaccines/antigens introduced in national immunization schedules, 2000 compared to July 2015.

Reproduced from World Health Organization. (2016). Progress towards global immunization goals – 2015 summary presentation of key indicators [PowerPoint slides], slide 11.

polio, with or without paralysis. Of those who develop paralysis, which primarily affects one or both legs, approximately 10% die acutely, 10% to 15% are left permanently unable to walk, and 10% to 15% are left lame (unable to walk normally).

Treatment for polio is entirely supportive in nature. Before widespread vaccination was undertaken, polio was the leading cause of lameness in LMICs. Many of its victims in these countries remain a visible sign of the ravages of the disease and will

TABLE 6-2 Recommended Routine Immunizations for Children: Summary of WHO Position Papers*

Disease/Vaccine		Age of First Dose	Dose in Primary Series	Booster Dose
Recommended for All Children				
Bacillus Calmette-Guérin (BCG)		As soon as possible after birth	1	
Diphtheria, pertussis, and tetanus (DPT)		6 weeks	3	12–23 months (DPT containing vaccine); 4–7 years (Td); and 9–15 yrs (Td)
Haemophilus influenzae b	(Option 1)	6 weeks (minimum)–59 months (maximum)	3	
	(Option 2)		2–3	At least 6 months (minimum) after last dose
Hepatitis B	(Option 1)	As soon as possible after birth (< 24 hours)	3	
	(Option 2)		4	
Human papillomavirus (HPV)		As soon as possible from 9 years of age (females only)	2 3 (if ≥ 15 years old)	
Pneumococcal (conjugate)	(Option 1)	6 weeks (minimum)	3	
	(Option 2)		2	9–15 months
Polio	bOPV + IPV	6 weeks	4 (IPV dose to be given with bOPV dose from 14 weeks)	
	IPV/bOPV sequential	8 weeks (IPV first)	1–2 IPV 2 bOPV	
	IPV	8 weeks	3	
Measles		9 or 12 months	2	
Rubella		9 or 12 months with measles containing vaccine	1	
Rotavirus	Rotarix	6 weeks (min) with DTP1	2	
	Rota Teq		3	

Recommended for Children Residing in Certain Regions				
Japanese B encephalitis	(Inactivated Vero cell derived)	6 months	2 (generally)	
	(Live attenuated)	8 months	1	
	(Live recombinant)	9 months	1	
Yellow fever		9–12 months, with measles	1	
Tickborne encephalitis		≥ 1 year: FSME-Immun and Encepur ≥ 3 years: TBE_ Moscow and EnceVir	3	At least 1 every 3 years

* Not including vaccines recommended only for children in selected high-risk populations or immunization programs with certain characteristics.
Modified from WHO. Summary of WHO Position Papers - Recommended routine immunizations for children. March 2017. Retrieved from: http://www.who.int/immunization/policy/Immunization_routine_table2.pdf?ua=1

need assistance long after acute cases of polio have been eradicated.

Killed injectable polio vaccine (IPV) and live OPV became available in the 1950s and 1960s, respectively. Both types of vaccines are safe and highly effective, and each has been used successfully to eliminate disease caused by wild-type poliovirus in high-income countries. Although there are extremely rare cases of polio caused by the vaccine strain of the virus when OPV is given, for many years WHO and other supporters of the EPI considered OPV to be preferable to IPV for routine use in LMICs. Reasons for preferring OPV included its extremely low cost (approximately $0.02 per dose); its ease of administration; its ability to induce intestinal immunity that inhibits shedding of wild-type poliovirus; and its transmission to household and other close contacts through the fecal–oral route, thereby providing repeated exposures to the vaccine and boosting immunity to polio through such contacts. However, for unclear reasons, the efficacy of OPV in LMICs has consistently been found to be lower than that in high-income countries—approximately 85% versus approximately 95% for the primary series (Patriarca, Wright, & John, 1991).

Descriptive Epidemiologic Features and Risk Factors

Before the widespread use of polio vaccine, polio was endemic in virtually all LMICs, and most children were asymptomatically infected during the first few years of life. Symptomatic acute polio was similarly seen primarily in infants and young children. Based on surveys of the prevalence of lameness in school-aged children, the annual incidence of symptomatic polio in LMICs was estimated to be in the range of 20 to 40 cases per 100,000 total population (LaForce, Lichnevski, Keja, & Henderson, 1980).

As oral polio vaccine came into widespread use and vaccine coverage increased, endemic infections with wild-type poliovirus decreased. However, vaccine coverage levels in the range of 40% to 80%, combined with a vaccine efficacy of approximately 85%, led to an accumulation of susceptible individuals and subsequent outbreaks in many countries with "good" EPI programs (Sutter et al., 1991). In the early 1980s, more than 50,000 cases of polio were being reported annually to WHO (Otten et al., 1992). However, as described in the next subsection, wild-type polio has now been eliminated in much of the world as a result of intensified surveillance and immunization efforts; as of 2017, it remained a problem in only three countries.

Current Approaches to Prevention and Control

In 1988, the WHA set a goal of interrupting polio transmission worldwide by 2000 and certifying that polio had been eradicated by 2005. The polio eradication effort put into place at that time was based

on a combination of ongoing routine immunization of infants, annual national immunization days, and house-to-house mop-up campaigns to vaccinate those persons who were missed by these other approaches (Hull, Ward, Hull, Milstien, & de Quadros, 1994). In addition, sensitive surveillance for and laboratory testing of specimens from individuals with acute flaccid paralysis were put into place to help identify cases of polio, thereby allowing targeting of additional vaccination efforts and monitoring of the impact of the eradication program.

The last confirmed case of paralytic polio caused by wild-type poliovirus in the Western Hemisphere was detected in Peru in 1991, and three WHO regions (Americas, Western Pacific, and European) had been certified as polio free by 2002 (Centers for Disease Control and Prevention [CDC], 2002). In 2015, wild poliovirus type 2 was officially declared eradicated, and no case of paralytic polio due to wild poliovirus type 3 has been detected anywhere since 2012. In 2016, a total of only 37 cases of polio caused by wild poliovirus type 1 occurred in three countries—Pakistan, Afghanistan, and Nigeria. In 2017, however, there was an outbreak of polio caused by vaccine-derived polio virus in Syria, likely due to the poor sanitation and inadequate vaccine coverage that has resulted from the destruction of the public health system in this war-torn country.

The Global Polio Eradication Initiative (GPEI) was launched in 1988, and by 2012 global polio incidence was reduced by 99%. Unfortunately, the emergence of circulating, vaccine-derived polio viruses (cVDPV)—which consist of genetically unstable OPV strain viruses that revert to the profile of the virulent parent strain—has complicated elimination, necessitating the withdrawal of OPV to complete eradication. In 2016, all countries still using trivalent oral polio vaccine successfully switched to bivalent (types 1 and 3) oral polio vaccine and committed to introducing at least one dose of inactivated polio vaccine into their routine immunization systems (Hampton et al., 2016). Ultimately, use of oral polio vaccine will cease altogether, and it will be replaced by inactivated polio vaccine.

Measles

Etiologic Agent, Clinical Features, and Vaccine Characteristics

Measles is caused by the measles virus. Although some genotypic variation occurs, all measles virus strains are considered to be of a single type. The measles virus is spread via the respiratory route and is transmitted extremely efficiently. It is highly infectious, and in the absence of vaccine-induced immunity, almost every child can be expected to develop measles if the virus is circulating in the community.

Measles is characterized initially by fever, cough, runny nose, and malaise, making it indistinguishable from many other viral respiratory infections for the first several days, during which the child is highly infectious. A characteristic rash then appears. Although most cases are self-limited, complications commonly include pneumonia, diarrhea, and ear infections. Less common complications include encephalitis and blindness. Measles is not amenable to antibiotic therapy, but treatment with vitamin A can reduce the case fatality ratio (Hussey & Klein, 1990).

Before the measles vaccine came into widespread use, measles was consistently one of the leading causes of death among children worldwide, accounting for an estimated 20% to 30% of such fatalities (Walsh, 1983). Although the estimates of the case fatality ratio for measles have varied from 1% to greater than 30%, depending in part on whether the studies were conducted in the community or were hospital based, it is clear that the most potent predictors of mortality among children with measles are young age; malnutrition, particularly vitamin A deficiency (Markowitz et al., 1989); and HIV infection. Furthermore, measles frequently leaves a child weakened and at increased risk of illness and death from other causes for a year or more after the acute episode.

The measles vaccine consists of a live, attenuated strain of the measles virus. It is safe, inexpensive, and highly effective when given to a child after circulating measles antibody acquired from the mother has disappeared. Because the maternal antibodies tend to disappear somewhat later and exposure to measles virus is substantially less common in high-income countries, the first dose of measles vaccine is typically given at 15 months of age in such countries. In LMICs, the intensity of exposure to measles and the poorly understood, more rapid decline in maternal antibodies combine to put infants at much greater risk of acquiring measles at a young age, when complications and death are more likely. As a result, the first dose of measles vaccine is typically given to infants at 9 months of age in LMICs.

Descriptive Epidemiologic Features and Risk Factors

In the absence of vaccination, every child in an area where measles virus is circulating would be expected to contract measles. In the early 1980s, an estimated 3 million children died annually of measles and its sequelae. By 2016, however, the number of measles deaths had declined to an estimated 89,780 per year (Dabbagh et al., 2017).

The age at which an unvaccinated child develops measles is a function of when maternal antibodies disappear (generally at 6 to 12 months of age) and the intensity of exposure to measles virus in the community. Thus, in crowded urban areas, most unvaccinated children will develop measles between 6 months and 5 years of age; in contrast, in more sparsely populated, rural areas, such children acquire measles at an older age (Walsh, 1983). Family size, travel patterns, and types and locations of social interactions (e.g., marketplaces) also influence the local epidemiologic features of measles. HIV infection appears to increase the risk of acquiring measles in infancy, presumably by decreasing the level of circulating maternal antibody in the infant.

Current Approaches to Prevention and Control

Like smallpox, measles can, in theory, be eradicated because the causative virus does not infect other species or live in the environment. However, because measles is more widespread and much more infectious than smallpox, and because substantial transmission of the virus occurs among infants prior to the age of routine vaccination, eradication of measles will be more difficult to achieve.

Rather than establish a goal of measles eradication, the WHA resolved in 2012 to reduce measles-related mortality by 95% by the end of 2015 and to achieve regional measles elimination in at least five WHO regions by the end of 2020. Regional Verification Committees in the American, European, and Western Pacific Regions of WHO had verified elimination of measles in 61 countries by the end of 2015. As with polio, improved routine immunization of infants and periodic mass vaccination campaigns targeting infants and children from 9 months to 5 (or even up to 14) years of age have been undertaken as complementary strategies, together with a move to ensure all children receive two doses of measles vaccine, improved surveillance, and improved case management. As a result, measles cases and deaths were reduced by 84% between 2000 and 2016 (Dabbagh et al., 2017). Despite these impressive gains, eradication of measles is unlikely in the immediate future due to immunization coverage gaps and weaknesses in health systems.

Diphtheria

Etiologic Agent, Clinical Features, and Vaccine Characteristics

Diphtheria is caused by the bacterium *Corynebacterium diphtheriae*. It is spread primarily via the respiratory route, although in LMICs the organism is also a cause of ulcerative skin lesions and can be transmitted from such lesions. The incidence of diphtheria and the morbidity and mortality attributable to it in such countries are largely unknown, but the disease is not believed to pose a major public health threat.

Diphtheria is a disease of the upper respiratory tract, manifested by fever, sore throat, an inflamed pharynx (and possibly nose and larynx), and a grayish membrane covering the inflamed mucosa. With involvement of the larynx, the airways can be blocked and death can result. The disease is toxin mediated, and use of both antibiotics and diphtheria antitoxin (which is rarely, if ever, available in LMICs) is beneficial in its treatment.

The diphtheria component of the DPT vaccine is composed of inactivated diphtheria toxin adsorbed to aluminum salts. Two or more doses of DPT result in protection against diphtheria in 90% to 100% of those vaccinated.

Descriptive Epidemiologic Features and Risk Factors

Although diphtheria is easier to diagnose than pertussis, it is likely underreported in many LMICs. Thus the 4,530 cases of diphtheria reported to WHO in 2015 almost certainly do not reflect the actual burden of disease (WHO, 2017a).

Most cases of diphtheria occur in young children, primarily among those living in impoverished, crowded conditions. Lack of vaccination is undoubtedly the most important risk factor for developing or dying from diphtheria.

Current Approaches to Prevention and Control

The current approach to reducing morbidity and mortality from diphtheria is to improve levels of vaccine coverage achieved through ongoing infant immunization programs (i.e., EPI) in various countries. Strategies for improving vaccine coverage include expanding the times when vaccinations are offered in clinics, reducing waiting times, and reducing the number of missed opportunities to vaccinate unvaccinated infants, among other options. Because vaccination does not lead to elimination of carriage of *C. diphtheriae* from the nasopharynx, ongoing control of diphtheria requires achieving and maintaining high levels of vaccine coverage among the target population.

Pertussis

Etiologic Agent, Clinical Features, and Vaccine Characteristics

Pertussis (whooping cough) is caused by the bacterium *Bordetella pertussis.* Like measles, pertussis is spread via the respiratory route and is highly contagious, particularly within a household and in crowded institutional settings. In classic cases of pertussis, nonspecific respiratory tract symptoms are followed by severe and protracted bouts of coughing that typically end with an inspiratory whooping sound. These bouts of coughing can persist for many weeks and be quite debilitating, even when complications such as pneumonia and neurologic damage do not develop. Antibiotic treatment has little or no impact on the natural course of the disease once symptoms have begun, but probably shortens the time during which an individual is infectious.

Pertussis is believed to be the cause of substantial morbidity and mortality in the absence of high levels of coverage with pertussis vaccine, but it is difficult to assess the proportion of respiratory infections and related deaths due to this cause. In part, this difficulty arises from the fact that many infants with pertussis never have the characteristic whoop seen in older children. Similarly, a growing body of evidence suggests that in high-income countries, and presumably in LMICs as well, *B. pertussis* is the cause of many cough illnesses in young adults that are never recognized as pertussis. Finally, the laboratory diagnosis of pertussis has been plagued by the insensitivity, nonspecificity, technical difficulty, and cost of the various diagnostic tests, making research studies difficult and routine surveillance extremely inaccurate.

Pertussis vaccines have, for many years, consisted of killed whole bacteria adsorbed to aluminum salts to make them more immunogenic. In most instances, pertussis vaccine is given to infants and young children as a part of the DPT vaccine. When a full series of three doses is given, the efficacy of the pertussis component of DPT is in the range of 80%. Because whole-cell pertussis vaccine contains many bacterial products, it is the most reactogenic component of DPT; in turn, the DPT vaccine is the most reactogenic of those included in the EPI. Thus, pain and tenderness at the injection site, with or without fever, are common after a DPT injection.

More serious but rare complications of whole-cell pertussis vaccine (e.g., encephalopathy) were at the center of a protracted debate in many high-income countries over its safety. Concern over these rare complications and attendant declines in vaccine acceptance led to the development and licensure of acellular pertussis vaccines that are far less reactogenic and equally efficacious, but also far more expensive than whole-cell pertussis vaccine. Because of this large difference in cost, the EPI continues to use whole-cell pertussis vaccine in almost all LMICs. Given recent evidence that the clinical protection induced by acellular pertussis vaccines wanes substantially after only three or four years, it is unlikely that LMICs will switch to using this vaccine.

Descriptive Epidemiologic Features and Risk Factors

The number of pertussis cases reported to WHO annually in the early 1980s was in the range of 1.5 to 2 million; by 1997, this number had decreased to fewer than 200,000 (WHO, 1998a). In the mid-1980s, it was estimated that more than 600,000 children died of pertussis annually. By 2008, the estimated annual death toll from pertussis had declined to approximately 89,000 (WHO, 2017b). As noted earlier, however, any estimate of the burden of disease caused by pertussis is likely to underestimate the actual toll due to the difficulty of making the diagnosis.

Limited studies suggest that most cases of pertussis in LMICs occur in infancy and early childhood and that the highest case fatality ratio is seen in infants. It is likely that poverty and the resultant crowding increase the risk of pertussis and that malnutrition increases the likelihood of dying among those who develop the disease, although lack of vaccination is undoubtedly the most important risk factor for developing or dying from pertussis at any age.

Current Approaches to Prevention and Control

As is the case for diphtheria, the current approach to reducing morbidity and mortality from pertussis is to improve levels of vaccine coverage through the EPI and strategies for improved vaccine coverage. Because vaccination does not lead to elimination of carriage of *B. pertussis,* ongoing control of pertussis requires high levels of vaccine coverage among the target population.

Tetanus

Etiologic Agent, Clinical Features, and Vaccine Characteristics

Tetanus is caused by the toxin produced by the anaerobic bacterium *Clostridium tetanus.* This bacterium is

commonly found in the gastrointestinal tract of many domesticated animals (e.g., cows, sheep, and goats). When deposited in the soil, *C. tetanus* cells form spores that are highly resistant to heat and desiccation and remain viable for years or even decades. When these spores are introduced into a wound or other suitable environment, they sporulate and the bacterial cells reproduce, forming and releasing a highly potent neurotoxin as they grow. Signs and symptoms produced by the neurotoxin include painful stiffening and spasms of the muscles, including those of the jaw (hence the common name "lockjaw"), and, particularly in newborn infants, a resultant inability to suck or otherwise feed.

Treatment of tetanus is largely supportive, even in the rare circumstance when tetanus antitoxin is available. It consists largely of giving muscle relaxants and fluids intravenously. Even with such treatment, the case fatality ratio is very high, particularly in infants with neonatal tetanus, of whom 80% to 90% will die.

The vaccine against tetanus, either in a single preparation or in DPT, is a toxoid—an inactivated form of tetanus toxin, adsorbed to aluminum salts. Tetanus toxoid (TT) is extremely safe and produces few reactions. The three doses of DPT given to infants and the two doses of TT given to women of childbearing age or pregnant women through the EPI produce immunity in 90% to 100% of those vaccinated.

Descriptive Epidemiologic Features and Risk Factors

While tetanus in adults is an avoidable and tragic illness, tetanus in newborn infants is a public health problem. Studies in the 1970s and 1980s showed that as many as 60 newborn babies per 1,000 (6%) developed neonatal tetanus in some low-income countries, primarily due to contamination of the umbilical stump, and that almost all these babies died (Stanfield & Galazka, 1984). Deaths due to neonatal tetanus accounted for one-fourth to three-fourths of all neonatal deaths and as much as one-fourth of infant mortality in these countries. Neonatal tetanus caused more than 500,000 deaths worldwide in 1993 (WHO, 1994), but that number had declined to an estimated 61,000 deaths by 2011 (WHO, 2017c).

Neonatal tetanus is more common in rural areas, particularly those where animal husbandry practices lead to substantial fecal contamination of the soil, and it tends to be more common during the rainy season (Schofield, 1986). Nevertheless, the key risk factors for neonatal tetanus clearly relate to the site where a delivery occurs, the level of training of the person assisting with the delivery, the manner in which the umbilical cord is cut, and the way the umbilical stump is treated. Because of the enormous diversity of cultural practices regarding how the cord is cut and what is placed on the umbilical stump (including mud, animal dung, clarified butter, and other nonsterile materials), the rate of and risk factors for neonatal tetanus vary substantially in different regions of the world (Stanfield & Galazka, 1984).

Current Approaches to Prevention and Control

Because the *C. tetanus* spores that cause neonatal tetanus are ubiquitous in soil and can persist there indefinitely, the organism itself cannot be eradicated. Neonatal tetanus, however, can be controlled or eliminated as a public health problem (defined as fewer than 1 case per 1,000 live births in each health district) by ensuring that a high proportion of women giving birth have received two doses of TT or that the delivery and subsequent cord care practices minimize the chance that *C. tetanus* spores will be introduced. Studies such as those conducted in Egypt (**FIGURE 6-2**) demonstrated clearly that immunization of women of reproductive age or of pregnant women has a dramatic impact on the risk of neonatal tetanus (CDC, 1996). Other studies suggest that training and equipping birth attendants so they can perform a clean delivery (the "three cleans"—delivery with clean hands, delivery on a clean surface, and use of clean instruments and dressings to cut and dress the umbilical cord) may be somewhat less effective in reducing the risk of neonatal tetanus but has a greater impact on the risk of neonatal mortality from all causes combined. These two approaches can be, and have been, used together. In recent years, the proportion of women giving birth in various geographic regions who have been adequately immunized with TT has increased substantially, but neonatal tetanus remains a problem in many LMICs where many deliveries still occur at home.

Obstacles to Prevention and Control

Despite Herculean efforts on the part of WHO, UNICEF, and others, it has been challenging to achieve and maintain high levels of vaccine coverage in many countries, particularly in rural areas within LMICs. By 2015, global coverage was at 86%. Current estimates suggest that worldwide, 19.5 million children remain unvaccinated, of whom an estimated 1.5 million will die of childhood vaccine-preventable diseases (WHO, 2018a).

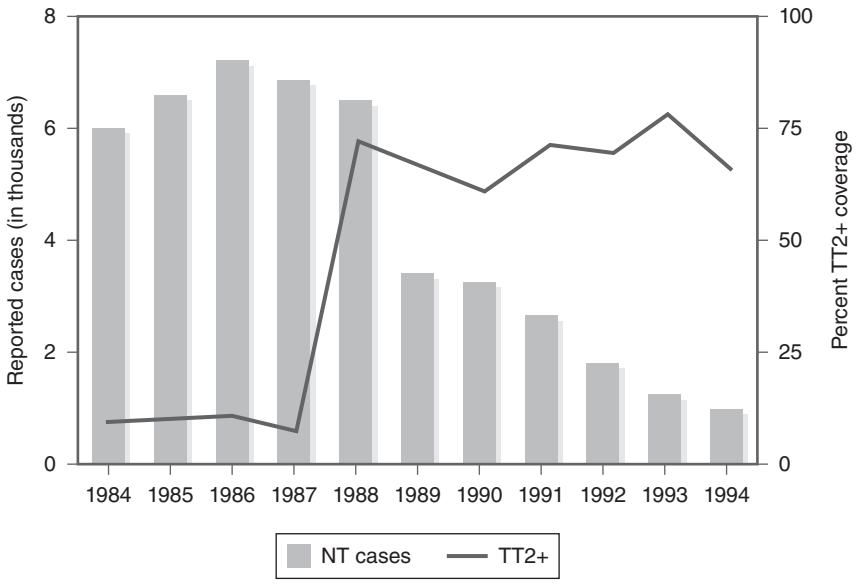

FIGURE 6-2 Number of reported cases of neonatal tetanus (NT) and percentage of pregnant women receiving at least two doses of tetanus toxoid (TT2+), by year, in Egypt, 1984–1994.

Centers for Disease Control and Prevention. (1996). Progress toward elimination of neonatal tetanus: Egypt, 1988–1994. *Morbidity and Mortality Weekly Report, 45,* pp. 89–92.

For a number of years, substantial controversy persisted regarding the relative merits of vertical approaches to vaccinating children (e.g., mass campaigns) and horizontal approaches (i.e., improving access to and use of primary care services that provide routine immunizations). Although the debate over vertical versus horizontal programs continues in some health areas, it has largely been replaced with respect to vaccination of infants and children by a broad consensus that the two approaches can be complementary, rather than conflicting. Thus, attempts to strengthen routine infant (and pregnant woman) immunization programs in LMICs around the world have proceeded in parallel with mass campaigns intended to hasten the eradication of polio and the elimination of measles. In 2012, the Global Vaccine Action Plan was implemented, with the goal of preventing millions of deaths by providing equal access to vaccines worldwide.

Further reduction or elimination of the childhood vaccine-preventable diseases discussed in this section is contingent on the availability of sustained funding of and technical support for immunization programs, stimulation of increased demand for vaccination on the part of parents and communities, expanded access to immunization services, and effective surveillance for these diseases. At the same time, there is a need to continue to develop, test, and make available new and improved vaccines; to expand local production of existing vaccines in LMICs; to ensure the potency and safety of the vaccines produced; and to ensure the availability and proper use (and disposal) of sterile injection equipment. The Global Alliance for Vaccines and Immunizations (GAVI; see **EXHIBIT 6-2**), together with the Bill and Melinda Gates Foundation and other partners, is working to ensure the earliest possible incorporation of other vaccines into the EPI. As existing and newly licensed infant and childhood vaccines are added to the group of vaccines recommended by WHO, countries with limited resources will need to establish their own priorities for which vaccines to add.

Based on the model of smallpox eradication, one argument cited to support the drive for worldwide polio eradication was that it would be possible to discontinue routine polio vaccination at some point after eradication was achieved. However, outbreaks of polio caused by circulating vaccine-derived polioviruses in Hispaniola, the Philippines, and Madagascar, together with the widespread presence of wild-type polio virus in numerous laboratories and vaccine production facilities around the world, have challenged previous notions about the need for ongoing polio vaccination after eradication (Fine, Oblapenko, & Sutter, 2004; Sutter, Cáceres, & Mas Lago, 2004). Thus, current plans call for the use of inactivated polio vaccine worldwide for at least some years following eradication of polio.

The inexplicable and unfortunate increase in all-cause mortality seen in infants (primarily female infants) given experimental high-titer measles vaccine at a young age has clearly set back efforts to develop a more potent measles vaccine (Aaby et al., 1994). Therefore, for the foreseeable future, efforts to eliminate measles will, of necessity, rely on the currently available vaccine. Important unanswered questions

EXHIBIT 6-2 The Global Alliance for Vaccines and Immunizations

An estimated 1.5 million infants and children still die each year from diseases that can be prevented by currently available vaccines. Several million more infants and children die each year from tuberculosis, malaria, and AIDS—infectious diseases for which new vaccines are urgently needed.

Numerous obstacles, many of which are external to the public health and healthcare delivery systems, make it difficult to achieve and sustain high levels of coverage with existing vaccines in LMICs. These obstacles include limited financial resources, insufficient numbers of trained healthcare workers, poor roads and other barriers to reaching remote parts of some countries, civil wars, and natural disasters. Other barriers hinder the development, testing, licensure, and ultimate availability of new vaccines, including the cost of research and testing (and hence the eventual cost of new vaccines, particularly those requiring technological sophistication, such as conjugated vaccines) and liability concerns on the part of potential manufacturers.

Recognizing these problems and seeking to increase the speed with which current and new vaccines reach the world's children, a group of international agencies—including WHO, UNICEF, the World Bank, and others—launched the Global Alliance for Vaccines and Immunizations (GAVI) in 2000. The mission of GAVI is "to fulfill the right of every child to be protected against vaccine-preventable diseases of public health concern." Its four-pronged approach includes accelerating the introduction and use of vaccines, strengthening the health systems that deliver immunizations, improving financing for immunizations, and shaping the vaccine market to make appropriate and affordable immunizations available to poor countries. To date, GAVI has been instrumental in helping make *H. influenzae* b conjugate vaccine, rubella-containing vaccine, pentavalent (DPT–Hib–hepatitis B) vaccine, and pneumococcal conjugate vaccine available to millions of children in poor countries, and it is currently working to speed the introduction of vaccines against rotavirus and HPV, among others (Loharikar et al., 2016).

relate to how best to use the currently available vaccine and which vaccination strategies or combinations of strategies will be most effective in interrupting transmission of this highly infectious agent, particularly in Africa. There is a clear need to sustain high levels of routine immunization against measles at or around 9 months of age and a second dose at some time after the first birthday. The relative importance of periodic mass campaigns remains to be determined. It is, at best, uncertain whether a new measles vaccine that is immunogenic at a younger age (in the face of circulating maternal antibodies) and that is safe can be developed and tested, or whether it is even needed to eliminate measles.

Historically, rubella vaccine was not included in the EPI package of vaccines, even though it has been available for 30 years and is both highly effective and very safe. However, because of growing recognition that congenital rubella syndrome is a problem in LMICs, rubella-containing vaccine had been included in the national immunization schedules in 149 countries as of 2016 (Loharikar et al., 2016).

In recent years, there has been growing interest in giving additional vaccines (i.e., other than tetanus toxoid) to pregnant women, in an effort to protect them (e.g., against influenza) and to protect their newborn babies prior to the time they can be vaccinated against pertussis or influenza (Omer, 2017). At the same time, there is ongoing work to develop other vaccines that might be administered to pregnant women to protect their newborn babies, such as a vaccine against group B *Streptococcus*.

Enteric Infections and Acute Respiratory Infections

Although it might seem odd to discuss enteric infections and acute respiratory infections (ARIs) together in one section, these seemingly disparate conditions have much in common. Each accounts for a substantial amount of childhood morbidity and mortality, as well as for a large proportion of outpatient visits and hospitalizations. Infants and young children almost uniformly experience multiple episodes of both types of illness, regardless of where they live. The identified risk factors for enteric infections and ARIs (e.g., poverty, crowding, lack of parental education, malnutrition, low birth weight, and lack of breastfeeding) overlap substantially, and most are difficult to change in the absence of major social change. Further, both enteric infections and ARIs are caused by a multitude of distinct microbial agents, for most of which no vaccine currently exists or is likely to be available in the near future. As a result, the overall approach to minimizing morbidity and mortality from both enteric infections and ARIs has been virtually identical—acceptance of the fact that

such infections and illnesses will occur, combined with attempts to ensure that prompt and appropriate care is sought and given.

Enteric Infections

Overview

Enteric infections encompass those viral, bacterial, and parasitic infections of the gastrointestinal tract that are, with the exception of typhoid fever, generally manifested as diarrhea, either alone or in combination with fever, vomiting, and abdominal pain. Although most episodes of diarrheal disease are mild and self-limited, the loss of fluids and salts accompanying severe diarrhea can be life threatening. Also, not all episodes of diarrheal disease are self-limited: Studies suggest that anywhere from 3% to 23% of diarrheal illnesses in infants and young children persist for longer than two weeks (Black, 1993). Both self-limited and persistent diarrhea can have a substantial negative impact on the growth of a child, through malabsorption of nutrients and reduced intake due to vomiting, loss of appetite, and undesirable changes in feeding practices in response to diarrheal illness. Thus, repeated episodes of diarrhea and persistent diarrhea often lead to malnutrition, which can in turn increase the likelihood of diarrhea persisting and producing a fatal outcome (El Samani, Willett, & Ware, 1988). It has been estimated that diarrheal disease has a more profound impact on the growth of children worldwide than any other infectious disease (see the *Nutrition* chapter).

Cholera, while in a sense just one of many causes of watery diarrhea, is in many ways a disease unto itself. It can produce the most dramatic fluid losses of any enteric infection and, in the absence of appropriate replacement of fluid and salts, can cause death within 24 to 48 hours of its onset. Cholera epidemics and pandemics can produce enormous numbers of cases and large numbers of deaths, resulting in profound social disruption. As a result, cholera has been accorded a special status by public health officials and agencies.

Many episodes of diarrheal disease in children in LMICs are accompanied by bloody stools or frank dysentery (abdominal cramps; painful, strained defecation; and frequent stools containing blood and mucus), which is usually the result of an invasive infection that produces local tissue damage and inflammation in the intestinal mucosa. Although the fluid loss that accompanies such episodes is generally not profound, life-threatening local intestinal and systemic complications can result. Damage to the intestinal mucosa can also lead to substantial losses of protein, resulting in growth retardation. The clinical management of such episodes poses a number of distinctive challenges (see "Current Approaches to Prevention and Control" later in this section).

On average, children younger than the age of 5 years in LMICs experience two to three episodes of diarrhea each year (Kosek, Bern, & Guerrant, 2003). The burden of disease attributable to diarrheal diseases worldwide is enormous, despite the impressive accomplishments of diarrheal disease control programs. The Global Burden of Disease (GBD) project estimated that more than 2.3 billion episodes of diarrhea occur annually and that diarrheal disease causes approximately 1.3 million deaths each year, 499,000 of which occur in children younger than 5 years of age (GBD 2015 Disease, 2016). Thus, diarrheal disease accounts for roughly 8.6% of all deaths among children in this age group (GBD 2015 Mortality, 2016).

Typhoid fever, which results from an enteric infection and, therefore, shares many individual- and community-level risk factors with diarrheal disease, is not accompanied by diarrhea. Although it can be life threatening, this disease has its most profound public health impact through its debilitating effects on school-age children, causing substantial morbidity and absenteeism from school and work (Medina & Yrarrazaval, 1983).

Etiologic Agents

As noted earlier, diarrheal disease can be caused by a wide variety of viral, bacterial, and parasitic infections. In cases of endemic diarrheal disease, one or more etiologic agents can be identified in 70% to 80% of patients when state-of-the-art laboratory testing is performed. However, many of these agents can also be found in the stools of children who do not have diarrhea, and multiple infectious agents may be present in the same child with diarrhea. Thus, the presence of a given causative agent in a stool sample may not mean that it is the cause of that episode of diarrhea. Recent studies have attempted to address this issue through various methods, including the use of quantitative detection methods and testing samples from control children without diarrhea to assess the causal role of various microbial agents (Liu et al., 2016; Platts-Mills et al., 2015).

These complications notwithstanding, the most important etiologic agents in young children in LMICs are rotavirus, enterotoxigenic *Escherichia coli* (ETEC), enteropathogenic *Escherichia coli* (EPEC), *Shigella* spp., *Campylobacter* spp., *Cryptosporidium* spp., and norovirus (Lanata et al., 2013; Liu et al., 2016; Platts-Mills et al., 2015). Rotavirus is the leading cause of

nonbloody diarrhea in infants and accounts for an estimated 38% of hospital admissions for diarrhea among children younger than 5 years of age (Lanata et al., 2013), whereas *Shigella* species and *Campylobacter* species appear to be the leading causes of bloody diarrhea (Platts-Mills et al., 2015). Amebiasis (infection with *Entamoeba histolytica*), although frequently diagnosed, appears to be an infrequent cause of bloody diarrhea in young children in LMICs. *Vibrio cholerae* is the cause of a substantial proportion of cases of nonbloody diarrhea in endemic areas, such as Bangladesh and India (Cholera Working Group, 1993; Nair et al., 1994); it is also the cause of large numbers of cases when epidemics of cholera occur in other regions, as demonstrated by recent or ongoing large outbreaks in Haiti, Mozambique, and Yemen (Luquero et al., 2016). Typhoid fever is caused by *Salmonella typhi*.

Descriptive Epidemiologic Features and Risk Factors

Children experience the highest risk of diarrheal illness between 6 and 11 months of age; the risk declines steadily thereafter (**FIGURE 6-3**) (Kosek et al., 2003). This age pattern is largely explained by the established risk factors for diarrheal disease and the likely sources of exposure to the causative agents.

The risk of diarrheal disease in young infants is determined in part by the feeding and hand-washing practices of the mother or other childcare providers. Breastfeeding and lack of exposure to contaminated food, water, and other environmental sources are protective factors. As infants grow and become mobile, however, they begin to encounter numerous potential sources of infection with the agents of diarrheal disease, including contaminated water and weaning foods, as well as human and animal wastes that have not been disposed of properly. Some evidence also indicates that uncontrolled fly populations can contribute to the risk of diarrheal illnesses—particularly those illnesses caused by etiologic agents requiring a small infectious dose (e.g., shigellosis). Overall, it is estimated that almost 90% of deaths due to diarrheal disease are attributable to unsafe water, inadequate sanitation, and poor hygiene (Black, Morris, & Bryce, 2003).

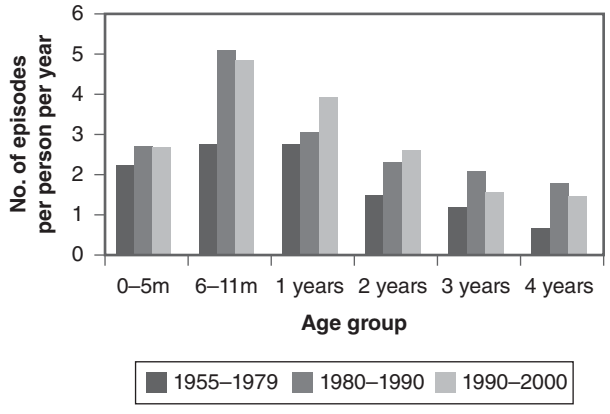

FIGURE 6-3 Median age-specific incidences for diarrheal episodes per child per year from three reviews of prospective studies in developing areas, 1955–2000.

Reproduced from Kosek, M., Bern, C., & Guerrant, R. L. (2003). The global burden of diarrhoeal disease, as estimated from studies published between 1992 and 2000. *Bulletin of the World Health Organization, 81,* pp. 199.

As noted earlier, diarrheal disease and malnutrition are intricately intertwined in infants and young children. Although it is not clear that malnutrition is associated with an increased incidence of diarrheal disease, strong evidence indicates that malnutrition increases the likelihood that a child with diarrhea will die or develop persistent diarrhea; diarrhea, in turn, has a negative impact on nutritional status and growth. Furthermore, strong evidence supports the contention that deficiencies of vitamin A and zinc are associated with increased morbidity and mortality from diarrheal disease.

Unlike diarrheal disease, typhoid fever has long been thought to be a problem primarily in school-age children. However, infections with *S. typhi* clearly occur in infants and preschool-age children, and such infections in this younger age group may be substantially underreported (Sinha et al., 1999). More than 20 million new cases of typhoid fever are believed to occur worldwide each year, with the highest incidence seen in South and Southeast Asia (Mogasale et al., 2014; WHO, 2015a). *S. typhi* infection is primarily acquired from contaminated food and water.

Current Approaches to Prevention and Control

A number of approaches to the primary prevention of diarrheal illness have been studied and found to be successful at lowering the rate of diarrheal illness in the community. These measures include water, sanitation, and hygiene interventions; promoting breastfeeding and proper weaning practices; providing vitamin A and zinc supplementation; vaccines for rotavirus and cholera; and various combinations of these interventions (Bhutta et al., 2013; Clasen et al., 2015). Although historical approaches focused on structural changes to improve communities' water supplies, it has become clear that interventions targeting water quality (i.e., those that protect water at the point of use) are more effective in preventing diarrhea than those focused on improving water supply.

Although these approaches have been shown to be effective in well-funded research studies, the feasibility

of fostering and sustaining such improvements across large areas and populations is directly linked to the availability of the financial resources and the political will to do so. Many children still lack access to these interventions (Bhutta et al., 2013). In addition, such interventions can generally succeed only when the community is invested in making them work and when they are designed and introduced within a culturally acceptable framework (see the *Culture, Behavior, and Health* chapter).

In parallel with the testing of such primary prevention approaches to reduce the risk of diarrheal disease, since the early 1980s enormous efforts have been directed toward ensuring that infants and children who develop diarrhea suffer a minimum of morbidity and mortality. These efforts have focused on prevention and early treatment of dehydration through proper case management in the home, maintenance of adequate nutritional intake to minimize the impact on growth, and appropriate treatment of infants and children who are brought to health facilities. Mothers and other caretakers of children are educated to use fluids available in the home to prevent dehydration, to use oral rehydration solutions (ORS) or cereal-based alternative solutions to prevent and treat dehydration, and to continue to breastfeed babies when they have diarrhea. ORS packets are now manufactured in many countries and widely available.

At the same time, mothers and healthcare providers have been discouraged from using the wide range of largely ineffective, often expensive, and sometimes dangerous antimicrobial and antidiarrheal agents that are available. Care providers should reserve these antimicrobial agents for the treatment of cholera and of dysentery suspected to be caused by shigellosis and limit the use of intravenous fluids to those who are severely dehydrated. Although promoting and sustaining such changes in diverse countries, often in the face of sometimes powerful cultural barriers, requires a major effort, studies from Egypt and elsewhere suggest that morbidity and mortality from diarrheal disease can be reduced substantially by such efforts (El-Rafie et al., 1990).

Perhaps in part because of the emphasis given to primary prevention and proper case management for diarrheal disease, the role of vaccines in reducing morbidity and mortality from enteric infections has been quite limited until recently. Vaccines against cholera and typhoid that represent substantial improvements over older vaccines are now available (Sur, Lopez, et al., 2009; Sur, Ochial, et al., 2009), as are newly licensed vaccines against rotavirus that have been shown to be efficacious in Africa, Latin America, and elsewhere (Madhi et al., 2010; Richardson et al., 2010). Although a few countries in which typhoid fever is a major public health problem in school-age children have begun to administer typhoid vaccines to members of this age group, a longstanding debate has focused on the proper role of vaccines against typhoid, cholera, and other enteric infections and the circumstances under which they should be given routinely in LMICs (Keusch & Cash, 1997). The availability of these new vaccines is leading to renewed discussion of how best to use typhoid and cholera vaccines (Levine, 2009; Sridhar, 2009), and rotavirus vaccines had been introduced in the EPI of more than 80 countries by 2016.

Obstacles to Prevention and Control and Directions for Future Research

The greatest obstacle to reducing further the toll taken by diarrheal disease in LMICs is the difficulty and expense of ensuring that everyone has regular access to clean, safe drinking water and adequate sanitation. To do so requires both structural and behavioral changes. In addition, cultural and legal adjustments are needed to create a more permissive and supportive environment for breastfeeding. Effective interventions are available that could result in a substantial reduction in diarrhea-associated morbidity and mortality, but scaling up existing interventions and ensuring equitable access remain significant challenges.

Acute Respiratory Infections

Overview

Acute respiratory infections comprise infections of various parts of the respiratory tract, ranging from mild viral and bacterial infections of the upper respiratory tract (e.g., the common cold, viral and group A streptococcal pharyngitis, and middle ear infections) to life-threatening infections of the lower respiratory tract (e.g., bronchiolitis and pneumonia caused by a variety of bacterial and viral agents). Although upper respiratory tract infections globally cause substantial minor morbidity and economic loss through lost time at work, they rarely result in severe morbidity or in mortality. Interestingly, studies suggest that the incidence of upper respiratory tract infections, although varying with age and season, is remarkably similar in free-living populations throughout the world. Because they do not pose a major public health problem and because no effective interventions against them exist, upper respiratory tract infections will not be discussed further in this chapter, except for group A streptococcal pharyngitis, which can lead to rheumatic fever and is discussed later in this section.

Lower respiratory tract infections, in contrast, are the cause of substantial morbidity and mortality, particularly among infants and young children living in low- and middle-income settings, even when those settings are within industrialized countries. In LMICs, particularly those with good childhood immunization and oral rehydration therapy programs, lower respiratory tract infections in general, and pneumonias in particular, are typically one of the leading causes of death among infants and children younger than 5 years of age (GBD 2015 Child, 2016). An estimated 703,000 children younger than 5 years of age died in 2015 from pneumonia and other lower respiratory tract infections, most of them in LMICs (GBD 2015 Mortality, 2016). However, the accuracy of such estimates is questionable for several reasons: Establishing a diagnosis of lower respiratory tract infection or pneumonia is difficult, particularly in settings where chest radiography is not available; many infants and young children die outside of hospitals; and other illnesses, such as malaria, make verbal autopsies (i.e., postmortem interviews of next-of-kin to determine the most likely cause of death) an unreliable means of establishing a definitive diagnosis.

Although pneumonia and other lower respiratory tract infections also cause substantial morbidity and mortality in older children and adults, this section focuses on these infections in infants and young children. Pneumonia in adults is discussed briefly later, as is influenza, an important cause of lower respiratory tract infections in children and adults.

Etiologic Agents, Clinical Features, and Vaccine Characteristics

Lower respiratory tract infections can be caused by a variety of viral and bacterial agents, either singly or in combination. Numerous studies conducted in various countries around the world show similar results concerning the etiologic agents responsible for these infections in infants and young children. Excluding respiratory tract infections caused by agents included in the EPI vaccines, the most important viral causes of lower respiratory tract infections are influenza, parainfluenza, respiratory syncytial virus (RSV), and adenovirus (Pavia, 2011). The most important bacterial causes of pneumonia, as determined by lung aspirate studies (in which a needle is passed through the chest wall into the affected lung parenchyma, thereby avoiding contamination of samples by flora in the upper airway), are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus* (Shann, 1986). Many infants and young children have evidence of dual infections (e.g., a virus and a bacterium). Moreover, in as many as one-third of the cases, no etiologic agent can be found, despite the use of state-of-the-art laboratory techniques.

Descriptive Epidemiologic Features and Risk Factors

Infants and young children living in low- and middle-income environments consistently have been found to experience high incidence rates of pneumonia. However, over the last two decades, there has been a significant reduction in pneumonia-related deaths in young children, likely due to a combination of improved access to health care, antibiotic therapy, and preventive vaccines (GBD, 2013; GBD 2015 Mortality, 2016). Despite this reduction, in 2015, 12.1% of deaths in children younger than 5 years of age were due to pneumonia and other forms of lower respiratory tract infections (GBD 2015 Mortality, 2016).

The single most important predictor of a child's risk of developing pneumonia or other lower respiratory tract infection is age. The cumulative incidence of lower respiratory tract infections is highest among young infants, but drops rapidly with increasing age, reaching markedly lower levels among children by the time they reach 2 or 3 years of age (Selwyn, 1990). Another important predictor of an increased risk of morbidity and mortality from lower respiratory tract infections is low birth weight. Other risk factors for either morbidity or mortality include exposure to indoor air pollution (from cooking, heating, and cigarette smoke), not breastfeeding, and malnutrition, including vitamin A deficiency. These factors are closely intertwined with poverty, inadequate access to health care, and with one another, so their independent effects can be difficult to disentangle (Berman, 1991). HIV infection is another important risk factor (Madhi, Peterson, Madhi, Khoosal, & Klugman, 2000).

Rheumatic fever following group A streptococcal pharyngitis occurs in a setting of poverty and household crowding. School-age children are primarily affected acutely, but the damage done to heart valves by this disease is usually permanent, producing lifelong disability. Population-based data concerning the incidence of acute rheumatic fever and the prevalence of rheumatic heart disease in LMICs are rarely available.

Current Approaches to Prevention and Control

In the 1980s, WHO, together with various partners, began a multifaceted research program intended to develop an approach to reducing the substantial

morbidity and mortality due to lower respiratory tract infections in infants and young children (WHO, 1981). This research program and the ARI control program that was subsequently developed were premised on the following observations:

- Upper respiratory tract infections, although frequent, are almost always benign and require only supportive care at home.
- At the time of the program's inception, many lower respiratory tract infections in infants and young children were not preventable with existing vaccines.
- The major known risk factors for morbidity and mortality from lower respiratory tract infections (e.g., age, low birth weight, malnutrition, and indoor air pollution) are impossible or difficult to change.
- Most morbidity and mortality from lower respiratory tract infections occur in locales where access to medical care is limited and where there are few, if any, diagnostic facilities (i.e., the ability to perform chest x-rays, microbiologic cultures, and other tests).

Given these circumstances, it was decided that an ARI control program based on triage performed by minimally trained village health workers according to readily observable clinical signs might be feasible, inexpensive, and effective at reducing at least mortality. As a result, a large body of multidisciplinary research relating to the various aspects of such a control program was commissioned and completed. Particularly important was research examining which readily observable clinical manifestations (e.g., cough, fever, respiratory rate, and chest indrawing), singly or in combination, best distinguished infants or young children with various levels of severity of respiratory tract infection (initially classified as mild, moderate, and severe, but later as no pneumonia, pneumonia, and severe pneumonia).

Based on this research, intervention programs were developed. These efforts were intended to train village health workers or their equivalents in how to assess and classify into one of these categories an infant or young child with signs of a respiratory tract infection. Based on their assessment, the village health workers were to recommend supportive care at home in cases of mild ARI (no pneumonia), provide an oral antimicrobial drug (either ampicillin or cotrimoxazole) and education about home care and follow-up in cases of moderate ARI (pneumonia), or refer the child immediately to the nearest hospital for assessment and inpatient care in cases of severe ARI (severe pneumonia). Well-designed intervention trials were carried out in a variety of countries to assess the efficacy of this approach in reducing mortality due to lower respiratory tract infections. As a meta-analysis of these trials showed, almost all of them successful in reducing mortality due to lower respiratory tract infections and all-cause mortality in infants and in children age 1 to 4 years (Sazawal & Black, 1992). One caveat should be noted: These trials typically assessed an intervention that included regular household visits by the village health workers in search of infants and children with signs of a respiratory tract infection.

Based on these favorable results, WHO promoted and supported the implementation of ARI control programs largely based on the model of having village health workers (or their equivalent) assess infants and young children with suspected ARI, classify them by severity of illness, and treat or refer them. The impact of such programs on mortality, as distinct from the impact seen in the intervention trials, has not been adequately assessed. On the one hand, these ARI control programs typically do not include a proactive, outreach component that ensures early case detection (i.e., regular household visits), as was present in the intervention trials, but instead rely solely on maternal recognition of illness and appropriate, timely care seeking; thus, they are not likely to have as large an impact as reported in the earlier trials. On the other hand, programs that include some form of regular household visits are likely to be difficult to sustain over the long term.

For a variety of reasons, the emphasis given to ARI control programs (and vertical disease-specific programs in general) by WHO and others has diminished in recent years, and attention has shifted to ensuring that any sick infant or child, regardless of his or her signs and symptoms, receives appropriate evaluation and care. This approach, referred to as the Integrated Management of Childhood Illness (IMCI), is described in **EXHIBIT 6-3** (WHO, 2012a). **TABLE 6-3** summarizes the interventions included in the IMCI program (WHO, 2012a). A recent systematic review and meta-analysis found that IMCI may reduce overall mortality in infants and children (relative risk [RR]: 0.85; 95% confidence interval [CI]: 0.78–0.93), but did not find consistent improvements in quality of care or vaccination coverage (Gera, Shah, Garner, Richardson, & Sachdev, 2016).

Prevention of rheumatic fever depends on the recognition of streptococcal pharyngitis and treatment with an appropriate antimicrobial agent (e.g., penicillin or erythromycin). In populations with high rates of acute rheumatic fever, school-based and other programs to detect and treat streptococcal pharyngitis have been suggested as a means to combat this disease,

EXHIBIT 6-3 Integrated Management of Childhood Illness

Throughout the 1970s and 1980s, concerted efforts were made to develop case management strategies for each of the infectious diseases that collectively accounted for the majority of morbidity and mortality among infants and young children in LMICs—measles, malaria, diarrheal disease, and acute respiratory infections. Although each of these disease-specific case management strategies has been shown to be effective at reducing severe morbidity and mortality when properly implemented, implementing multiple distinct disease-specific programs that all target the same healthcare providers can lead to overlap, inefficiency, and competition for the attention of an overworked healthcare worker. As a result, various programs within WHO and UNICEF collaborated in the development of the Integrated Management of Childhood Illness (IMCI), now referred to as the Integrated Management of Newborn and Childhood Illness (IMNCI) in some countries. This strategy attempts to assemble into a single, more efficient program the approaches of the various disease-specific control programs (Gove, 1997).

The IMCI program comprises three main components: improving case-management skills of healthcare workers, improving overall health systems, and improving family and community health practices, especially as they relate to the illnesses that collectively account for the majority of severe morbidity, mortality, and healthcare provider visits among infants and young children (see Table 6-3) (WHO, 2016b).

TABLE 6-3 Child Health Interventions Included in Integrated Management of Childhood Illness

Case Management Interventions	Preventive Interventions
Pneumonia	Immunization during sick child visits (to reduce missed opportunities)
Diarrhea	Nutrition counseling
Dehydration	Breastfeeding support (including the assessment and corrections of breastfeeding technique)
Dysentery	
Persistent diarrhea	
Meningitis, sepsis	
Malaria, measles, malnutrition, anemia	
Ear infection	

Data from World Health Organization (WHO). (2012). Recommendations for management of common childhood conditions.

although their effectiveness has rarely been assessed (Bach et al., 1996; Lennon et al., 2017).

Obstacles to Prevention and Control and Directions for Future Research

Primary prevention of lower respiratory tract infections, while in part requiring improvements in living conditions and socioeconomic status, is increasingly possible due to the growing availability of affordable vaccines against some of the major etiologic agents. The safe, highly effective conjugate vaccine against *H. influenzae* type b, which led to the virtual disappearance of invasive infections caused by this organism in the United States and other high- and middle-income countries, is now recommended by WHO for inclusion in the EPI of all countries. In turn, funding from GAVI resulted in the introduction of this vaccine in all GAVI-eligible countries by 2014. A number of studies conducted in diverse populations have documented a substantial reduction in meningitis and/or pneumonia following introduction of Hib conjugate vaccine (Hammitt et al., 2016; Mulholland et al., 1997; Pilishvili et al., 2013; Scott et al., 2013).

Similarly, conjugate pneumococcal vaccines including the most important serotypes of *S. pneumoniae* have been tested and shown to have excellent efficacy and safety. A conjugate pneumococcal vaccine including the seven serotypes that collectively accounted for approximately 80% of invasive infections in infants in the United States was approved for use in that country in 2000 and subsequently in other wealthy countries; its widespread use had a profound impact on the rate of invasive pneumococcal infections among infants in high-income countries. Conjugate pneumococcal vaccines with an expanded number of serotypes (e.g., 11 or 13) are now available, and funding from GAVI has made them affordable for 57 of the world's poorest countries to introduce. When (or, indeed, if) vaccines against the various viruses (other than

influenza) that are important causes of lower respiratory tract infections in infants and small children (e.g., RSV) will become available is uncertain.

Several barriers exist to reducing morbidity and mortality due to lower respiratory tract infections through means other than vaccination and improvement of living conditions. The first set of barriers relates to ensuring that the parents or guardians of a sick child will seek and have access to appropriate care in a timely fashion. A detailed discussion of care-seeking practices and obstacles to obtaining medical care is beyond the scope of this chapter, but suffice it to say that the obstacles are multifaceted and difficult to overcome. Many challenges also arise in ensuring that those ill infants and children who are brought to medical care facilities receive timely and appropriate care, including adequate assessment, treatment, and follow-up. Finally, concerns have focused on the likelihood that increased use of currently effective and inexpensive antimicrobial agents—particularly use of inappropriate or inadequate regimens—may lead to the development of resistant strains of bacteria (particularly *S. pneumoniae*), which may then not respond to currently available inexpensive, oral treatment regimens. Indeed, all WHO regions have reported decreased susceptibility of *S. pneumoniae* to penicillin, with some reports showing that more than 50% of samples have reduced susceptibility (WHO, 2014a).

Bacterial Meningitis

Overview

Meningitis is a nonspecific term that encompasses inflammation of the meninges (the membranous lining that covers the brain and spinal cord), which can be caused by a wide variety of infectious and noninfectious agents. Such inflammation, regardless of its cause, tends to produce a similar clinical picture—headache, stiff neck, fever, and variable other features. There is substantial overlap between the manifestations of meningitis, which is sometimes referred to as spinal meningitis or cerebrospinal meningitis, and those of many other infectious diseases. Although meningitis can be caused by a wide variety of viruses and other infectious agents (e.g., mycobacteria and parasites), the disease caused by certain bacteria poses a substantial public health threat. Therefore, this section is confined to a discussion of bacterial meningitis, excluding tuberculous meningitis, which is discussed briefly later in the section on tuberculosis.

From a public health perspective, it is important to subdivide bacterial meningitis into its endemic and epidemic forms. Endemic bacterial meningitis, while differing in a number of subtle ways with regard to its descriptive epidemiologic features and the distribution of etiologic agents in LMICs versus high-income countries, poses a similar set of challenges in these two different settings. Epidemic bacterial meningitis, for reasons that remain unexplained, has almost entirely ceased to be a public health problem in industrialized countries since World War II, although small clusters of cases or hyperendemic disease can still be a vexing problem. In contrast, in a number of LMICs, particularly those in the "meningitis belt" of sub-Saharan Africa, periodic epidemics of bacterial meningitis continue to occur on a scale never documented in high-income countries. These epidemics can be of such a magnitude and geographic scope as to be properly called public health disasters.

In high-income countries, suspected bacterial meningitis is considered a medical emergency, requiring appropriate clinical specimens for diagnostic testing be obtained and parenteral antimicrobial therapy in a hospital to be initiated immediately. Even under these ideal conditions, case fatality ratios for bacterial meningitis range from 3% to 25%, with the ratio depending primarily on the specific etiologic agent and the age of the patient. Further, many patients who survive the acute episode will be left with one or more serious sequelae, including deafness, blindness, mental retardation, and seizure disorders. Although the clinical outcomes of hospitalized cases of bacterial meningitis do not, in general, differ between LMICs and high-income countries, the resources available for treating such patients are much more limited in LMICs. Furthermore, epidemics involving tens of thousands of such cases cannot be dealt with easily by countries with extremely constrained health budgets and facilities.

Endemic Meningitis

Etiologic Agents

Studies of the etiology of endemic bacterial meningitis in LMICs have been hampered by the need for a reasonably well-equipped and staffed microbiology laboratory to conduct such studies. Even so, a number of hospital-based studies have been performed in areas where or in time periods when epidemic meningitis has not been present. These studies are in general agreement that the leading causes of endemic bacterial meningitis in these settings are *S. pneumoniae, H. influenzae,* and *Neisseria meningitidis*; before the introduction of *H. influenzae* b and pneumococcal conjugate vaccines, these same pathogens were responsible for most cases of bacterial meningitis in

high-income countries. Reviews have documented the important role of *H. influenzae* b and *S. pneumoniae* in bacterial meningitis (and other syndromes) in LMICs (O'Brien et al., 2009; Watt et al., 2009). Other organisms that account for a reasonable proportion of cases in high-income countries, such as group B *Streptococcus* and *Listeria monocytogenes*, appear to be infrequent causes of meningitis in LMICs, although this apparent difference may be artifactual. At the same time, meningitis due to *Salmonella* species appears to be more common in LMICs than in high-income countries.

Descriptive Epidemiologic Features and Risk Factors

The overall cumulative incidence of endemic bacterial meningitis in LMICs appears to be four or five times that in high-income countries, although the data are limited. Somewhere between 1 in 60 and 1 in 300 children die of bacterial meningitis before the age of 5 years in nonepidemic areas (Greenwood, 1987). Endemic bacterial meningitis is primarily a problem in infants and young children, although age-specific incidence rates vary with the etiologic agent. Notably, meningitis caused by *H. influenzae* b occurs almost exclusively during the first 12 to 24 months of life. Although the highest incidence rates of meningitis due to *S. pneumoniae* and endemic meningitis due to *N. meningitidis* occur in the first 12 to 24 months of life, cases can also occur in older children and adults. Endemic bacterial meningitis probably occurs at approximately equal incidence rates among males and females.

Because the three leading causes of endemic bacterial meningitis are all spread via respiratory droplets, poverty and the resulting crowding increase the risk for this disease. Failure to breastfeed has been shown to be a risk factor in high-income countries and probably increases the risk in LMICs as well. Host factors also play an important role in determining the risk of endemic bacterial meningitis—most notably sickle cell disease and HIV infection. Sickle cell disease is associated with a markedly increased risk of infection with *S. pneumoniae*. Meningitis due to *S. pneumoniae*, like that caused by *Salmonella*, also occurs at a substantially increased rate among HIV-infected children and adults. In addition, malnutrition and anemia have been suspected to be risk factors for bacterial meningitis.

Current Approaches to Prevention and Control

Until recently, little could be done to prevent endemic bacterial meningitis in LMICs. Today, however, bacterial meningitis due to *H. influenzae* b and many serotypes of *S. pneumoniae* is preventable with vaccines produced by conjugating the bacterial polysaccharide to one of several protein molecules. The widespread use of these vaccines has led to the virtual elimination of meningitis due to *H. influenzae* b and to sharp reductions in the incidence of meningitis due to *S. pneumoniae* in high-income countries. Funding from GAVI is now making these vaccines more widely available in poor countries (see Exhibit 6-2). Although a portion of the cases of endemic meningitis attributable to *N. meningitidis* could be prevented with existing purified polysaccharide and conjugate vaccines against serogroups C, Y, and W-135 and more recently developed vaccines against serogroup B, these vaccines are in use in only a few LMICs (e.g., Brazil and Cuba are routinely using a vaccine against serogroup B *N. meningitidis*).

Chemoprophylaxis—that is, giving a short course of an antimicrobial agent to individuals in close contact with someone with bacterial meningitis due to *N. meningitidis* or *H. influenzae* type b—has been used with some success in high-income countries, but has not been widely advocated in LMICs because of the small percentage (less than 5%) of endemic cases that occur in close contacts of a known case, the cost and availability of the antimicrobial agents, the limited duration of the protection achieved, concerns about promoting the development of antimicrobial resistance, and logistical problems related to implementation.

Obstacles to Prevention and Control and Directions for Future Research

The primary obstacle to preventing endemic meningitis due to *H. influenzae* b and *S. pneumoniae* in LMICs has been the cost of the highly effective and safe conjugate vaccines now used in high-income countries. As economic barriers to the introduction of these vaccines in LMICs are removed, cases of endemic meningitis due to these organisms may be markedly reduced or nearly eliminated. Prevention of endemic meningococcal meningitis in most LMICs must await the widespread availability of serogroup B and C conjugate vaccines that are effective in infants, provide protection against multiple serotypes of serogroup B, and are affordable.

Epidemic Meningitis

Etiologic Agents

Epidemic bacterial meningitis is almost always caused by *N. meningitidis*. More specifically, serogroup A *N. meningitidis* causes most such epidemics, although

epidemics due to serogroup C and serogroup W-135 have also been well documented (Sidikou et al., 2016; WHO, 2013). Serogroup B *N. meningitidis*—one of the most important causes of endemic bacterial meningitis—has led to "epidemics" in a variety of high-income and LMICs, but these outbreaks are never of the scope and intensity of those caused by serogroup A, differing in overall attack rates by as much as two orders of magnitude.

Descriptive Epidemiologic Features and Risk Factors

Epidemic bacterial meningitis, generally caused by serogroup A *N. meningitidis,* is one of the most interesting but least understood infectious diseases. Epidemics involving hundreds of thousands of cases and cumulative incidence rates of almost 1,000 to 2,000 cases per 100,000 total population have been observed in the "meningitis belt" of Africa (**FIGURE 6-4**) for more than 100 years (Moore, 1992). An epidemic there in the 1990s was one of the largest ever recorded and extended into parts of Africa not previously considered to be in the meningitis belt. In this region of Africa, epidemics in a given area typically last for 2 or 3 years and recur every 5 to 15 years. They occur only during the hot, dry season (January to April) and dissipate when the rains and cooler weather arrive, only to return the next dry season. The interepidemic period can vary from a few years to a decade or more, likely reflecting a combination of the time it takes to reaccumulate enough susceptible individuals to sustain an epidemic, the introduction of a new virulent strain of *N. meningitidis*, prior use of meningococcal vaccine in the population, and other poorly defined factors (Moore, 1992).

Epidemics of meningococcal meningitis have also occurred in Asia and Latin America. In western China and Nepal, the epidemics have followed a pattern similar to that seen in Africa, except that they occur during the cold, dry season rather than the hot, dry season. In Latin America, Brazil has borne the brunt of such epidemics due to both serogroups A and C. Epidemics have also occurred in countries in the Middle East (e.g., Saudi Arabia) and the Pacific (e.g., New Zealand).

Current Approaches to Prevention and Control

Historically, efforts to reduce morbidity and mortality from epidemic meningococcal meningitis were reactive in nature. That is, once an epidemic was detected, a vaccination campaign was implemented as rapidly as possible, and the antimicrobial agents and other materials needed to treat cases appropriately were made available in the affected area. This approach was rightly criticized on the grounds that numerous delays arose when mounting such campaigns, during which time many cases (and resulting morbidity and mortality) occurred. Such reactive vaccination campaigns were almost inevitably disruptive of other health programs, and the extent to which they reduced the size of the epidemic was often

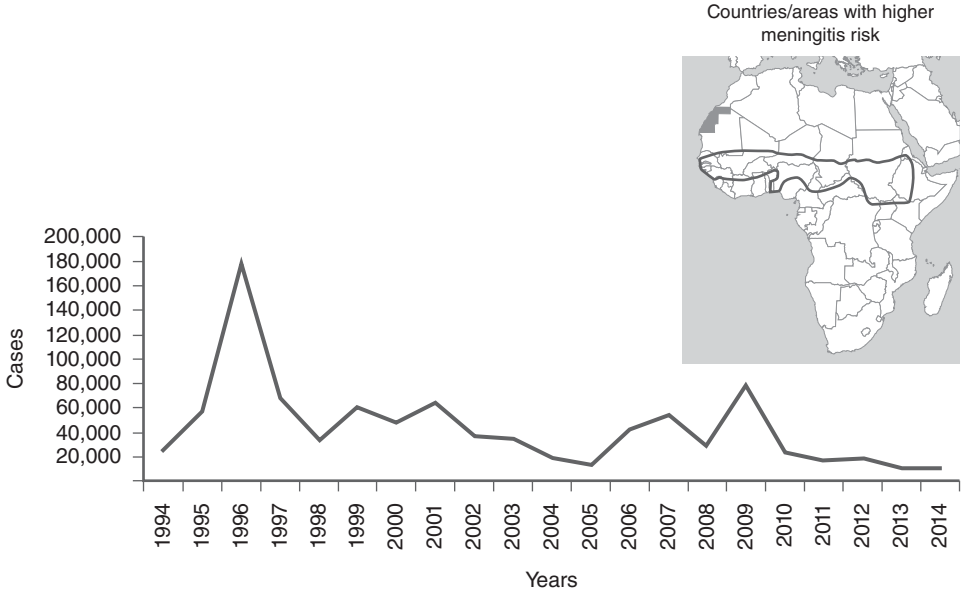

FIGURE 6-4 Trends of epidemic meningitis cases in the African Belt countries, 1994–2014.

Reproduced from World Health Organization. (2014). Global health observatory (GHO) data. Retrieved from http://www.who.int/gho/epidemic_diseases/meningitis/en/

debated. Furthermore, shortages of the purified polysaccharide vaccine used in these campaigns often occurred (Wakabi, 2009).

One alternative approach to improving the control of such epidemics that was suggested in the 1990s was to enhance surveillance for bacterial meningitis in areas susceptible to epidemics (e.g., the meningitis belt of Africa), use a predetermined threshold rate of cases to declare an epidemic and mount a vaccination campaign, and stockpile vaccines and other supplies and equipment in the immediate area (WHO, 1995). Unfortunately, projections suggest that even these steps resulted in the prevention of no more than 40% to 50% of the cases that would otherwise have occurred, and initial attempts to establish such early detection and response capabilities demonstrated the limitations of this approach.

Recognizing the limitations of an approach to controlling or preventing epidemic meningococcal meningitis epidemics using the purified polysaccharide vaccines against serogroup A, a group of vaccine manufacturers and philanthropic organizations developed a monovalent (i.e., serogroup A only) conjugate vaccine (MenAfriVac) using an approach similar to that employed in making the *H. influenzae* b and *S. pneumoniae* vaccines used to successfully immunize infants. MenAfriVac was introduced into countries in the "meningitis belt" beginning in 2010, targeting individuals 1 to 29 years of age. By the end of 2015, it had been introduced into 16 countries in sub-Saharan Africa. Since then, no epidemics of meningitis caused by serogroup A *N. meningitidis* have occurred in the region (WHO, 2013). Continued use of the vaccine in infants when they reach 1 year of age may help sustain this remarkable achievement.

Obstacles to Prevention and Control and Directions for Future Research

While use of MenAfriVac has, thus far, prevented the recurrence of epidemics of meningitis caused by serogroup A *N. meningitidis* in the countries in Africa's "meningitis belt," epidemics caused by both serogroup W-135 and serogroup C have occurred in Niger, Burkina Faso, and other countries in recent years (MacNeil et al., 2014; Sidikou et al., 2016). Thus, even if widespread use of MenAfriVac in the region continues to prevent outbreaks caused by serogroup A *N. meningitidis*, it may be necessary to add conjugate vaccines (or vaccine components) that provide protection against other serogroups of *N. meningitidis* to adequately control or prevent large-scale epidemics of meningitis in this region in the future.

Mycobacterial Infections

Overview

Although many species of mycobacteria can infect people, only two cause sufficient human illness in LMICs to warrant discussion here—*Mycobacterium tuberculosis*, the cause of tuberculosis (TB), and *Mycobacterium leprae*, the cause of leprosy. Although *Mycobacterium bovis* (which is closely related to *M. tuberculosis*) can cause TB in humans, it accounts for only a small percentage of cases, and these cases are generally not distinguishable from or in need of different treatment than cases caused by *M. tuberculosis.* Other than *M. leprae*, the various nontuberculous mycobacteria cause opportunistic infections that occur almost exclusively in immunocompromised individuals. Whereas these nontuberculous mycobacteria—particularly *Mycobacterium avium* complex—have caused substantial morbidity and mortality among AIDS patients in high-income countries, they appear to be uncommon in AIDS patients in LMICs.

Tuberculosis and infection with *M. tuberculosis* are, by every indicator available, among the most important public health problems in the world. Approximately one-third of the world's population (2 billion persons) is believed to be infected with *M. tuberculosis*, and in 2015 there were 10.4 million new cases of TB and 1.8 million deaths from TB, including 400,000 deaths of people with HIV infection (WHO, 2016c). Because suppression of the body's immune system is the most important determinant of which individuals infected with *M. tuberculosis* will subsequently develop TB, the AIDS epidemic has had disastrous consequences for the control of TB, which was underfunded and inadequate in most LMICs even before the arrival of HIV. In recognition of the gravity of the problems posed by this infection, WHO declared TB to be a global emergency in 1993.

A disease that many believe to have been leprosy was described in the Old Testament of the Bible. Leprosy occupies a unique position among human diseases, in part because of the disfigurement that it can produce and in part because of the belief in many cultures that it represents some form of divine punishment. Although leprosy was endemic to Europe during the eleventh through thirteenth centuries, it had virtually disappeared from there by the eighteenth century, long before modern medicine arrived. There is speculation that the rise of TB and infection with *M. tuberculosis* produced cross-immunity to *M. leprae* and led to the disappearance of leprosy from Europe. Some support for this theory comes from

the observation that BCG—the vaccine intended to prevent tuberculosis—appears to be at least partially effective in preventing leprosy. Whatever the cause of its near-total (but not complete) absence from high-income countries, leprosy today is largely confined to a shrinking number of LMICs.

Tuberculosis

Etiologic Agent, Clinical Features, and Vaccine Characteristics

Compared with other bacteria, mycobacteria are slow growing and have special nutritional needs. *M. tuberculosis* can be recovered from clinical specimens, particularly those from the respiratory tract, when appropriate artificial media and techniques are used, but the process takes many weeks and requires a laboratory with a modest level of sophistication and resources. Furthermore, it can be difficult to obtain a specimen of respiratory tract secretions, particularly from a child. Although monitoring of treatment progress for TB still relies on smear microscopy and culture, the availability of new technologies—including molecular tests such as Xpert MTB/RIF, whose use was endorsed by WHO in 2010—is dramatically changing the diagnostic landscape for TB. However, the relatively high cost of the latest technologies compared to smear microscopy has limited adoption of these technologies in some LMICs (Pai & Schito, 2015).

Descriptive Epidemiologic Features and Risk Factors

M. tuberculosis is spread via respiratory droplets produced when an individual with active pulmonary TB, particularly smear-positive TB (in which more organisms are present in the sputum), coughs or sneezes. Individuals in close contact with a person with untreated TB—particularly household contacts—are at highest risk of becoming infected. In LMICs, the highest incidence rates of pulmonary TB occur in men and women of reproductive age, meaning that there are often infants and young children in the household in close contact with individuals with active pulmonary TB. As a result, a high proportion of individuals will be exposed to and infected with *M. tuberculosis* in childhood.

Although a small proportion of infected infants and children will develop pulmonary or extrapulmonary TB soon after becoming infected, in most instances the immune system successfully walls off, but does not kill, all of the *M. tuberculosis* organisms. As these infected children grow up, various factors—particularly HIV infection and malnutrition—can reduce the ability of the immune system to keep the organisms in check, and reactivation TB can occur. Before the AIDS epidemic, it was estimated that 5% of persons infected as children developed TB soon after infection and another 5% developed TB at some point later in life. However, untreated HIV infection is such a potent inhibitor of cell-mediated immunity (the part of the immune system that holds *M. tuberculosis* infection in check) that a high proportion of untreated, dually infected individuals (i.e., infected with both HIV and *M. tuberculosis*) can be expected to develop TB unless they die of something else first or receive preventive therapy.

Almost 2 million people die from TB and 8 to 10 million people experience the onset of the disease each year, with 95% of these deaths and illnesses occurring in LMICs (WHO, 2016c). Although TB is a major public health problem in almost every LMIC, the burden of disease attributable to it varies by region and country, in part because of longstanding historical differences in the incidence of TB and the prevalence of infection with *M. tuberculosis*, in part because of local differences in the adequacy of TB control programs, and in part because of differences in the extent of the HIV/AIDS epidemic. Based on admittedly incomplete passive surveillance for reported cases of TB and on tuberculin skin test surveys, it appears that sub-Saharan Africa has the highest average annual risk of infection with *M. tuberculosis* and the highest crude incidence rate of cases of TB (**FIGURE 6-5**). The largest numbers of cases of TB are seen in India, Indonesia, China, Nigeria, Pakistan, and South Africa, which account for 60% of TB cases globally (WHO, 2016c). Because of the HIV/AIDS epidemic and unrelated demographic changes (e.g., population growth and increases in the numbers of individuals surviving to their thirties and forties), it has been projected that the number of new TB cases will increase in coming years in LMICs worldwide.

Although TB occurs in individuals in all socioeconomic strata, it is quintessentially a disease of poverty. Through its effect on crowding, poverty increases the risk of airborne transmission of *M. tuberculosis*. At the same time, through its negative effect on nutritional status, poverty increases the risk that someone infected with *M. tuberculosis* will develop TB. HIV infection is also more prevalent among poor populations, further increasing the likelihood that an infected individual will develop TB. Finally, through its effect on access to curative medical care, poverty increases the likelihood that a patient with symptomatic pulmonary TB will remain untreated and hence infectious for a longer period of time, which in turn increases the incidence of TB in LMICs.

Current Approaches to Prevention and Control

TB control programs exist in almost all LMICs, although enormous variability exists in terms of the resources at those countries' disposal and their effectiveness. The current approach to controlling TB in LMICs is based on a strategy of rapid detection of and provision of effective multidrug therapy to all infectious persons (i.e., patients with pulmonary TB, particularly smear-positive patients).

Since 1995, a key component of WHO recommendations has been directly observed treatment, short-course (DOTS), which involves the use of a standardized multidrug short-course regimen, with direct observation of drug ingestion for at least the first two months of treatment. In 2014, WHO adopted the End TB Strategy (**TABLE 6-4**), which includes three key pillars:

- Integrated patient-centered care and prevention
- Bold policies and supportive systems
- Intensified research and innovation (WHO, 2014b)

In the face of the limited resources available to ensure prompt diagnosis and treatment of infectious cases of TB among those who present spontaneously to health facilities, there has been an understandable reluctance in LMICs to devote scarce resources to actively searching for other cases in the households of affected individuals or in the community. Similarly, prophylactic treatment of latent TB infection in the general population has not been considered a high priority or an effective use of limited resources. In addition, the use of a single drug, such as isoniazid, to reduce the likelihood of TB in individuals infected with *M. tuberculosis* (as practiced in a number of high-income countries) has raised the specter of inadvertent single-drug therapy of patients with unrecognized TB and resultant promotion of the development of drug-resistant strains of *M. tuberculosis.* However, preventive therapy is effective in preventing TB among HIV-infected individuals in LMICs (Whalen et al., 1997). Thus, WHO recommends isoniazid preventive treatment for HIV-positive persons living in areas with a high prevalence of *M. tuberculosis* infection (i.e., where more than 30% of the population has latent *M. tuberculosis* infection) and for those with latent *M. tuberculosis* infection or exposure to an infectious case of pulmonary TB.

TABLE 6-4 Post-2015 Global Tuberculosis Strategy Framework

Vision	■ A world free of TB ■ Zero deaths, disease, and suffering due to TB
Goal	End the global TB epidemic
Milestones for 2025	■ 75% reduction in TB deaths (compared to 2015) ■ 50% reduction in TB incidence rate (fewer than 55 TB cases per 100,000 population) ■ No affected families facing catastrophic costs due to TB
Targets for 2035	■ 95% reduction in TB deaths (compared with 2015) ■ 90% reduction in TB incidence rate (approximately 10 TB cases per 100,000 population) ■ No affected families facing catastrophic costs due to TB

Principles

1. Government stewardship and accountability, with monitoring and evaluation
2. Strong coalition with civil society organizations and communities
3. Protection and promotion of human rights, ethics, and equity
4. Adaptation of the strategy and targets at the country level, with global collaboration

Pillars and Components

1. Integrated, patient-centered care and prevention
   A. Early diagnosis of TB, including universal drug-susceptibility testing and systematic screening of contacts and high-risk groups
   B. Treatment of all people with TB, including those with drug-resistant TB, and patient support
   C. Collaborative TB/HIV activities and management of comorbidities
   D. Preventive treatment of persons at high risk and vaccination against TB
2. Bold policies and supportive systems
   A. Political commitment, with adequate resources for TB care and prevention
   B. Engagement of communities, civil society organizations, and public and private care providers
   C. Universal health coverage policy and regulatory frameworks for case notification, vital registration, quality and rational use of medicines, and infection control
   D. Social protection, poverty alleviation, and actions on other determinants of TB
3. Intensified research and innovation
   A. Discovery, development, and rapid uptake of new tools, interventions, and strategies
   B. Research to optimize implementation and impact and promote innovations

Immunization at birth with BCG is a standard part of the EPI in every LMIC, and BCG coverage is high in almost every such country. Infant immunization with BCG appears to be quite effective at reducing the risk of disseminated TB (e.g., tuberculous meningitis) in infants and children, but the vaccine's efficacy against pulmonary TB in this age group is probably no better than 50% to 60%. Infant immunization with BCG probably has, at best, only a modest effect on the risk of developing pulmonary TB as an adult; consequently, it has little or no impact on the spread of *M. tuberculosis* in the community.

Obstacles to Prevention and Control and Directions for Future Research

The rapid growth of multidrug-resistant TB (MDR-TB; i.e., TB resistant to the first-line anti-TB drugs isoniazid and rifampicin) and the emergence of extremely drug-resistant TB (XDR-TB; i.e., TB resistant to isoniazid, rifampicin, fluoroquinolones, and kanamycin, capreomycin, or amikacin) have complicated TB control efforts. Both MDR-TB and XDR-TB require lengthy treatment with second-line drugs, which are both more expensive and more toxic than the first-line drugs. Although WHO supports universal access to treatment of drug-resistant TB, scaling up of treatment availability is not always possible, due to lack of laboratory capacity to diagnose the drug-resistant form of the disease and lack of funds for both capacity building and treatment. Capacity to detect MDR-TB, however, has been greatly enhanced with the rollout of Xpert MTB/RIF.

Both the numbers of deaths and the incidence rate of TB have declined since 2000. At present, the principal obstacles to reducing TB-related morbidity and mortality in LMICs are economic and operational in nature. Increased financial and technical assistance will be needed in many countries to ensure that currently available strategies for controlling TB are fully implemented.

At the same time, further research is needed in multiple areas if control of TB is to be achieved and sustained. Development of new drugs that are effective against *M. tuberculosis*, affordable and safe, and able to clear the infection with a shorter duration of treatment is a high priority, and many candidates are currently in the development pipeline. Similarly, development of a vaccine against *M. tuberculosis* that can prevent pulmonary TB is a high priority, with more than a dozen candidate vaccines currently in clinical trials. To support the development of an effective vaccine, more research is needed to establish immunologic correlate(s) of protection, and there is a great need for a human challenge model to help with the evaluation of vaccine candidates.

Leprosy

Etiologic Agent, Clinical Features, and Vaccine Characteristics

M. leprae cannot be grown on artificial media. In research laboratories, it can be isolated and propagated in the foot pad of a mouse or in armadillos, but these techniques have no relevance to diagnosing

leprosy. Thus, the diagnosis of leprosy is made on clinical grounds, together with histopathologic examination of tissue biopsy material. *M. leprae* grows even more slowly than *M. tuberculosis*. Its slow growth is highly relevant to the control and prevention of leprosy because of the consequent need to treat those who are infected for prolonged periods of time (months to years) and the resulting difficulty of ensuring compliance with antimicrobial therapy long after the individual feels well.

Descriptive Epidemiologic Features and Risk Factors

Although it is clear that prolonged, close contact (e.g., living in the same household) with someone with untreated leprosy—and particularly with someone having a high burden of organisms (i.e., multibacillary leprosy)—is associated with a substantially increased risk of acquiring the disease, the routes of transmission are ill defined. It is assumed that transmission occurs primarily through skin-to-skin contact or exposure to respiratory tract (e.g., nasal) secretions. Environmental or animal reservoirs of *M. leprae* are thought to have little or no role in human infections. The exceedingly long incubation period for leprosy, which is believed to be years to decades, makes any study of transmission very difficult.

Leprosy is primarily a disease of poverty. Even within a single relatively homogeneous community, it is disproportionately seen among the lowest-income members. In the past, leprosy has often been described as being more common in rural than in urban populations and as having an association with proximity to water (e.g., lakes) or humidity. Even so, clear differences in the prevalence of leprosy between neighboring communities are not well explained.

In the mid-1980s, the number of cases of leprosy worldwide was estimated to be between 10 and 12 million. The incidence of leprosy was 4 to 6 cases per 1,000 population, and the prevalence in affected countries often exceeded 10 individuals per 1,000 population. By 1998, control efforts had reduced the number of prevalent cases by more than 90%, to an estimated 829,000 cases worldwide (WHO, 1998b). This decline has continued, with WHO (2016d) reporting that there were 211,973 newly detected cases in 2015.

Although leprosy previously existed throughout the world, and a handful of individuals living in high-income countries such as the United States still develop leprosy each year (a few of whom have never traveled outside the United States), leprosy is now largely confined to a shrinking number of countries. In 2015, 14 countries accounted for 94% of new cases (WHO, 2016d).

Current Approaches to Prevention and Control

Early attempts to control leprosy were based on case finding and prolonged (i.e., multiyear) or lifetime treatment with dapsone, which had the advantages of being inexpensive and having few side effects. However, this approach failed to control leprosy, at least in part because *M. leprae* developed resistance to dapsone and because it was difficult to ensure ongoing patient compliance with treatment over many years.

In the early 1980s, multidrug treatment with two or three effective antimicrobial agents (depending on the stage of leprosy) was introduced and has produced a greater than 90% reduction in leprosy cases. WHO had set a goal of eliminating leprosy as a public health problem (i.e., achieving a prevalence of 1 case or fewer per 10,000) by the year 2000; that goal was met at the global level in 2000, but has not yet been met at the country level. Further progress in reducing leprosy burden has been hampered by reduced funding for treatment and control efforts. In addition, use of disease prevalence as an indicator of program success was recognized as problematic due to the lengthy incubation period of leprosy. Currently, progress is monitored using the annual number of new cases diagnosed.

In a renewed effort to combat this disease in 2015, WHO adopted the Global Leprosy Strategy, 2016–2020. Its goal is to further reduce the global and local leprosy burden through early detection of cases and prompt treatment to reduce disability and transmission (WHO, 2016d, 2016e).

Obstacles to Prevention and Control and Directions for Future Research

Because of its extremely long incubation period and the fact that infected individuals may transmit *M. leprae* for substantial periods of time prior to becoming symptomatic and receiving treatment, it is likely that incident cases of leprosy will continue to occur in substantial numbers for years to come, even if the current leprosy control strategies substantially reduce transmission (Meima, Smith, van Oortmarassen, Richardus, & Habbema, 2004).

The role, if any, for a vaccine in the immunotherapy or the prevention of leprosy remains uncertain. Numerous studies—both experimental and observational in nature—have suggested that BCG vaccine, which is given primarily to prevent various

forms of disseminated TB in children, offers some protection against leprosy. A meta-analysis performed in 2006 showed an overall protective effect of 61% in observational studies and an overall protective effect of 26% in experimental studies, providing further evidence that BCG is modestly effective against leprosy, and that two doses of BCG are more effective against leprosy than a single dose (Setia, Steinmaus, Ho, & Rutherford, 2006). Whether other candidate mycobacterial vaccines will offer even greater protection than BCG remains uncertain, as does their role, if any, in leprosy control.

Sexually Transmitted Infections and AIDS

Overview

Sexually transmitted infections have historically been one of the most neglected areas of medicine and public health in LMICs. Until the advent of the HIV/AIDS epidemic in the 1980s, remarkably little attention was paid to STIs in such countries, despite the fact that they collectively cause enormous morbidity, loss of productivity, and infertility, and result in substantial healthcare expenditures. The fact that human immunodeficiency virus—the cause of AIDS and all its attendant morbidity and mortality—is transmitted sexually, together with the fact that the sexual transmission of HIV is facilitated by the presence of other STIs, has focused attention on and brought an infusion of resources (albeit still inadequate) into this long-neglected area.

The myriad challenges confronting the treatment and control of STIs in LMICs are multifaceted and complex. Among the most daunting are the difficulty of changing human sexual behavior; the asymptomatic nature of many STIs, particularly among women; the lack of simple, inexpensive diagnostic tests for such infections; and the lack of readily accessible, inexpensive, easy-to-administer, single-dose treatment regimens for most STIs.

Etiologic Agents

A variety of viruses and bacteria can be transmitted sexually (**TABLE 6-5**), including some (e.g., HBV) that are not traditionally grouped with other STIs. In this chapter, HBV is discussed with the other viruses that cause hepatitis. Many infectious agents that are transmitted sexually can also be transmitted via contaminated blood or injection equipment, and vertically from a mother to her newborn infant.

Of the infectious agents transmitted sexually, some initially cause ulcerative lesions, primarily on or near the genitalia (e.g., *Herpes simplex, Treponema pallidum*, and *Haemophilus ducreyi*), others initially cause urethral or vaginal discharge (e.g., *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Trichomonas vaginalis*), and others cause only systemic manifestations (e.g., HIV). HPV, selected subtypes of which cause genital warts, plays an important role in the pathogenesis of cervical dysplasia and carcinoma, as well as in carcinoma of the anus, penis, and the head and neck, but HPV infections are initially silent. Asymptomatic or minimally symptomatic infection with many of the sexually transmitted agents is common, greatly exacerbating the problem of interrupting transmission and reducing the prevalence and incidence of infection.

Many of the agents transmitted sexually produce not only acute symptoms referable to the lower genital tract, but also other, often more serious manifestations. For example, untreated infections with *N. gonorrhoeae* and *C. trachomatis* can ascend through the genital tract and produce pelvic inflammatory disease, tubal infertility, and ectopic pregnancy. Untreated primary syphilis in young adults can lead to life-threatening cardiac and neurologic complications due to tertiary syphilis years later. In addition, congenital syphilis—the result of infection of a baby at the time of birth—produces profound systemic manifestations. As noted earlier, infection with HPV of selected subtypes is strongly associated with subsequent cervical dysplasia and cervical cancer, as well as other cancers. Finally, HIV causes profound damage to the host immune system and a virtually 100% case fatality ratio in the absence of treatment with antiretroviral drug regimens.

Descriptive Epidemiologic Features and Risk Factors

Data concerning the incidence of STIs in LMICs are considered highly unreliable due to substantial underdiagnosis and underreporting. According to one estimate, 357 million new adult cases of curable STIs (e.g., gonorrhea, chlamydia, syphilis, and trichomoniasis) occurred worldwide in 2012, the vast majority of which were in LMICs (**FIGURE 6-6**) (Newman et al., 2015).

Although difficult to estimate, the prevalence of viral STIs, including infections involving Herpes simplex type 2 (HSV2), HPV, and HIV, is high. In 2012, there were an estimated 417 million people infected with HSV2 and 291 million women with HPV infections (WHO, 2016f). The passive surveillance for AIDS in place in most LMICs is also not

TABLE 6-5 Sexually Transmitted Infections of Importance in Low- and Middle-Income Countries

Agent	Disease	Vertical Transmission to Newborn Babies	Transmission by Blood Products
Bacteria			
Treponema pallidum	Syphilis	Yes	Yes
Neisseria gonorrhoeae	Gonorrhea, pelvic inflammatory disease	Yes	Yes
Chlamydia trachomatis	Cervicitis, urethritis, lymphogranuloma venereum, pelvic inflammatory disease	Yes	No
Haemophilus ducreyi	Chancroid	No	No
Viruses			
Human immunodeficiency virus (HIV)	AIDS	Yes	Yes
Herpes simplex	Genital herpes	Yes	No
Human papillomavirus (HPV)	Genital warts, cervical dysplasia and cervical carcinoma, penile and anal carcinomas, and head and neck cancers	Yes	No
Hepatitis B virus[a]	Acute and chronic hepatitis, cirrhosis, and hepatocellular carcinoma	Yes	Yes
Other			
Trichomonas vaginalis	Vaginitis	No	No

[a] Discussed in the section on viral hepatitis.

very sensitive or specific, making it necessary to estimate the prevalence of HIV infection and the incidence of AIDS cases. The most recent estimate is that there were 36.7 million persons in the world living with HIV/AIDS in 2016, including 1.8 million people who became infected in that year (UNAIDS, 2017a). Sub-Saharan Africa continues to have the highest burden, with 70% of all people living with HIV residing there and nearly two-thirds of new infections occurring there (**FIGURE 6-7**) (UNAIDS, 2016a; WHO, 2016g). An estimated 35 million people had died of AIDS since the beginning of the epidemic and 14 million children had been orphaned (UNAIDS, 2016a, 2017a). The vast majority of AIDS-related deaths have occurred in LMICs, particularly sub-Saharan Africa.

The prevalence of various STIs, particularly HIV, has been investigated in many LMICs. The groups typically examined are those who can be studied easily and inexpensively, such as commercial sex workers, patients being treated for STIs or TB, injection-drug users, pregnant women or women giving birth, and blood donors. The prevalence of HIV infection among commercial sex workers is up to 10 times greater than the prevalence among the general population (UNAIDS, 2017b). Encouragingly, the prevalence of HIV infection among pregnant women in sub-Saharan Africa decreased

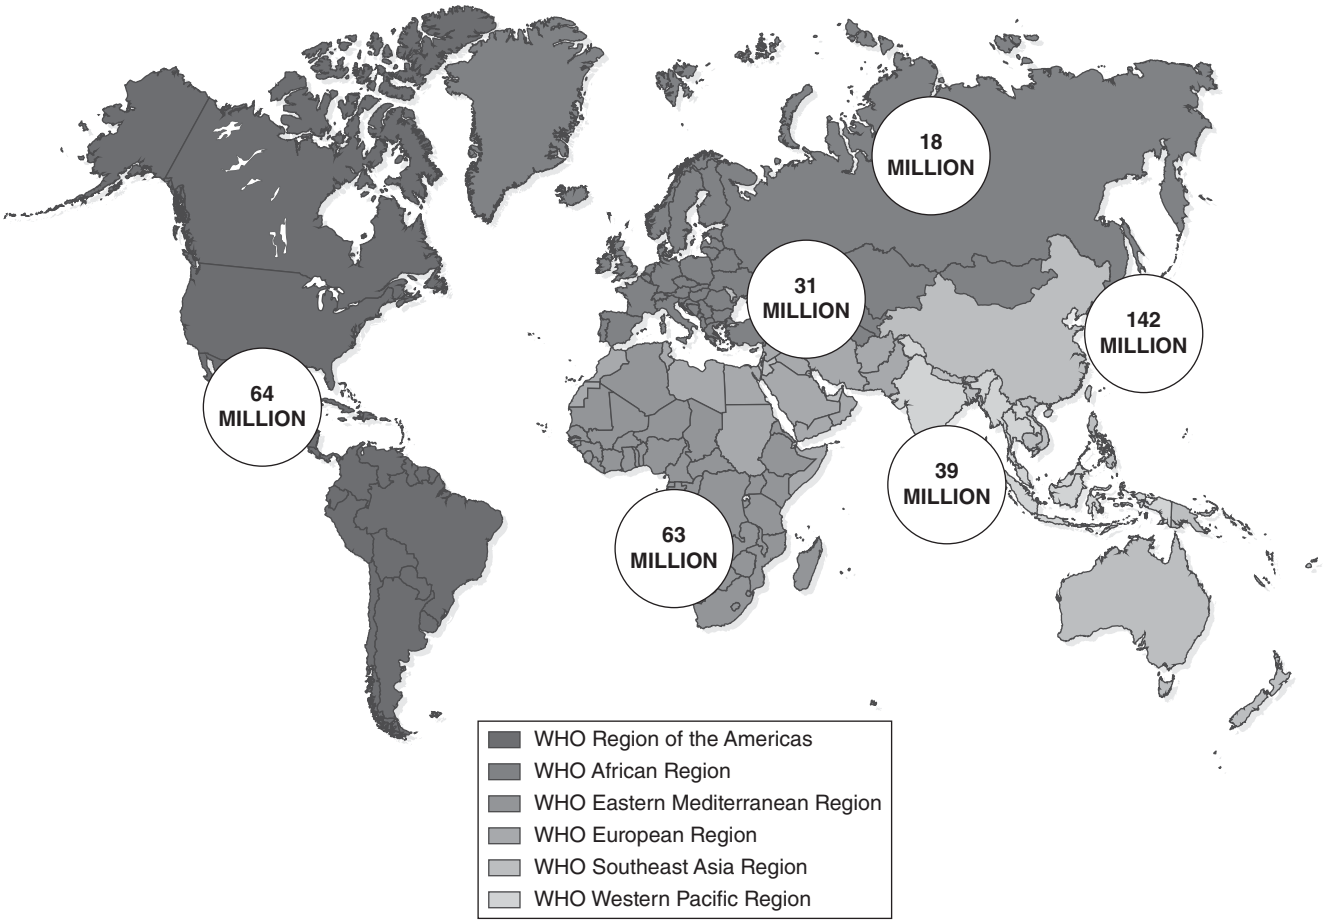

FIGURE 6-6 Estimated new cases of curable STIs, 2012.

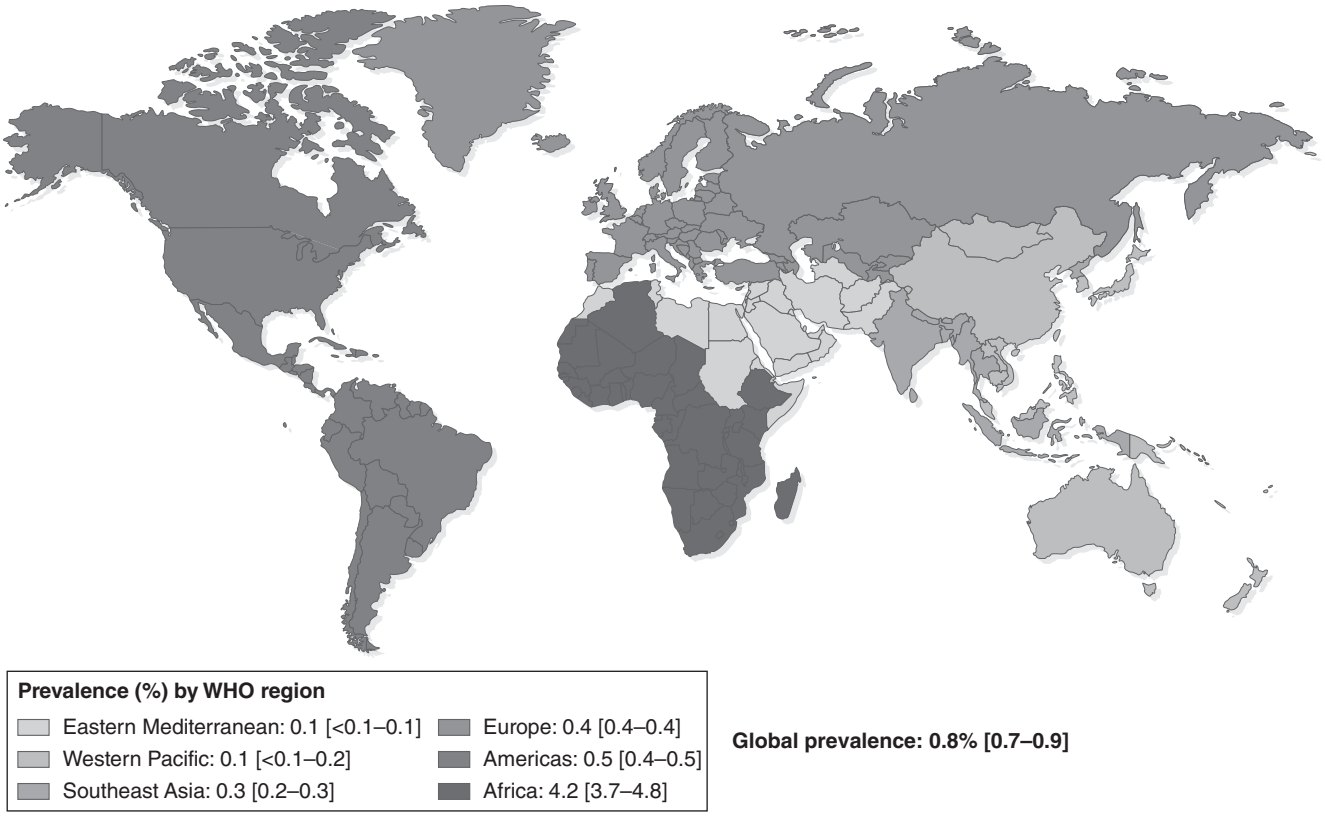
Reprinted from World Health Organization. (2016). Global health sector strategy on sexually transmitted infections 2016–2021. http://apps.who.int/iris/bitstream/10665/246296/1/WHO-RHR-16.09-eng.pdf?ua=1

by 18% between 2003 and 2012 (Eaton et al., 2014); however, high prevalence of HIV infection is still seen in pregnant women in the worst-affected areas of sub-Saharan Africa. Because an estimated 15% to 45% of untreated HIV-infected pregnant women will transmit the virus to their newborn babies at or soon after delivery, large numbers of HIV-infected infants are also found wherever many women of reproductive age are infected. The result of widespread HIV infection among men and women of reproductive age and among infants in the most severely affected countries, in the absence of antiretroviral treatment (ART), was a reversal of prior gains in life expectancy, increases in infant and child mortality, an enormous increase in the number of orphaned children, and projected future declines in population size. However, better access to ART dramatically reduced the number of HIV-infected infants and led a 48% reduction in AIDS-related deaths globally between 2005 and 2016 (UNAIDS, 2016b, 2017a).

Given that the etiologic agents under discussion are transmitted through sexual contact, it is not surprising that the highest incidence and prevalence of these infections are seen among those men and women who are most sexually active, typically those 15 to 49 years of age. In addition, the most important risk factors for STIs—number of sexual partners, concurrency of sexual partnerships, type of sexual partners, and whether barrier protection (e.g., a male condom) is used—are directly or indirectly related to the likelihood of exposure to one of these etiologic agents. Thus, individuals with large numbers of sexual partners (e.g., commercial sex workers) who do not use barrier protection and those who have unprotected sex with such individuals, as well as those with multiple concurrent sexual partners, are at highest risk. In societies in which it is considered acceptable for men to frequent commercial sex workers or have multiple concurrent sexual partners while women are expected to have a single partner, many married women acquire STIs from their husbands. Other risk factors for STIs, including HIV, have also been demonstrated, such as lack of male circumcision.

It is important to note the complex interplay between HIV infection and other STIs. There is strong evidence that infection with both ulcerative



The boundaries and names shown and the designations used on this map do not imply the expression of any opinion whatsoever on the part of the world health organization concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries. Dotted and dashed lines on maps represent approximate border lines for which there may not yet be full agreement.

FIGURE 6-7 HIV prevalence in adults (15–49 years of age) by WHO region, 2016.

Reprinted from World Health Organization. (2017). Prevalence of HIV among adults ages 15 to 49, 2016 by WHO region. http://www.who.int/gho/hiv/hiv_013.jpg?ua=1

and non-ulcerative STIs increases the likelihood of HIV being transmitted sexually between partners, either through the presence of disrupted mucosa or due to the presence in the genital tract of increased numbers of inflammatory cells and lymphocytes that can bind HIV.

Current Approaches to Prevention and Control

The current approach to the prevention and control of STIs, including HIV, focuses on improving the availability of and access to high-quality diagnostic and treatment services (especially in the case of HIV/AIDS), changing sexual practices through education and health promotion, increasing the availability and use of barrier methods that reduce transmission (e.g., male and female condoms), encouraging male circumcision, shortening the time between the onset of symptoms and the seeking of appropriate care, reducing the stigma attached to STIs, and improving surveillance. Not surprisingly, given the enormous cultural diversity that exists around the world, the approaches to delivery of risk-reduction messages (e.g., school-based programs, billboards, and radio), the groups that are targeted (e.g., the entire population; individuals of reproductive age; school-age children; or high-risk groups, such as commercial sex workers, migrant workers, truck drivers, and adolescent girls), and the messages that are delivered (e.g., abstinence before marriage, monogamy, and condom use) have varied greatly. Additionally, while voluntary medical male circumcision has proved to be effective in reducing the acquisition of a number of STIs, including HIV, and could substantially reduce HIV transmission, scaling up the delivery of male circumcision remains a challenge for a number of reasons (Tobian, Kacker, & Quinn, 2014; WHO, 2016h).

Because the laboratory facilities and trained staff needed to identify a specific etiologic agent in a given patient with a suspected STI are often lacking in many LMICs, WHO (1991) has developed and promoted a

syndromic approach to the management of STIs. This approach relies on classifying patients with a suspected STI into various groups depending on their symptoms and findings on physical examination (e.g., women with a vaginal discharge, men with urethral discharge and dysuria, and patients with genital ulcer) and then treating them with a regimen designed to cover the treatable etiologic agents that are likely to be responsible (e.g., *N. gonorrhoeae* and *C. trachomatis* when a cervical or urethral discharge is present). **EXHIBIT 6-4** provides an example of this approach.

The finding that an intensive (and relatively expensive) regimen of AZT (zidovudine) given to HIV-infected pregnant women in the United States substantially reduced vertical transmission of HIV to their newborn babies led to trials of simpler and less expensive AZT regimens in Thailand and the Ivory Coast. These trials showed that even these simpler regimens, which are given entirely by mouth and for a shorter period of time, were partially effective in reducing vertical transmission of HIV. As a consequence, this regimen was made available in many LMICs (Shaffer et al., 1999; Wiktor et al., 1999). Since that time, recommendations for the prevention of mother-to-child transmission of HIV have rapidly evolved. In 2015, WHO released recommendations that all HIV-infected pregnant and breastfeeding women receive ART.

For many years, the prohibitive cost of antiretroviral drugs meant that the implementation of wide-scale AIDS treatment programs in LMICs such as those of sub-Saharan Africa was unthinkable. As a result, fewer than 10% of people in LMICs who needed ART had access to it in 2003. However, the introduction of generic competition in the global antiretroviral market precipitated spectacular decreases in the costs of these drugs, making it conceivable to include ART in the effort to reduce HIV-associated morbidity and avert early mortality for all affected groups. Efforts to expand access to ART, including the WHO's 3 by 5 initiative (a plan to treat 3 million people with ART by 2005); the establishment of the Global Fund to Fight HIV/AIDS, Tuberculosis, and Malaria; and the U.S. President's Emergency Plan for AIDS Relief (PEPFAR), which initially sought to treat 2 million people in selected LMICs, are now bearing fruit. In 2016, an estimated 20.9 million HIV-positive people were receiving ART (UNAIDS, 2017a). In hard-hit areas, such as eastern and southern Africa, the number of people on ART has nearly doubled since 2010 (UNAIDS, 2016b). Studies have demonstrated substantial declines in mortality among HIV-infected adults in LMICs resulting from such efforts (Jahn et al., 2008; Mermin et al., 2008), but substantial expansion of these programs is still needed to meet the needs of all HIV-infected persons who could benefit from such treatment.

Obstacles to Prevention and Control and Directions for Future Research

Enormous obstacles to changing sexual behaviors exist, although progress was clearly made in reducing the frequency of high-risk sexual behaviors and the incidence of HIV infection in Thailand (**EXHIBIT 6-5**) (Celentano et al., 1996; Nelson et al., 1996; Rojanapithayakorn & Hanenberg, 1996) and Uganda (Kilian et al., 1999) in response to the AIDS epidemic. In many societies, it remains socially

EXHIBIT 6-4 Syndromic Management of Genital Ulcer

A study in Lesotho illustrates the promise and drawbacks of the syndromic approach (Htun et al., 1998). In an attempt to validate STI flowcharts for the management of genital ulcer, researchers found that syndromic protocols would have provided adequate treatment for at least 90% of their patient population, while the traditional, clinically directed protocol would have provided adequate treatment for only 62% of those same patients. At the same time, syndromic protocols would have led to the overtreatment of primary syphilis in approximately 60% of patients, while the clinically directed protocols would not have resulted in any such overtreatment.

Several similar studies have shown that syndromic case management of STIs using flowcharts often leads to both improved treatment in many patients and overtreatment in some patients. In general, to determine the appropriateness of implementing the syndromic approach in a given region, the costs of overtreatment (including the cost of the drugs themselves), the risk of promoting drug resistance, and the stigma of an STI diagnosis (which can lead to domestic violence against women) must be weighed against the benefits of improved treatment, including reductions in STI and HIV transmission, decreases in sequelae from untreated infections, and increased patient satisfaction. In view of the high prevalence of STIs in many LMICs, this tradeoff is often considered acceptable.

EXHIBIT 6-5 A Successful Public Health Program: The Declining Spread of HIV Among Thai Military Conscripts

In the late 1980s, heterosexual commercial sex was found to contribute significantly to the rapid spread of HIV in Thailand. Thai authorities responded swiftly to this observation and implemented public health programs that substantially increased the number of commercial sex acts protected by condoms, which in turn led to significant reductions in the rate of HIV infection among young men in Thailand. This case study tells the story of this public health success.

The first national serosurvey for HIV conducted in Thailand found that HIV was exceedingly common among commercial sex workers. In June 1989, 44% of sex workers in the northern province of Chiang Mai were positive for HIV, a figure that would climb to 67% by June 1993 (Celentano et al., 1996). Commercial sex in Thailand was relatively common; for example, in the period from 1991 to 1993, more than 70% of Thai military conscripts were found to have engaged in at least one commercial sex act during their period of service. Because military conscripts are selected by a national lottery, these findings were applicable to the general population of young men in Thailand; thus, commercial sex was believed to be a common source of HIV infection.

To address this situation, Thai authorities implemented an HIV/AIDS prevention and control program that included the 100% Condom Campaign to promote condom use in commercial sex establishments. Under this campaign, free condoms were distributed to all sex establishments and the use of condoms was actively enforced by Thai authorities. The campaign was accompanied by mass advertising to promote condom use during commercial sex.

In the years following the initiation of the condom campaign, the use of condoms in sex establishments increased dramatically. National behavioral surveillance data revealed that the percentage of commercial sex acts in which condoms were used rose from approximately 14% in the years prior to 1989 to more than 90% by 1993 (Rojanapithayakorn & Hanenberg, 1996). Although the prevalence of HIV among sex workers remained high, the prevalence among newly inducted military conscripts declined from more than 10% in 1991 and 1993 to approximately 7% in 1995 (Nelson et al., 1996) and to 0.5% in 2009 (Rangsin et al., 2015). Further, this decline occurred in the absence of a visible AIDS epidemic (Rojanapithayakorn & Hanenberg, 1996). Experts attribute these heartening findings at least in part to the swift implementation of the Thai HIV/AIDS prevention and control program, and especially to the success of the 100% Condom Campaign.

acceptable—even desirable—for men to visit commercial sex workers and have multiple concurrent sex partners. Many men do not want to use condoms, and a woman may risk physical abuse, rejection, or loss of financial support if she tries to insist that a condom be used by her husband, boyfriend, or customer. Women who learn they are infected with HIV also risk abandonment or abuse if they share this information. Thus, changing sexual behaviors requires the education of men as well as women, and reducing the incidence of STIs, including HIV, requires raising the status and improving the power of women in society. Similarly, economic and other practices that contribute to or promote risky sexual behaviors (e.g., forcing men to live apart from their wives so that they can earn a living wage) need to be addressed.

Prevention of HIV infection in adolescent girls and women in sub-Saharan Africa is particularly challenging. Sub-Saharan African girls and young women (age 14–25) are being infected at two to four times the rate of boys and young men of the same age group (Shisana et al., 2014; UNAIDS, 2014), likely as the result of complex social, behavioral, and biological factors. Sexual relationships with older men have been shown to be a key risk factor for acquisition of HIV infection in women of this age group (Schaefer et al., 2017). Older men not only have a higher prevalence of HIV infection than younger men, but relationships between older men and young women also often cross socioeconomic strata. Such a power differential leaves these women in a poor position to negotiate condom use and may result in forced sex.

The global rise in antibiotic-resistant gonorrhea is complicating treatment of this once relatively easily treatable STI. Indeed, there is now widespread resistance to ciprofloxacin, once the first-line drug of choice, and increasing resistance to azithromycin and ceftriaxone (Wi et al., 2017). In 2016, WHO began recommending that azithromycin and ceftriaxone be used together as a first-line treatment of gonorrhea in an attempt to slow or prevent the emergence of strains resistant to all available antibiotics. More research is urgently needed to develop new antibiotics to treat gonorrhea (and other bacterial infections) and to make available rapid, point-of-care diagnostic tests, ideally ones that also detect antimicrobial resistance.

Vaccines against STIs, and particularly against HIV, are needed but have proved difficult to develop. Vaccines against HPV have been shown to be highly effective in preventing infection and cervical dysplasia caused by HPV types 16 and 18 and five other HPV genotypes that together cause approximately 90% of cervical cancer cases worldwide; it is expected that cervical cancer caused by these types will also be

prevented by use of the same vaccines (Castle & Maza, 2016; Chatterjee, 2014). However, it will be decades before declines in cervical cancer attributable to these vaccines will become apparent.

The development of vaccines against HIV has been beset by many problems, and there is continuing disagreement about which type of vaccine (i.e., inactivated whole virus, subunit, genetically engineered, live, attenuated, and so on) is likely to be safe and effective. Trials of a subunit HIV vaccine begun in the United States and Thailand in 1998–1999 showed that this vaccine was not effective in preventing acquisition of HIV infection (Cohen, 2003). To date, the only trial of an HIV vaccine to show any efficacy was a study in Thailand that showed at best a modest level of protection (Rerks-Ngarm et al., 2009). Although the vaccine had only modest efficacy, the trial did prove useful in increasing knowledge about the correlates of protection, and this knowledge has been used in designing subsequent candidate HIV vaccine evaluations. In 2016, a large efficacy trial of an HIV vaccine regimen began in South Africa, with results expected in 2020.

In the absence of vaccines against HIV and other STIs (other than HPV), other approaches to reducing morbidity and mortality beyond primary prevention of infection through behavior change are needed. For example, while women in high-income countries generally have access to regular screening for cervical dysplasia, which has been shown to be a highly effective tool for the secondary prevention of invasive cervical cancer, such programs are not available to most women in LMICs because of the cost and the need for moderately sophisticated laboratory support. In LMICs, the "see and treat" approach, which involves visual inspection of the cervix using acetic acid, is typically used, as it is less costly and invasive than a PAP smear and can be done in low-resource settings. However, scaling up this approach has proved difficult, leading to the exploration of other methods, such as primary screening for the presence of high-risk HPV types, as well as other methods, such as self-collection of samples, to make screening more culturally acceptable. Cervical cancer screening will continue to play an important role in cervical cancer prevention for years to come, despite the introduction of HPV vaccines.

As noted earlier, universal access to antiretroviral therapy to treat HIV infection in LMICs has become a top priority for international public health policy makers, not only to reduce morbidity and mortality among those already infected, but also because evidence shows that wide-scale treatment can reduce transmission of HIV at the population level (i.e., "treatment as prevention"). Although significant advances have been made in expanding access to ART, numerous challenges remain on this front. The current programs are not yet reaching many of those already infected with HIV, and large disparities in access to ART remain to be addressed. Thus, in the absence of an effective HIV vaccine, new approaches to identifying those at risk, reducing stigma, and assuring treatment are needed and will still play an important role once an HIV vaccine does become available.

Viral Hepatitis

Overview

Hepatitis, which entails inflammation of the liver, can be caused by many different viruses (as well as bacteria, protozoa, chemical agents, and some noninfectious diseases). However, at least five viruses specifically infect the liver—hepatitis viruses A, B, C, D, and E. Each belongs to a different family and has unique epidemiologic features, necessitating diverse approaches to control and prevention of hepatitis.

Viral hepatitis is a major global public health problem. All five primary hepatitis viruses can cause acute disease. HBV, HCV, and hepatitis D virus (HDV) can also produce chronic infection. In many LMICs, such persistent infections are the primary cause of serious liver disease, including chronic hepatitis, cirrhosis, and hepatocellular carcinoma; the last is a common cancer that is almost always fatal. Globally, an estimated 1.4 million deaths are attributable to acute and chronic infection with HBV and HCV (WHO, 2016i). In total, an estimated 240 million people are chronically infected with HBV and 130 to150 million people are chronically infected with HCV (WHO, 2016i).

Hepatitis A virus (HAV) and hepatitis E virus (HEV) cause acute self-limited disease; they do not cause chronic infection. Transmitted by the fecal–oral route, these viruses are endemic in many LMICs with suboptimal environmental sanitation. HAV infections are typically asymptomatic when they occur in infants. In older children and adults, they generally produce a self-limited illness that leads to few deaths. HEV infection results in more substantial morbidity and mortality, particularly when it occurs in pregnant women.

Etiologic Agents

The five primary hepatitis viruses (A, B, C, D, and E) account for almost all cases of viral hepatitis. Although other viruses (e.g., Epstein-Barr virus and cytomegalovirus) occasionally cause inflammation

of the liver, infections with these viruses do not principally involve the liver. GB virus C (formerly called hepatitis G virus) does not appear to cause liver disease (Bowden, 2001). The following discussion is limited to the five primary hepatitis viruses.

Descriptive Epidemiologic Features and Risk Factors

The prevalence of chronic HBV infection is moderate to high throughout LMICs. The highest prevalence of HBV infection is seen in East Asia and sub-Saharan Africa, with 6% of the adult population being chronically infected with this virus (WHO, 2017m). High prevalence and incidence of HBV infection are also seen in the Amazon Basin and the southern regions of central and eastern Europe. In these areas, most people who acquire HBV do so at the time of birth (through vertical transmission from an infected mother). Most such infections produce no acute clinical manifestations, but the likelihood of chronic infection and the risk of progression to chronic liver disease increase significantly as the age of acquisition of HBV decreases.

The most common routes of HBV transmission in LMICs are perinatally (from mother to child) and horizontally (from one child to another). Transmission of HBV through the use of nonsterile needles for medical injections is also thought to be significant. Less frequent modes of transmission of HBV in LMICs include sexual intercourse and needle sharing among injection drug users, the two principal modes of transmission in high-income and some middle-income countries. Additionally, practices such as tattooing, scarification, circumcision, body piercing, and acupuncture with nonsterile instruments can spread HBV.

HDV is a replication-defective virus, so that HDV infection can be acquired only in the presence of HBV infection. The distribution of HDV infection varies markedly by region, but it generally corresponds to the distribution of HBV infection, although some interesting exceptions to this pattern exist. For example, HDV infections are relatively rare in East and Southeast Asia, even though the prevalence of HBV infection in these regions is high (Margolis, Alter, & Hadler, 1997). The primary mode of transmission of HDV is through percutaneous exposure to blood, as may occur through the use of nonsterile needles and syringes for medical injections and the transfusion of unscreened blood. Perinatal and sexual transmission of HDV can occur, albeit infrequently.

HCV infection is widespread throughout the world. Although HCV is not as infectious as HBV, HCV infection is much more likely to become chronic; in fact, 55% to 85% of HCV-infected persons become chronically infected (WHO, 2017d). The prevalence of HCV infection varies by WHO region, with a majority of regions having a prevalence among adults ranging from 0.5% to 1.0%; a higher prevalence is seen in the WHO Eastern Mediterranean and European regions—2.3% and 1.5%, respectively. The principal modes of transmission of HCV in LMICs are believed to be the reuse of needles and syringes for medical injections, needle sharing among injection-drug users, and the transfusion of unscreened blood. HCV also can be spread perinatally and sexually, although transmission by these means is less common.

HAV infection is endemic in most LMICs. The primary mode of transmission of this virus is via the fecal–oral route, through either person-to-person contact or the ingestion of contaminated food or water. In areas with poor sanitation, HAV infection is essentially universal during the first few years of life, producing lifelong immunity. As sanitation improves, individuals are more likely to escape exposure to HAV in childhood. If they are infected as teenagers or adults, the clinical manifestations can to be more severe, albeit self-limited. Fatalities from HAV hepatitis are uncommon.

HEV is also endemic in many LMICs, where it causes substantial morbidity and mortality. HEV infection can be particularly deadly among pregnant women, with case fatality ratios approaching 30% among women infected during their last trimester (Jaiswal, Jain, Naik, Soni, & Chitnis, 2001; Khuroo, Teli, Skidmore, Sofi, & Khuroo, 1981). In endemic areas, HEV can produce cyclic, sometimes large outbreaks, as well as sporadic cases of hepatitis. HEV, like HAV, is acquired through the fecal–oral route, principally through ingestion of contaminated water. Person-to-person transmission of HEV can occur but is rare.

Current Approaches to Prevention and Control

A safe and effective vaccine for HBV has been available since 1982. In the early 1990s, WHO recommended integrating the HBV vaccine into the national immunization programs of all countries by 1997. In 2004, WHO further recommended that all infants receive a first dose of HBV vaccine as soon as possible following birth, with the goal being that all children would receive the vaccine within 24 hours of birth. This first dose is to be followed by two or three additional doses to complete the HBV vaccine series. As of 2015, an

estimated 84% of infants globally received three doses of HBV vaccine; however, coverage for receipt of the first dose of vaccine within 24 was lower, at only 39% (WHO, 2017m). Vaccination of older children and adults is given lower priority, with recommendations based on the epidemiologic features of HBV in the country, as well as vaccination levels in children.

Chronic HBV infection can be treated with interferon or antiviral drugs such as entecavir or tenofovir. With the advent of more effective drugs with limited side effects, as well as evidence that treatment can prevent liver failure and hepatocellular carcinoma, there have been calls for treatment to be provided to HBV-infected individuals in LMICs (Thursz, Cooke, & Hall, 2010).

Vaccination against HBV infection is also effective in preventing HDV coinfection. (As noted earlier, HDV infection requires the presence of HBV.) However, additional strategies are needed to prevent HDV superinfection among chronic carriers of HBV. Because there is no vaccine against HDV per se, the prevention of such superinfections depends on reducing percutaneous exposures to blood in medical and nonmedical settings among those persons who are chronically infected with HBV.

There is no vaccine against HCV at this time, and combating viral hepatitis has not historically been a high priority. However, with the adoption of the Sustainable Development Goals, viral hepatitis has been given high priority. WHO released its first global strategy for viral hepatitis in 2016 (WHO, 2016i). Treatment of chronic HCV infection has been rapidly evolving, with the current preferred treatment regimens including sofosbuvir, daclatasvir, and sofosbuvir/ledipasvir in combination. These regimens, which have remarkably few side effects and an excellent safety profile, can provide cure rates as high as 95%, a dramatic increase over previous regimens, which cleared the virus in only approximately 40% of patients. However, the prices of these drugs must be reduced substantially if large numbers of individuals in LMICs are to gain access to them.

Interrupting the transmission of HCV is also an important component of the strategy to decrease the prevalence of HCV infection globally. WHO (2017d) recommends the following measures to prevent HCV (and HBV) infection:

- Hand hygiene, including surgical hand preparation, hand washing, and use of gloves
- Safe and appropriate use of healthcare injections
- Safe handling and disposal of sharps and waste
- Provision of comprehensive harm-reduction services to people who inject drugs, including sterile injecting equipment
- Testing of donated blood for hepatitis B and C (as well as HIV and syphilis)
- Training of health personnel
- Promotion of correct and consistent use of condoms (WHO, 2017d)

The epidemiologic features of HAV infection vary by region and degree of sanitation, necessitating diverse approaches and control measures aimed at this virus. An effective vaccine against HAV is available and can be useful in controlling the periodic outbreaks among older children and adults that occur in areas of low endemicity. Although traditionally given as a two-dose series, the vaccine has been shown to be highly effective when only one dose is given to healthy individuals. However, this vaccine is licensed for use only in children age 1 year or older. In most LMICs, HAV infection is highly endemic and typically acquired during infancy and early childhood, when it produces little morbidity or mortality. Consequently, the prevention of HAV infection in LMICs through the use of HAV vaccine has not been a priority.

A vaccine for HEV has been developed and licensed in China, but is not currently available in other countries. Improved environmental sanitation—especially the provision of clean drinking water—remains the best strategy for preventing HEV infections.

Obstacles to Prevention and Control and Directions for Future Research

Preventing HBV and HCV infections remains a major global public health goal. Universal coverage with the HBV vaccine can dramatically reduce the incidence of HBV infection and serious liver disease and represents the best hope for decreasing the acute and delayed morbidity and mortality caused by this virus. Unfortunately, the cost of supplying and distributing this relatively inexpensive vaccine in settings that have many competing needs remains a significant barrier to achieving universal immunization. Depending on their cost, combined vaccines may help alleviate this difficulty in the future. However, giving the first dose of the vaccine within 24 hours of birth is difficult to achieve in many LMICs, especially where many births occur at home.

Many obstacles to preventing HBV and HCV infection through means other than vaccination exist. In spite of the existence of an efficacious HBV vaccine and an effective drug regimen for curing HCV infection, without a major expansion of current public health interventions, the number of people living with chronic HBV infection is expected to remain at high levels for the next four to five decades, while the

number of people living with chronic HCV infection is expected to increase. Nevertheless, given both tools that are currently available and those in the development pipeline, control of the viral hepatitis epidemic is possible. Control will require an investment in and expansion of interventions to provide vaccines for viral hepatitis, prevent mother-to-child transmission, increase the use of universal precautions, provide comprehensive care packages to injection drug users, and provide treatment to chronically infected individuals.

Malaria and Other Arthropod-Borne Diseases

Overview

Blood-sucking arthropods—including mosquitoes, flies, bugs, fleas, mites, and ticks—are efficient vectors for a host of pathogenic protozoa, bacteria, viruses, and worms that cause tremendous suffering and death around the world. Transmitted by mosquitoes, malaria is undoubtedly the most important parasitic disease in tropical regions of LMICs. Malaria caused an estimated 429,000 deaths in 2015, primarily among African children (WHO, 2016j). Mosquitoes also transmit dengue fever (an estimated 390 million infections per year; WHO, 2017l), Zika, yellow fever, filariasis, chikungunya, and Japanese encephalitis, while various other arthropods spread trypanosomiasis, leishmaniasis, onchocerciasis (river blindness), and plague, to name but a few arthropod-borne diseases. The public health importance of arthropod-borne diseases can scarcely be overstated: They contribute substantially to morbidity and mortality in affected countries and significantly retard social, economic, and developmental progress in those regions. The 2015–2016 Zika virus and 2013–2015 chikungunya pandemics demonstrate that emerging arthropod-borne diseases will continue to be a threat worldwide.

Etiologic Agents and Clinical Features

As noted earlier, arthropod-borne diseases are caused by a wide variety of pathogens. This section limits its discussion to malaria, dengue fever, yellow fever, Zika, American trypanosomiasis, and African trypanosomiasis. Note, however, that many of the prevention and control issues discussed in the context of these diseases are applicable to other arthropod-borne diseases. Onchocerciasis is discussed in the section on infectious causes of blindness.

Malaria is a febrile disease caused by five species of the parasitic *Plasmodium* protozoa: *P. malariae, P. falciparum, P. vivax, P. ovale,* and *P. knowlesi*. Dengue is caused by the four dengue viruses, which produce a spectrum of disease ranging from undifferentiated fever; to classic dengue fever, which is self-limiting and rarely fatal; to dengue hemorrhagic fever, which is characterized by plasma leakage and hemorrhage that can progress to shock and death. Yellow fever is caused by a virus of the same name; it is characterized by fever and, in severe cases, hemorrhage, jaundice, and liver and kidney involvement. Zika is caused by a cousin of the dengue and yellow fever viruses, Zika virus. It generally produces a mild, self-limited illness; however, in pregnant women, infection can lead to severe birth defects or loss of the pregnancy. In addition, Zika virus infection can lead to neurologic problems in adults, including Guillain-Barré syndrome and encephalitis.

American trypanosomiasis (Chagas disease) is caused by the protozoan parasite *Trypanosoma cruzi*. Acute infections are usually mild, but approximately one-third of infected individuals develop more severe chronic manifestations after several years of asymptomatic infection, including gastrointestinal tract damage, neurologic involvement, and cardiac damage leading to heart failure.

African trypanosomiasis (also known as sleeping sickness) is caused by two subspecies of the protozoan parasite *Trypanosoma brucei*—namely, *T.b.* rhodesiense and *T.b.* gambiense. Individuals infected with *T.b.* rhodesiense develop symptoms within weeks to months, whereas those infected with *T.b.* gambiense develop symptoms over a period of months to years. In both cases, the disease follows a course of central nervous system derangement, coma, and certain death if left untreated.

Descriptive Epidemiologic Features and Risk Factors

Although malaria is found in 91 countries around the world, more than 90% of cases occur in Africa (WHO, 2016j). The parasite is transmitted between humans (who serve as the reservoir) by the female *Anopheles* mosquito. In endemic areas, where transmission is constant, individuals who survive gradually develop immunity to severe disease. As a consequence, young children (who have not yet developed immunity) and pregnant women (who have depressed immune function) experience the highest rates of malaria morbidity and mortality. Susceptible individuals who enter endemic areas (e.g., migrant laborers, displaced persons, and travelers) are also at risk. Of the five species of malaria parasite, *P. falciparum* causes the most severe disease, with *P. vivax, P. malariae,* and *P. ovale*

causing milder forms of illness. Evidence suggests that infection with *P. knowlesi* may be more widely distributed than initially thought, as well as more severe, with approximately 1 out of 10 patients developing life-threatening disease (Cox-Singh et al., 2008; Daneshvar et al., 2009).

As many as 3.9 billion people live in areas where they are at risk for dengue virus infection, resulting in an estimated 390 million infections each year, of which 96 million present with clinically apparent dengue infection (Bhatt et al., 2013; Brady et al., 2012). Major epidemics of severe dengue have largely been limited to South and Southeast Asia and Latin America, whereas epidemics of dengue fever are more widespread.

Four dengue virus serotypes exist, all of which produce the same spectrum of clinical disease. Infection with one serotype produces lifelong immunity to that serotype, but confers only transient cross-protection against the others. Preexisting antibodies, resulting from either a prior infection with another dengue serotype or transfer to infants of maternal dengue antibodies, are a risk factor for developing severe disease. In addition, viral virulence factors are thought to influence the clinical outcome of infection. Dengue viruses have an urban or peri-urban transmission cycle (human–mosquito–human) in which the mosquitoes *Aedes aegypti* and *Aedes albopictus* are the principal vectors. Frequently, multiple dengue virus serotypes cocirculate in endemic urban cycles that periodically erupt in widespread epidemics (Gubler, 1998). A rural transmission cycle is also possible, but is less important from the public health perspective.

Yellow fever virus is endemic in 34 countries in sub-Saharan Africa and 13 countries in South America (WHO, 2018b). A recent modeling study estimated that the burden of yellow fever in 2013 in Africa, where a majority of the cases are seen, was 130,000 severe cases with 78,000 deaths (Garske et al., 2014). Yellow fever has an urban transmission cycle in which mosquitoes (typically *A. aegypti*) transmit the yellow fever virus between humans. Major epidemics of yellow fever occur when the virus is acquired by the urban vector and introduced to susceptible populations. Yellow fever also follows sylvatic and rural transmission cycles.

American trypanosomiasis (Chagas disease) occurs mainly in the Americas and is an important public health problem in Latin America, where it is estimated that 6 to 77 million persons are infected with *T. cruzi* (WHO, 2017e). Historically, *T. cruzi* has been (and continues to be) endemic in rural areas, where a variety of wild and domestic animals serve as reservoirs for the parasite. This parasite is transmitted to humans by the bite of triatomine bugs, which infest houses built with materials that shelter the bugs (e.g., thatched roofs or cracked mud walls). In recent decades, rural migration has introduced the disease to urban areas, where *T. cruzi* then spreads via transfusion of infected blood. Congenital infection also occurs. Despite these alternative transmission routes, the triatomine vector remains the most important source of infection.

African trypanosomiasis is found exclusively in sub-Saharan Africa, where the disease occurs in rural, endemic pockets in 36 countries. In recent years, control efforts have led to a massive reduction in the number of new cases, with an estimated 50,000 to 70,000 cases in 2006 declining to 2,804 reported cases in 2015 (WHO, 2017f). Although African trypanosomiasis was nearly eliminated by the early 1960s, its incidence soared in the following decades, and devastating epidemics occurred in the wake of civil disturbance, war, and population movements. Recently, a dramatic reduction in incidence and associated mortality has been achieved through improved case finding and treatment. The parasite that causes African trypanosomiasis, *T. brucei*, is transmitted to humans by the bite of the tsetse fly. Cattle and wild animals are the major reservoirs for *T.b.* rhodesiense, which is found in eastern and southern Africa, whereas humans are the major reservoir for *T.b.* gambiense, which is found in western and central Africa.

Current Approaches to Prevention and Control

The historical context of the current malaria control strategy is helpful in understanding how approaches to prevention and control evolve over time (Trigg & Kondrachine, 1998). In the 1950s, malaria prevention programs focused on parasite eradication through the use of antimalarial drugs (e.g., chloroquine) to eliminate human infection and reduce the parasite reservoir, and on residual insecticides (e.g., dichlorodiphenyltrichloroethane [DDT]) to interrupt malarial transmission via its mosquito vector. By the late 1960s, the incidence of malaria had been greatly reduced in areas that implemented these programs, including Latin America and tropical Asia. These improvements proved unsustainable, however—in part because of the rigidity of the eradication program, which was vertically structured and failed to consider regional differences in malaria epidemiology and public health infrastructure. Malaria resurged in the following decades (along with other mosquito-borne diseases, including dengue fever and yellow fever) as vector-control programs were not sustained.

Global malaria eradication was declared a failure and abandoned.

In the early 1990s, the international community identified malaria as a leading public health priority (again) and began to formulate new strategies for its control. In 1998, the Roll Back Malaria (RBM) Partnership was established to coordinate an international effort to reduce the global burden of malaria—the first such campaign in more than three decades. By 2009, thousands of organizations throughout the world were participating in RBM. The discovery of artemisinin and the development of artemisinin-based combination treatments (ACTs), which can be mass-produced relatively inexpensively and are highly effective against malaria parasites that have developed resistance to chloroquine and sulfadoxine–pyrimethamine, resulted in WHO recommending these agents as the first-line treatment for *P. falciparum* infection. A resultant increase in the deployment of ACTs has led to enhanced control of malaria.

In 2008, RBM released the Global Malaria Action Plan, which used a number of key tools, including long-lasting insecticide–treated bed nets, indoor residual spraying, intermittent preventive treatment during pregnancy, other vector-control strategies, improved diagnosis, and prompt provision of treatment. As a result, the incidence of malaria was reduced by 41% between 2000 and 2015. In 2015, the WHA adopted the Global Technical Strategy for Malaria 2016–2030 (GTS), with the goals of reducing the incidence of malaria by 90% by 2030 compared to the 2015 incidence, eliminating malaria from 35 countries where it was endemic in 2015, and preventing the reestablishment of malaria in malaria-free countries.

Currently, there is no licensed malaria vaccine, although several are currently under development. The most promising malaria vaccine to date is RTS,S, an adjuvanted recombinant vaccine that has been shown to reduce clinical malaria cases by 26% following a three-dose primary series and 39% when a fourth dose is administered 18 months after the primary series (RTS,S Clinical Trials Partnership, 2015). Vaccine efficacy waned following the fourth dose, however, so additional booster doses may be necessary to provide long-term protection. Pilot studies of such regimens are set to begin in a number of countries in Africa in 2018.

There is no specific treatment for dengue fever or dengue hemorrhagic fever beyond attentive clinical management. In 2015, Dengvaxia, a tetravalent vaccine for dengue virus, was licensed. In 2016, WHO recommended that countries highly endemic for dengue consider introducing this vaccine. By the end of that year, seven countries had approved use of Dengvaxia. Unfortunately, this vaccine is of limited use in the control of dengue, as it is currently licensed only for children aged 9 years and older and adults, due to its low efficacy in sero-naïve individuals. In addition, the efficacy of the vaccine is lower against dengue virus serotype 2. Five additional dengue vaccine candidates were under development in 2017, including two that are in Phase III clinical trials. Until an efficacious vaccine that protects against all four serotypes is widely used, the control and prevention of dengue fever will largely depend on mosquito control, disease surveillance, and epidemic preparedness. A key component of the control of *Aedes* mosquitos is source reduction through elimination of mosquito breeding sites.

Immunization is the most important prevention measure against yellow fever. The yellow fever vaccine, designated as 17D, is safe, effective, and affordable; it requires only a single dose to provide multiple-year, likely lifelong protection. To prevent and control yellow fever in endemic areas, WHO (1998c) recommends routine infant immunization against yellow fever (within the EPI), mass immunization campaigns (e.g., preventive catch-up campaigns), vigilant case and vector surveillance, reactive immunization to contain outbreaks, and careful management of the vaccine supply. Since 2004, WHO has maintained a stockpile of approximately 6 million doses of yellow fever vaccine for emergency response, though this supply may not be enough if several concomitant large outbreaks occur. In response to the large-scale outbreaks in Angola and Democratic Republic of the Congo in 2016, the global stockpile was increased; however, the global supply has been stretched to keep up with increased demand.

For American trypanosomiasis (Chagas disease), it is currently recommended that all acute infections be treated, as well as chronic infections in children. A mounting body of evidence suggests that treatment of all chronic infections may reduce the severity of illness; however, the drugs used in the treatment of acute manifestations (benznidazole and nifurtimox) are toxic, so treatment of chronic infections in adults depends on each individual's health status. Prevention and control of American trypanosomiasis currently focus on interrupting vector-related transmission and preventing transmission via the transfusion of infected blood. Vector-control efforts center on eradicating strictly domestic triatomine bugs and controlling domestic infestations of other (sylvatic) triatomine bugs, predominantly through indoor residual insecticide spraying in areas at high risk for American trypanosomiasis. The prevention

of transfusion-related transmission is accomplished by screening all blood donors for *T. cruzi* antibodies and rejecting blood donations that test positive. The results of these efforts are encouraging, with the global burden of American trypanosomiasis having dropped substantially since the 1990s.

In 2007, WHO launched the WHO Global Network for Chagas Elimination, with the goal of eliminating American trypanosomiasis by 2010. That goal was not met, and, the past decade has seen spread of Chagas disease into areas previously considered non-endemic. In addition to the previously mentioned control measures, the WHO network is working to increase surveillance and access to diagnosis and treatment, as well as to develop new treatments and improved diagnostic tests.

The current strategy for the control and prevention of African trypanosomiasis caused by *T.b.* gambiense involves active case finding and early treatment, which reduces the human reservoir by curing the infection. Passive surveillance for *T.b.* gambiense infection is problematic because infected individuals are often infectious for months to years before they develop symptoms that lead to (passive) detection. In contrast, passive surveillance and epidemic preparedness are often adequate to control the transmission of *T.b.* rhodesiense, which quickly leads to symptoms of infection. The drugs used to treat African trypanosomiasis have significant drawbacks, including high levels of toxicity. The first-stage drugs, pentamidine and suramin, and second-stage drugs, melarsoprol and eflornithine, are provided by WHO to countries in which this disease is endemic.

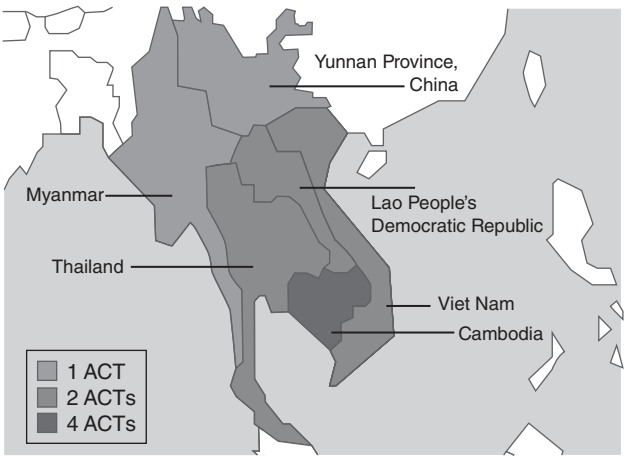
Obstacles to Prevention and Control and Directions for Future Research

Insecticide resistance presents a major challenge to prevention strategies based on vector control. Vectors for malaria, dengue, and yellow fever have all developed resistance to multiple insecticides, including both the classic insecticides (e.g., DDT) and their replacements (e.g., organophosphates). Alternative insecticides have been developed but are often more costly and toxic than the first-line agents. The dynamic ecology of vector-borne pathogens is an additional barrier to effective vector control. For example, changing land-use patterns, shifting weather patterns, urbanization, and population movements may result in new foci for disease transmission. Moreover, national and international travel and commerce present continuing opportunities for reinfestation, necessitating continuous surveillance, even in areas that have achieved good vector control.

Drug resistance poses a serious problem for control strategies that rely on chemotherapy to treat disease and subsequently decrease transmission through the reduction of parasite load in humans. Nowhere is this problem more evident than in the history of the management of malaria. Drugs that once provided inexpensive and effective means of antimalarial prophylaxis and therapy became severely compromised by resistance in many parts of the world, resulting in substantially increased morbidity and mortality. The discovery and use of ACTs, in combination with other interventions, has resulted in a renewed ability to control malaria—but resistance to ACTs was first detected in Cambodia in 2008 and has spread since that time (**FIGURE 6-8**). In addition, sporadic reports of ACT-resistant malaria continue to crop up, making careful monitoring to detect drug resistance essential for continued success.

Other barriers to the prevention and control of arthropod-borne diseases include the intermittent disruption of public health services as a consequence of civil disturbance or war and the ever-present problem of limited resources. Problems include the difficulty of sustaining support for successful control measures (e.g., indoor insecticide spraying to control the vector-borne spread of American trypanosomiasis) once the disease has been brought under control and, therefore, is no longer a public health priority.

Future prospects for the improved prevention of arthropod-borne disease rest primarily on vaccine development. Current research is focused on developing additional tetravalent dengue fever vaccines and vaccines against malaria and Zika virus.



ACT, artemisinin - based combination therapy

Helminthiasis

Overview

Approximately 1.5 billion people are believed to be chronically infected with parasitic helminths (WHO, 2017g). The vast majority of these individuals live in LMICs, where environmental sanitation is poor. Each parasite produces different manifestations, depending on the site, intensity, and length of infection. The host response also influences the clinical course of infection. In general, children experience the heaviest worm burden, and persistent infection throughout childhood is common in LMICs. Heavy, prolonged infection adversely affects growth, development, and educational achievement, and significantly increases childhood morbidity. In adults, helminthiases can produce acute and chronic morbidity, leading to impaired productivity, chronic disability, and reduced quality of life.

In terms of global prevalence, morbidity, and mortality, the most important helminthic infections are schistosomiasis (207 million infections), ascariasis (807 million to 1.2 billion infections), trichuriasis (800 million infections), hookworm (576 to 740 million infections), onchocerciasis (26 million infections), and lymphatic filariasis (120 million infections) (CDC, 2013, 2017, 2018; WHO, 2017h). Although many of these infections are minimally symptomatic, the number of clinically significant cases is substantial. This section focuses on schistosomiasis and the most common intestinal helminthiases—that is, ascariasis, trichuriasis, and hookworm. Dracunculiasis, a disease of considerable historical importance, is also considered.

Etiologic Agents and Clinical Features

Human schistosomiasis (also known as bilharziasis) is caused by a group of blood trematodes (flukes) known as schistosomes. The three main species that infect humans are *Schistosoma mansoni, Schistosoma japonicum,* and *Schistosoma haematobium*. Two other species, *Schistosoma mekongi* and *Schistosoma intercalatum*, also parasitize humans, but such infections are uncommon and will not be discussed further. Acute schistosomiasis (Katayama fever) is characterized by fever and chills, abdominal pain, diarrhea, and enlargement of the spleen or other organs. Infection with *S. japonicum* is most commonly associated with acute disease, although any type of schistosomiasis can cause these findings. Chronic disease is initiated by the deposition of schistosome eggs in the body, which induces inflammation and scarring. Chronic infection with *S. mansoni* or *S. japonicum* can lead to hepatosplenic and intestinal involvement, although most infected individuals remain asymptomatic. Chronic infection with *S. haematobium* is associated with urinary tract disease, and a much higher proportion (50% to 70%) of infected individuals are symptomatic (WHO, 1993). *S. haematobium* infection is also associated with an increased risk of bladder cancer.

The most common intestinal helminthiases of humans are caused by *Ascaris lumbricoides*, *Trichuris trichiura* (whipworm), and two species of hookworm, *Ancylostoma duodenale* and *Necator americanus*. These parasites produce a diverse range of clinical manifestations, although persons with light infections generally remain asymptomatic. When worm burdens are high, *A. lumbricoides* infection is associated with malnutrition and stunted growth. *A. lumbricoides* is also the largest of the intestinal helminths, measuring 15 to 35 centimeters in length; thus, single worms can cause obstruction and inflammation of the appendix, bile duct, or pancreatic duct, and a bolus of worms can cause intestinal obstruction leading to death. Trichuriasis is associated with abdominal pain, diarrhea, and general malaise when moderate worm loads are present, whereas nutritional deficiencies, anemia, and stunted growth can result from heavier worm loads. Hookworms attach to the intestinal mucosa leading to chronic blood loss (Hotez et al., 2006). The major clinical manifestations of hookworm infection are iron-deficiency anemia and hypoalbuminemia.

Dracunculiasis is caused by *Dracunculus medinensis* (Guinea worm), a long (60 to 90 centimeters), thin nematode. Symptoms of the disease are caused by the migration of the worm to the subcutaneous tissues and its eruption through the skin. Clinical manifestations can include the formation of a blister or bleb at the site where the worm will emerge (usually the ankle or foot), hives, nausea, vomiting, diarrhea, and asthma. The blister ulcerates as the worm emerges, and local pain typically persists until the worm is expelled or extracted, which can take several weeks. Secondary infection of the worm track is common. Severe disability generally lasting one to three months occurs in most persons who become infected, with 0.5% of infected individuals experiencing permanent disability (Hunter, 1996). Even short-term disability can have a substantial economic impact if the worm emerges during the months when important agricultural work is performed (Hopkins, 1984).

Descriptive Epidemiologic Features and Risk Factors

Schistosomiasis is the single most important helminthic disease and the second most important parasitic disease (after malaria) worldwide. An estimated 218 million persons in 78 countries and territories harbor this infection, resulting in an estimated 3.3 million disability-adjusted life-years (DALYs) lost each year (Hotez et al., 2014; WHO, 2017h). *S. mansoni*, the most widespread of the schistosomes, is found in parts of Africa, the Middle East, the Caribbean, and South America; *S. haematobium* is restricted to Africa and the Middle East; and *S. japonicum* is currently found only in the Western Pacific countries. Overall, the vast majority of people requiring treatment for schistosome infections (90%) reside in sub-Saharan Africa (WHO, 2017h).

The life cycle of the schistosome is quite complex, and a complete description is beyond the scope of this chapter. Nevertheless, a brief discussion is necessary to understand how infection plays out in human hosts. Adult worms live, mate, and deposit their eggs in the blood vessels lining the human intestines (*S. mansoni* and *S. japonicum*) or bladder (*S. haematobium*). These eggs migrate into the intestine or bladder and are passed out in the excreta. When deposited in fresh water, the eggs develop into immature parasites (miracidia) that infect fresh-water snails. The immature parasites then develop into infective larvae (cercariae). When released into the surrounding water, the larvae swim about. Those coming in contact with humans during this time penetrate through the skin and eventually reach the vascular system, completing the cycle. Thus, the maintenance of schistosomes in a given area requires the presence of the intermediate host, the contamination of water with egg-laden excreta, and the exposure of humans to contaminated water.

Because schistosomes do not multiply in the human host, the intensity of infection is largely determined by the rate at which new worms are acquired. Studies have shown that the infection rate for schistosomes typically peaks during childhood and then declines with advancing age (Butterworth, Dunne, Fulford, Ouma, & Sturrock, 1996; Hagan, 1996). This finding is thought to reflect age-dependent changes in both water exposure and immunity to infection.

The public health impact of intestinal helminthiases on LMICs is substantial. As noted earlier, *A. lumbricoides*, *T. trichiura*, and hookworm each infect 740 million to 1.2 billion individuals globally (CDC, 2013, 2017, 2018). Although the morbidity and mortality associated with intestinal helminthiases are relatively low, the burden of illness is considerable due to the extremely high prevalence of these infections (WHO, 2017g).

A. lumbricoides, T. trichiura, and hookworm share a relatively simple life cycle. The parasites mature and mate in the human intestine and produce eggs that are passed out in the feces. When deposited on moist soil, these eggs develop into the infective form of the parasite. (Because this part of the life cycle is spent in soil, these worms are collectively referred to as geohelminths.) Humans acquire the parasite when contaminated soil is ingested or, in the case of hookworm, when the infective larvae in the soil penetrate exposed skin. Thus, the maintenance of these helminths requires the deposition of feces in soil and the exposure of humans to that soil. For *A. lumbricoides* and *T. trichiura*, the peak intensity of infection typically occurs among young children; in contrast, for hookworm, the peak occurs among adults (Bundy, Hall, Medley, & Savioli, 1992).

Dracunculiasis is contracted by drinking contaminated water. Parasitic larvae then migrate to the abdominal cavity, where they mature into adult worms over the course of a year. After copulation, the gravid female worm migrates through the body to the subcutaneous tissue and then secretes irritants that ulcerate the skin and expose the worm. When the affected body site is immersed in water, the worm expels clouds of larvae. The larvae are consumed by copepods (minute fresh-water crustaceans, also known as water fleas), which are in turn ingested by humans who drink contaminated water. Dracunculiasis occurs in individuals of all ages, but is less common in very young children, possibly because breastfeeding reduces their level of water consumption (Hunter, 1996).

A global campaign to eradicate dracunculiasis was launched in the 1980s as a part of the United Nations International Drinking Water Supply and Sanitation Decade (1981–1990). Since then, the incidence of this disease has declined from 4 million reported cases in 1981 (Hopkins, Ruiz-Tiben, & Ruebush, 1997) to 25 confirmed cases in 2016 (WHO, 2017i). Endemic disease is now confined to just three African countries, and dracunculiasis is likely to be the next disease that is eradicated.

Current Approaches to Prevention and Control

The major strategies to control helminthic infections focus on preventive chemotherapy, environmental sanitation and health education, and control or eradication of the intermediate host. No antihelminthic vaccines are currently available.

For the control of schistosomiasis and infection with geohelminths, WHO emphasizes controlling morbidity by reducing the intensity of infection (the number of worms per person) rather than reducing the prevalence of infection (the number of persons with worms). The former is achieved in the short term through regular deworming, despite reinfection, whereas the latter requires improved environmental sanitation, intermediate-host control (in the case of schistosomiasis, for example), or both, and is viewed as a long-term goal. WHO recommends preventive treatment for schistosomiasis, soil-transmitted helminthiases, lymphatic filariasis, and onchocerciasis. This approach is possible because safe, effective, and inexpensive oral treatments are available for these common helminthiases. Five neglected tropical diseases—schistosomiasis, lymphatic filariasis, onchocerciasis, soil-transmitted helminthiases, and trachoma—are currently controlled through an integrated approach to tailored preventive chemotherapy (**FIGURE 6-9**) (WHO, 2017j). In this approach, six drugs are used in differing combinations, depending on which diseases are present, to both treat infected individuals and reduce transmission in the communities. This approach has not only reduced morbidity, but also led to increased control and is contributing to elimination of these diseases. More than 1.5 billion people were in need of preventive chemotherapy for these diseases in 2015.

Ultimately, most helminthiases are diseases of poor sanitation. Providing for the sanitary disposal of human excreta prevents the contamination of soil and water, thereby breaking the chain of transmission. However, environmental improvements must be made at the community level to be effective. Improvements in environmental sanitation are complemented by health education to promote healthy behaviors. For example, WHO has determined that schistosomiasis could be largely prevented by eliminating indiscriminate urination and defecation, and increasing compliance with medical interventions (WHO, 1993).

Control of the intermediate host species for certain helminths, such as snail control for schistosomiasis, can also play an important role in preventing transmission. The primary strategies for snail control include application of molluscicidal agents and environmental management. Recent reviews have indicated that regular applications of molluscicides can significantly contribute to elimination efforts (King, Sutherland, & Bertsch, 2015; Sokolow et al., 2016). Control of the intermediate host plays a crucial role in preventing the transmission of dracunculiasis. Much of the success of the dracunculiasis eradication campaign has been achieved by teaching people to pour drinking water through a finely woven cloth or to use a small straw-like device to filter out the tiny fleas that carry the *Dracunculus* parasite. Chemical eradicants have also played a role.

Obstacles to Prevention and Control and Directions for Future Research

Major obstacles to the effective implementation of chemotherapy-based interventions are related to the logistical and financial difficulties of treating the large number of individuals in need. In addition, chemotherapy does not address the conditions that led to the

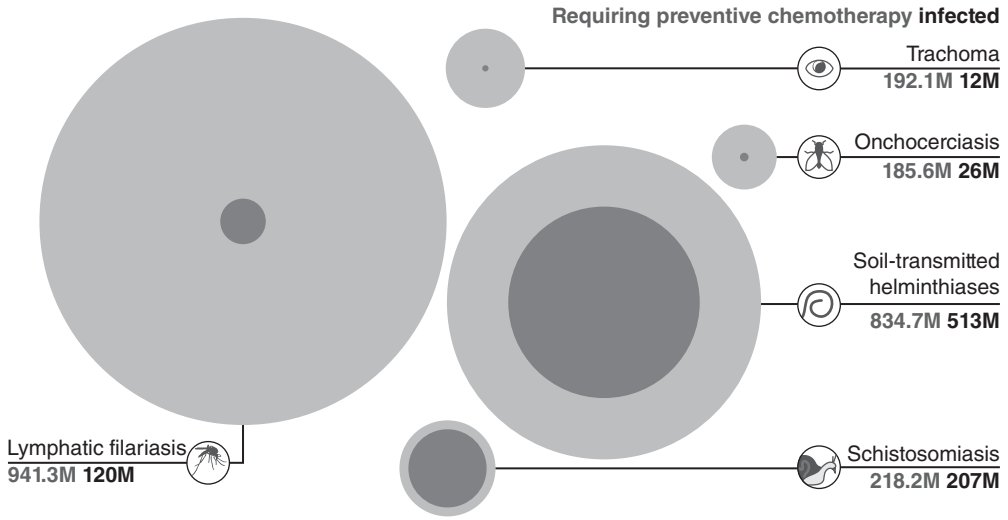

FIGURE 6-9 Five neglected tropical diseases amenable to preventive chemotherapy.

Reprinted from World Health Organization. (2017). *Crossing the Billion.* Geneva, Switzerland: Author.

primary infection; thus, reinfection is likely to occur, necessitating repeated treatments and further costs.

Adequate environmental sanitation is generally viewed as the only long-term solution to the control of intestinal helminthiases and schistosomiasis. However, providing safe drinking water and adequate disposal facilities in LMICs has proved to be an extremely difficult, costly, and lengthy process. Current control efforts emphasize targeted chemotherapeutic interventions to relieve the immediate burden of disease while maintaining universal sanitation as a long-term goal.

Although a massive reduction in the burden of illness caused by the *Dracunculus* parasite has been achieved, as with any disease, the last cases are the most difficult to find, particularly in areas with political instability or conflict. Furthermore, the recent finding of *D. medinensis* infection in dogs in endemic areas poses a major obstacle to achieving eradication. Further research is needed to understand risk factors for infection in dogs and the role of dogs in the transmission cycle.

Zoonoses

Overview

Zoonoses are defined as diseases and infections that are naturally transmitted between vertebrate animals and humans. Zoonotic agents include a wide variety of bacteria, viruses, protozoa, and helminths, while their nonhuman hosts include wild animals and birds, food and draft animals, and household pets.

More than 200 different zoonoses are currently recognized (Hart, Trees, & Duerden, 1997). Zoonotic infections have a worldwide distribution and collectively produce significant morbidity and mortality. For example, indigenous rabies, which has a global distribution, causes more than 59,000 deaths annually (WHO, 2017k). *Yersinia pestis*, the bacterium that causes plague, remains enzoonotic in many parts of Africa, Asia, and South America, and in the southwestern United States. Although only 3,248 cases of human plague were reported to WHO between 2010 and 2015, the control of human plague remains a public health priority because of its epidemic potential and relatively high case fatality ratio. In LMICs, important zoonoses include rabies, plague, anthrax, leptospirosis, leishmaniasis, African trypanosomiasis, and a number of hemorrhagic fever viruses. Foodborne zoonoses, such as salmonellosis, campylobacteriosis, and certain *E. coli* infections, also contribute to the global burden of disease, while occupational zoonoses such as brucellosis, echinococcosis, and Q fever have regional significance. Finally, zoonotic infections are a rich source of emerging diseases, such as severe acute respiratory syndrome (SARS), avian influenza in humans, Nipah virus encephalitis, variant Creutzfeldt-Jakob disease, and Ebola hemorrhagic fever.

Although zoonoses have a worldwide distribution, LMICs bear a greater burden of these diseases than high-income countries. This divergence reflects, in part, differences in opportunities for exposure to zoonotic pathogens. Residents of LMICs typically experience more frequent and intimate contact with animals, and they often live in situations of suboptimal environmental sanitation (which promotes exposure to infective material, such as contaminated animal excreta). In addition, many control measures that are readily available in high-income countries (e.g., mass veterinary vaccination of domesticated animals) may not be available or affordable in LMICs.

Zoonotic pathogens are transmitted to humans by five major routes:

1. Inhalation: Transmission occurs when infective materials are aerosolized and inhaled.
2. Ingestion: Transmission occurs when humans consume contaminated meat, milk, or blood from infected animals or when food-stuffs (e.g., fruits and vegetables), drinking water, or hands are contaminated with infective materials, which are then ingested.
3. Nontraumatic contact: Transmission typically occurs when pathogens enter through the skin (or mucosal surfaces or conjunctivae) as a result of direct or indirect contact with animal hides, hair, excreta, blood, or carcasses.
4. Traumatic contact: Transmission occurs via animal bites or scratches.
5. Arthropod: Transmission occurs by biting arthropods that feed on animals and humans.

For some zoonoses, humans are incidental, dead-end hosts. Human-to-human transmission of rabies or anthrax, for example, is extremely rare. For other zoonoses, humans may serve as a reservoir for infection, transmitting pathogens to other humans or even back to animals.

Zoonoses produce a wide variety of diseases with distinct clinical and epidemiologic characteristics. In addition, they are associated with many different animals occupying a number of ecologic niches, both urban and rural. Approaches to the control and prevention of zoonoses necessarily reflect these differences. The general principles underlying these strategies

often include good animal husbandry (including vaccination when appropriate), environmental sanitation, vector control, and the control or elimination of animal reservoirs (e.g., rats or other wild animals). The One Health approach recognizes the interplay of human health, animal health, and the environment, and encourages collaborative efforts across multiple disciplines to improve the health of all (see the *Public Health Infrastructure* chapter for more information on this approach).

Rather than attempting to survey the entire range of zoonoses, this section is limited to a detailed discussion of rabies and leptospirosis, which are important zoonoses in many LMICs.

Etiologic Agents and Clinical Features

Rabies is caused by the rabies virus, which is a Lyssa virus belonging to the Rhabdoviridae family. Typically transmitted by the bite of a rabid animal, human rabies is an acute, encephalitic disease that is almost always fatal. Following inoculation, there is an asymptomatic incubation period typically lasting one to three months, although periods as short as a few days and as long as several years have been reported (Fishbein, 1991). Post-exposure prophylaxis must be initiated during this period to be effective.

The prodromal period for rabies begins with the early signs of disease, which include nonspecific symptoms (e.g., fever and malaise) and abnormal sensations near the site of inoculation. This stage is followed by a 2- to 10-day period of acute neurologic dysfunction that manifests as furious rabies in approximately 80% of cases and paralytic (dumb) rabies in the remainder (Fishbein, 1991). Furious rabies is characterized by periods of extreme agitation and hyperactivity interspersed with periods of normalcy. Hydrophobia, aerophobia, combativeness, and hallucination may also occur. Features of paralytic rabies include paresthesias, weakness, and paralysis. The almost inevitable final stage of rabies (both furious and paralytic) is coma followed by death.

Leptospirosis is an acute febrile disease caused by pathogenic bacteria of the genus *Leptospira*. The clinical course of the disease is variable: The majority of infections are asymptomatic or result in mild disease, but 5% to 10% of persons who become infected will develop more severe manifestations, including kidney failure and pulmonary hemorrhage (Levett, 2001). Ocular involvement may occur as well.

Leptospira bacteria are classified serologically into 200 serovars arranged in 24 serogroups; alternatively, the organism may be classified genotypically into genomospecies (Vinetz, 2001). The serologic classification scheme is more frequently used in epidemiologic studies. Certain serovars were once thought to be associated with more severe disease, but evidence supporting this hypothesis is lacking (Levett, 2001; Vinetz, 2001).

Descriptive Epidemiologic Features and Risk Factors

Rabies is a disease of animals; humans are incidentally infected and only rarely transmit the virus. Animal reservoirs include dogs, cats, and wild animals (notably foxes, skunks, wolves, coyotes, raccoons, mongooses, and bats). Most human rabies cases are acquired from dogs, which are the source of more than 95% of fatal rabies infections in humans in LMICs. In countries where immunization of domestic animals is common, wild animals constitute the principal reservoirs of infection and human rabies is extremely rare.

Rabies virus is present in the saliva of infected animals and is typically transmitted to humans by the bite of a rabid animal. It may also be transmitted when intact mucous membranes are exposed to infective saliva. Not every exposure results in infection. Nevertheless, if infection occurs, it is almost always fatal in the absence of post-exposure prophylaxis.

Leptospirosis has a worldwide distribution, but its incidence is difficult to assess. In general, the incidence and prevalence of infection are low in high-income countries and higher in LMICs. For example, in some LMICs, prevalence of antibodies to leptospirosis in the range of 18% to 48% has been reported, suggesting that exposure to the causative organism is common in such settings (Ellis, 1998). As with rabies, human infection with *Leptospira* is incidental, and humans do not contribute to the transmission of the bacteria. The main animal reservoirs for *Leptospira* serovars that cause human disease are rats, dogs, pigs, and cattle.

Transmission of leptospires to humans typically occurs in one of two ways: (1) through contact with water that has been contaminated with the urine of infected animals or (2) through direct contact with infective animal urine. The bacteria infect humans by entering through broken skin, water-softened intact skin, mucosal surfaces, or conjunctivae. Human leptospirosis is an occupational disease among those whose professions involve contact with host animals (e.g., dairy farmers) or water (e.g., rice farmers). Home and recreational exposures are also becoming increasingly

important, particularly in LMICs. In addition, periodic flooding due to heavy rains can produce large epidemics of leptospirosis.

Current Approaches to Prevention and Control

The control of human rabies is achieved by the prevention of human exposure to the virus and the prevention of disease through post-exposure prophylaxis when exposure does occur. Historically, rabies vaccines were not deemed suitable (i.e., sufficiently inexpensive, safe, and effective) for mass pre-exposure immunization of humans. However, research is currently under way to gather evidence to support investment in rabies vaccination programs in Africa and Asia (WHO, 2017k).

The prevention of human exposure to rabies in LMICs primarily depends on the control of dog rabies, which can be achieved through the widespread use of the canine rabies vaccine. The mass vaccination of pet dogs and the elimination of stray or feral dogs has been successful in reducing human and dog rabies in many countries. For example, in the Americas, the incidence of human rabies was reduced by more than 95% and dog rabies was reduced by more than 98% between 1983 and 2016 (WHO, 2017k).

The prevention of human disease once exposure to rabies virus has occurred depends on good local wound care (e.g., flushing with soap and water) and post-exposure prophylaxis, which entails passive immunization with immunoglobulin and active immunization with the rabies vaccine. Although the complete post-exposure regimen almost always prevents disease, this regimen must be delivered during the incubation period: Neither immunization nor other treatments alter the course of disease once symptoms develop. There are no diagnostic tests that can detect rabies infection in humans prior to the onset of symptoms; thus, all individuals with suspected or possible infections must receive prophylactic treatment.

The prevention of human leptospirosis focuses on interrupting the transmission of leptospires to humans. Preventive measures include the vaccination of certain host animals (e.g., cattle) or the elimination of others (e.g., rats). Human vaccination has met with limited success and is not widely applied. Environmental control strategies aimed at reducing hazards such as stagnant bodies of water or the periodic flooding of residential areas, as well as educational campaigns aimed at decreasing unnecessary water exposures, may enhance prevention efforts. Occupational improvements that curtail contact with host animals or contaminated water are also desirable. Antibiotic therapy and supportive care remain the treatment of choice, although evidence supporting the effectiveness of antibiotic therapy is limited.

Obstacles to Prevention and Control and Directions for Future Research

The major obstacle to the improved control of rabies is the difficulty of achieving adequate vaccine coverage among dog populations in LMICs. At least 70% of the canine population must be vaccinated in endemic areas to control rabies. Ensuring the delivery of vaccine to stray and feral dogs (or eliminating these dogs altogether) is especially problematic. With sustained effort, WHO considers the global elimination of urban (canine) rabies to be an attainable goal.

The future control of leptospirosis is less promising. Animal vaccination may not be economically feasible for many farmers, and vaccines are not available or appropriate for every host species. The elimination of wildlife hosts (e.g., rats) is usually not feasible. Improvements in working and living conditions to reduce contact with animals and their excreta are desirable (for many reasons), yet difficult to achieve in LMICs. Until these difficulties are overcome, the control of leptospirosis must rely on health education to reduce risky behavior, veterinary education to promote good animal husbandry, and medical education to ensure the prompt diagnosis and treatment of leptospirosis.

Viral Hemorrhagic Fevers

Overview

The viruses that cause hemorrhagic fever (HF) belong to five different families (**TABLE 6-6**), and the illnesses they produce have distinct epidemiologic features. Despite their differences, these viruses produce a common clinical picture that is characterized by fever and hemorrhage, as their name suggests. Hemorrhagic manifestations can include petechiae, ecchymoses, bleeding gums, nosebleeds, vaginal bleeding, and bleeding from other mucosal surfaces, producing bloody urine, stool, and vomit. Complications can include cardiovascular and neurologic disturbances, shock, and death.

The spectrum of disease typically associated with each type of virus varies substantially. For example, Lassa virus infections are inapparent or result

TABLE 6-6 Distribution and Modes of Transmission of Viral Hemorrhagic Fevers

Family, Genus, and Virus	Disease	Principal Means of Transmission	Principal Locations
Flaviviridae			
Flavivirus			
Dengue	Dengue HF	Mosquito	Asia, Latin America
Yellow fever	Yellow fever	Mosquito	sub-Saharan Africa, South America
Kyasanur Forest disease	Kyasanur Forest	Tick	India
Omsk HF	Omsk HF	Tick, muskrat	Russia
Alkhurma HF	Alkhurma HF	Tick	Egypt, Saudi Arabia

Abbreviation: HF, hemorrhagic fever.

in mild symptoms in many people, yet cause severe life-threatening disease in others. Ebola virus and Marburg virus, by comparison, appear to cause severe disease in virtually all those infected. The severity of the clinical illness that results from infection also varies according to differences in host response, viral virulence factors, and dose.

Infection with the HF viruses is, in general, relatively rare (Lassa virus is a notable exception). Although outbreaks are dramatic and lead to major responses on the part of public health and other officials, such infections do not typically have the same public health impact in terms of morbidity and mortality as the infectious diseases that more commonly afflict inhabitants of most LMICs (WHO, 1985). However, because most HF viruses are extremely virulent and capable of causing epidemics, developing strategies to control these viruses is a public health priority. In addition, some of the viruses, such as the South American HF viruses, pose regional public health hazards within their areas of endemicity.

All HF viruses are thought to be zoonotic. These viruses have been proven or are suspected to be transmitted from animals to humans by an arthropod vector (e.g., ticks or mosquitoes) or by direct or indirect contact with the animal reservoir (e.g., rodents or bats) of the virus (see Table 6-7). In endemic areas, the temporal distribution of many viral HFs follows seasonal changes in the activity and density of the vector or animal reservoir or seasonal changes in human activity. The age and sex distributions of infection and disease caused by some HF viruses reflect differences in exposure to the vector or reservoir, whereas other viruses affect persons of all ages and both sexes.

Several of the HFs have only recently been recognized and had their agents characterized. For example, the South American HFs, Ebola HF, and Marburg HF appear to have emerged in just the past 50 years, presumably as a result of increased human activity or settlement in areas where these viruses were already circulating among their zoonotic hosts. In some instances, such as with Argentine HF, the geographic range of the virus has expanded beyond its initial focus (Vainrub & Salas, 1994). The development of control and prevention strategies for newly emerging infections can pose special difficulties because investigators have not yet conducted the research needed to formulate treatment modalities, vaccines, vector-control strategies, and other preventive measures.

Etiologic Agents and Clinical Features

Although at least 19 different HF viruses exist (see Table 6-6), the public health significance of each virus differs substantially. The most prominent (in terms of incidence of disease) are the Lassa, yellow fever, and dengue viruses. The latter two are discussed in the section on arthropod-borne diseases. Ebola virus and Marburg virus are notable for their epidemic potential and extraordinarily high case fatality ratios, whereas the South American HFs caused by the Junin, Machupo, and Guanarito viruses have regional public health importance. Detailed discussion of the remaining HF viruses is beyond the scope of this chapter.

Descriptive Epidemiologic Features and Risk Factors

Ebola HF emerged in 1976 when concurrent epidemics occurred in Democratic Republic of the Congo (formerly Zaire) and Sudan. These outbreaks were caused by distinct subtypes of the virus and were characterized by high case fatality ratios (88% in Democratic Republic of the Congo and 53% in Sudan). In total, 602 persons were infected and 431 died in the two outbreaks. A number of subsequent outbreaks occurred in Africa between 1979 and 2012. These outbreaks were limited in size and scope, resulting in fewer than 500 cases, and many of them were much smaller, with variable case fatality ratios (25% to 82%). Then, in December 2013, an unprecedented Ebola outbreak began in West Africa, resulting in a total of 28,616 suspected, probable, or confirmed cases and leading to 11,310 deaths (**EXHIBIT 6-6**).

The natural reservoir for Ebola has yet to be identified, but it is generally believed that the first person in an outbreak becomes infected through a spillover event—for example, due to contact with an infected primate or fruit bat. Epidemics of Ebola HF have been sustained by person-to-person transmission through direct physical contact with infected patients or corpses (or with their bodily fluids or tissues) and the use of unsterile needles for medical injections. Sexual transmission of Ebola virus through contact with semen from a man who had recovered from Ebola was suspected in the recent West African epidemic.

The first recognized outbreak of Marburg HF occurred in Marburg, Germany, in 1967 among laboratory workers (and their contacts), who acquired the infection from monkeys imported from Uganda. Since then, small numbers of cases have been reported in South Africa (1975), Kenya (1980 and 1987), and Uganda (2007 and 2008); in addition, more than 200 cases were identified in Democratic Republic of the Congo from 1998 to 2000 (Bausch et al., 2003). In 2004–2005, the largest outbreak to date occurred in Angola, involving 252 cases and 227 deaths (case fatality ratio of 90%) (Towner et al., 2006). The case fatality ratio of Marburg HF ranges from 21% to 90%.

Like Ebola, Marburg virus is also transmitted by person-to-person contact. Fortunately, airborne transmission does not appear to be common for either virus. Bats and nonhuman primates also play a role in the transmission of Marburg virus (Towner et al., 2007).

Lassa virus is widely distributed across West Africa, where it causes substantial morbidity and mortality. Although its incidence is poorly defined, it has been estimated that 100,000 to 300,000 new infections occur each year, with 5,000 deaths (Ogbu, Ajuluchukwu, & Uneke, 2007). Maternal death, fetal death, and permanent deafness are common complications of this disease (Cummins et al., 1990; Monson et al., 1987; Richmond & Baglole, 2003).

Lassa virus is maintained in a rodent reservoir that is commonly found in the home. Virus is shed in rodent urine and droppings, and rodent-to-human transmission is believed to occur by aerosolization or ingestion of rodent excreta or by inoculation through broken skin. Rodent-to-human transmission may also occur when infected rodents are consumed as food (Ter Meulen et al., 1996). Person-to-person transmission occurs in community and hospital settings, and makes a substantial contribution to epidemics of Lassa fever. This mode of transmission requires direct contact with infected persons. Person-to-person airborne

EXHIBIT 6-6 Ebola Outbreak, 2013–2016

The Ebola outbreak that occurred between December 2013 and April 2016 is by far the largest Ebola outbreak to date. The outbreak consisted of more than 28,000 reported confirmed, suspected, or probable cases, including 11,310 deaths. However, given the difficulty in collecting data on this outbreak, these numbers likely significantly underestimate the toll.

The outbreak has been traced back to an initial case that occurred in late December 2013 in a 2-year-old boy in Guinea, who likely acquired the virus through zoonotic transmission. All subsequent transmissions most likely occurred through the person-to-person route. Unlike previous outbreaks, which had occurred in rural and isolated areas, this outbreak spread into a large city, Conakry, and from there onward. Cases appeared in Liberia in late March 2014 and in Sierra Leone in May 2014. In August 2014, WHO declared the Ebola outbreak to be an international public health emergency. By that point, due to the spread of the virus into urban areas with mobile populations, outbreaks in all three affected countries were undergoing exponential growth. A massive international response, which was criticized by many as being too little, too late, was needed to end the outbreak.

Ultimately, the outbreak was controlled using traditional methods: finding symptomatic cases; isolating them; when possible, admitting patients to Ebola treatment centers and providing supportive care; tracing contacts of cases; and providing safe burials for the dead. Additionally, vaccination with a vaccine developed and deployed on an emergency basis, which began in Guinea in April 2015, helped to reduce transmission and prevent flare-ups.

transmission occurs rarely, if ever. Sexual transmission can occur, but the importance of this mode of transmission is unknown.

Argentine HF, which is caused by Junin virus, was first described in 1955 in agricultural workers in the Argentine pampas. Several hundred cases of Argentine HF occur each year in large, primarily agricultural regions of the pampas. The region of endemicity is expanding, however, and is now nearly 10 times larger than the initial compass (Vainrub & Salas, 1994).

Bolivian HF, which is caused by Machupo virus, was described in northeastern Bolivia, which is the only known endemic area. Outbreaks of Bolivian HF occurred in the 1960s and early 1970s, including large epidemics that affected hundreds of individuals. Although no cases were reported from 1976 to 1992, possibly due to effective host control, a small outbreak in 1994 and subsequent outbreaks in 2007, 2008, and 2011 have marked its reemergence.

Venezuelan HF, which is caused by Guanarito virus, was first recognized in 1989. During the period from September 1989 to January 1997, 165 cases were reported within the small region of central Venezuela where Guanarito virus is endemic (De Manzione et al., 1998).

For infections caused by the Argentine, Bolivian, and Venezuelan HF viruses, the case fatality ratio is in the range of 15% to 33% (De Manzione et al., 1998; Doyle, Bryan, & Peters, 1998). Each of these viruses is associated with a rodent reservoir that maintains the virus in the wild. As with Lassa fever, rodent-to-human transmission occurs by the aerosolization or ingestion of virus-laden rodent excreta or by inoculation through broken skin. The rodent that carries Junin virus typically dwells in agricultural fields, whereas the rodent that carries Machupo virus readily enters the home. Rodent-control strategies must take such differences into account. Person-to-person transmission of Junin, Machupo, and Guanarito viruses is considered rare, and nosocomial outbreaks are uncommon.

Current Approaches to Prevention and Control

Field trials have demonstrated that a live, attenuated Junin virus vaccine is safe and provides effective protection against Argentine HF (Maiztegui et al., 1998); it may also provide cross-protection against Bolivian HF. Vaccines are not available for Lassa fever or Marburg HF, although several candidate Lassa fever vaccines are under development. A vaccine for Ebola, called VSV-EBOV, has been shown to be very efficacious and is currently available for use in flare-ups in Africa (Henao-Restrepo et al., 2017). Several other candidate Ebola vaccines are currently in development or undergoing clinical trials.

In the absence of vaccines, reducing the morbidity and mortality caused by HF viruses depends on preventing primary transmission by limiting exposures to virus reservoirs and vectors and controlling secondary transmission (e.g., person-to-person transmission in the hospital, household, or community setting) through patient isolation and barrier nursing. In addition, the use of antiviral drugs or convalescent serum is effective in some instances.

Strategies to limit exposure to the virus are determined by the unique characteristics of the associated animal reservoir or vector and the distinct ways in which the various viruses are transmitted. For example, the rodent that carries Machupo virus is frequently found in and around the home, and aggressive rodent eradication measures through trapping and poisoning appear to have been quite successful in controlling Bolivian HF (Kilgore et al., 1995). Conversely, the rodent reservoir of Junin virus lives in crop fields, where trapping and poisoning are difficult, necessitating the development of alternative rodent abatement strategies. Eradication (or even control) of the rodent reservoir of Lassa virus in West Africa is not considered feasible due to the density and wide distribution of the rodent that carries the virus. Thus, preventing the primary transmission of Lassa virus has relied on educating at-risk communities about ways to reduce opportunities for exposure, such as never leaving food items uncovered and never consuming rodents as food.

Historically, nosocomial and person-to-person transmission of Lassa fever, Ebola HF, and Marburg HF have contributed significantly to devastating outbreaks of these diseases. (The South American HF viruses are rarely transmitted by these routes.) Field experience indicates that epidemic control of limited outbreaks can be achieved through simple barrier nursing techniques (e.g., wearing gloves, gowns, and masks; sterilizing equipment; and isolating patients), and epidemiologic studies support this conclusion. For example, serologic studies in Sierra Leone found that hospital personnel who used barrier techniques when caring for patients with Lassa patients had no greater risk of infection than the local population (Helmick, Webb, Scribner, Krebs, & McCormick, 1986). Traditional Ebola control measures include rapid diagnosis, isolation of cases, contact tracing, provision of supportive treatment, and safe burial practices.

At present, few specific treatments are available for the viral HFs. During the 2013–2016 Ebola epidemic, two experimental drugs, ZMapp and TKM-Ebola,

were used on a limited emergency basis. A subsequent small trial of ZMapp failed to meet the preset superiority cut-point, but the therapy did appear to be beneficial (PREVAIL II Writing Group, 2016). Ribavirin (an antiviral drug) is effective in the treatment of Lassa fever (McCormick et al., 1986). Laboratory data suggest that ribavirin may also be effective in treating South American HFs, although clinical data supporting this usage are incomplete (Doyle et al., 1998). Convalescent serum is useful in the treatment of Argentine HF (WHO, 1985), but donors are not plentiful. Most people in LMICs are not able to afford these therapies.

Obstacles to Prevention and Control and Directions for Future Research

The major obstacle to containing outbreaks of viral HFs (especially Ebola HF, Marburg HF, and Lassa fever) is inadequate disease surveillance, which results in delayed response and increased opportunities for epidemic spread. In many LMICs, disease surveillance is impeded by the difficulty of making an early diagnosis in areas where illnesses with similar initial manifestations (e.g., malaria, influenza, typhoid fever, leptospirosis, meningococcemia, and hepatitis) are prevalent. The lack of ready access to diagnostic laboratories exacerbates this difficulty. In addition, because epidemics are unpredictable in time and place, surveillance efforts are difficult to maintain. Other obstacles to the control and prevention of viral HFs include the costliness of sustaining readiness for infection control measures (e.g., maintaining supplies for barrier nursing), lack of information about the vectors and reservoirs of the Ebola and Marburg viruses, the difficulty of developing and maintaining vector- and rodent-control programs, and the limited availability of ribavirin (especially for the treatment of Lassa fever).

Infectious Causes of Blindness

Overview

Severely decreased visual acuity or complete blindness is profoundly disabling in any setting, but perhaps even more so in LMICs. Among the known causes of blindness, two infectious agents play important etiologic roles in selected regions of the world: *C. trachomatis*, the cause of trachoma, and *Onchocerca volvulus*, the cause of onchocerciasis, also known as river blindness.

Trachoma

Etiologic Agents

C. trachomatis is a small bacterium that lives within selected types of human cells and is difficult to grow in the laboratory. Although *C. trachomatis* is also the cause of STIs, as discussed previously, different immunotypes of the bacterium cause trachoma and genital tract infections. Those that cause trachoma are spread via a person-to-person route, most probably through eye and possibly nasal secretions on the hands. *C. trachomatis* is also spread mechanically by flies and probably by fomites such as washrags and handkerchiefs. Repeated episodes of infection in young (preschool) children lead to scarring of the eyelids, which then causes in-turned eyelashes that abrade the corneal surface, leading to subsequent corneal opacification and reduced visual acuity or blindness in adults.

Descriptive Epidemiologic Features and Risk Factors

Trachoma is an important cause of preventable blindness across the world. It is estimated that 229 million people live in areas endemic for trachoma, spread across 53 countries (Taylor, Burton, Haddad, West, & Wright, 2014). Approximately 21 million persons have active trachoma, of whom 2.2 million are blind or severely visually impaired. Trachoma is a disease of poverty that was described by the ancient Egyptians and previously was found throughout the world. It disappeared from Europe and almost all of the United States long before antimicrobial agents became available in the 1930s and 1940s; improved standards of living and personal hygiene are credited with its disappearance.

Trachoma is not a reportable condition, and what is known of its descriptive epidemiologic features comes from numerous surveys. This disease persists in hot LMICs, particularly in North Africa, the Middle East, sub-Saharan Africa, and drier regions of India and Southeast Asia. In hyperendemic areas, infection of the eye is generally universal in children by their fifth birthday, but active disease is seen largely in older children. Repeated reinfection in children leads to the permanent damage to the eyes that results in subsequent blindness or visual impairment in adulthood. Although infection in childhood appears to be equally common in boys and girls, the blinding complications appear to be more common in women, perhaps because of repeated exposure to infected children.

Risk factors for trachoma in children largely relate to facial cleanliness, the presence of flies, and cultural practices that lead to an increased likelihood of

person-to-person transmission of the etiologic agent, such as sharing washcloths and ways in which eye makeup is applied.

Current Approaches to Prevention and Control

Intervention studies have demonstrated that mass treatment with a variety of topical or oral antimicrobial agents and health educational programs that lead to improved facial cleanliness can substantially reduce the prevalence of trachoma in a community, as can fly control (Bhosai, Bailey, Gaynor, & Lietman, 2012; Emerson et al., 2004; House et al., 2009). Reductions in disease incidence in LMICs in the absence of a specific control program have also been documented as access to water, access to health care, and hygiene have improved.

The current approach to reducing trachoma-associated blindness in endemic areas is summarized by the acronym SAFE:

- **S**urgery to correct eyelid deformity
- **A**ntibiotics to treat acute eye infection and reduce sources of infection in the community
- **F**acial cleanliness
- **E**nvironmental change that enhances availability of water and reduces the prevalence of flies

In 1997, WHO launched a new trachoma control program—called Global Elimination of Trachoma by 2020 (GET 2020)—based on this approach. In 2016, more than 260,000 people with trachomatous trichiasis were provided with corrective surgery and more than 86 million people received antibiotics to eliminate trachoma through the integrated approach to preventive chemotherapy.

Obstacles to Prevention and Directions for Future Research

Trachoma is likely to remain a persistent problem in endemic areas until rising socioeconomic conditions result in better access to water, improved personal hygiene and sanitation, reductions in the numbers of flies, and improved access to healthcare services. Community-wide treatment with antimicrobial agents can lead to marked reductions in trachoma in such areas, but these reductions have proved difficult to sustain unless such treatment is made a routine part of regularly available health services and is accompanied by improvements in hygiene. Although a vaccine against trachoma has been discussed for many years, it remains unclear whether an effective vaccine can or will ever be developed.

Onchocerciasis

Etiologic Agents

O. volvulus is a filarial parasite that is spread through the bite of one of several species of *Simulium* black flies. During the bite of an infected female fly, larvae enter the body. There, they ultimately develop into adult worms that form nodules, usually over bony prominences. Adult worms can survive inside these nodules for as long as 15 years. The female adult worm produces microfilariae that migrate to the skin and the eye and are ingested by female flies when they bite an infected person, thereby completing the cycle.

In the skin, an inflammatory response to dead and dying microfilariae can lead to incapacitating itching and various types of degenerative, often unsightly, skin changes. In the eye, heavy and prolonged infection of the cornea with the microfilariae leads to opacification and reduced visual acuity or total blindness. The microfilariae can be detected by taking small snips of skin, immersing them in saline, and examining the saline microscopically.

Descriptive Epidemiologic Features and Risk Factors

Onchocerciasis is found only in a band of sub-Saharan African countries, parts of South America, and the Eastern Mediterranean. Approximately 26 million people worldwide are believed to be currently infected with the parasite, and 185.6 million people require preventive chemotherapy (WHO, 2017j). Onchocerciasis is the world's second leading cause of preventable blindness due to infection. Within affected regions, onchocerciasis occurs in clusters, largely determined by distance from the black fly breeding sites. The intensity of infection (and hence the risk of visual impairment) increases with age, as the burden of adult female worms producing microfilariae increases. This burden tends to be greater in men than in women, perhaps reflecting work-related exposures to the flies.

Current Approaches to Prevention and Control

Approaches to the control of onchocerciasis and prevention of the blindness it causes have included vector control, mass treatment of infected individuals, and nodulectomy (removal of nodules to reduce the source and number of microfilariae that migrate to the eyes). Early attempts to control onchocerciasis targeted the *Simulium* flies that serve as vectors, the immature stages of which require running water (e.g., rivers and streams) for their development. Initially, DDT was the pesticide added to rivers that served as

the breeding grounds for the vector. Beginning in the 1970s, other agents that target the larval stages of the fly (e.g., temefos) were used with great success, particularly in West Africa. These programs permitted resettlement of fertile areas that had been abandoned because of onchocerciasis, but the flies' development of resistance to temefos required switching to other larvicidal agents in some areas.

The control of onchocerciasis was revolutionized in the late 1980s with the introduction of ivermectin, a single dose of which eliminates microfilariae for a number of months. Because ivermectin does not kill the adult worms, repeated treatment (e.g., every 6 to 12 months) of infected individuals over many years is needed to provide continued suppression of the number of microfilariae and to prevent visual damage. Treatment every 3 months may be even more effective at reducing both the number of female worms in nodules and the severity of symptoms (Gardon et al., 2002). In a noteworthy humanitarian gesture, the manufacturer of ivermectin has made a commitment to provide the drug for free "for as long as necessary to as many as necessary." Globally, control is managed through an integrated approach of preventive chemotherapy. Currently, nearly 400 million doses of ivermectin are distributed each year for preventive treatment of onchocerciasis or the combination of onchocerciasis and lymphatic filariasis (WHO, 2017j).

Obstacles to Prevention and Directions for Future Research

Currently, the goal is to eliminate onchocerciasis worldwide. Since the implementation of an integrated approach in 2008, major gains have been made toward achieving this goal, including the elimination of the disease in four countries in the Americas.

Antimicrobial Resistance

Antimicrobial resistance (AMR) is one of the greatest public health challenges of the twenty-first century. Antimicrobial agents that kill or inhibit the growth of microorganisms consist of three main classes: disinfectants, antiseptics, and antibiotics. The term "antibiotics," while initially used to refer only to antibacterial agents, now also includes antiviral, antiparasitic, and antifungal agents. Resistance to antimicrobial agents used to treat specific infections, such as gonorrhea, malaria, and tuberculosis, has been addressed in the relevant chapter sections and thus will not be addressed here.

Antibiotics are used to treat a wide variety of infections. Global consumption of antibiotics has been estimated at more than 70 billion doses per year (Van Boeckel et al., 2014), with use increasing due to economic growth and the resultant increased access to and use of antibiotics in LMICs.

In spite of the massive increase in antibiotic consumption globally, insufficient access to effective and affordable antibiotics remains a major public health problem in low-resource settings, where lack of or delayed access to antibiotics is responsible for many more deaths than antibiotic resistance (Laxminarayan et al., 2016). Nevertheless, AMR is clearly a growing problem that contributes to the burden of infectious disease morbidity and mortality, although the magnitude of the problem is difficult to quantify.

Public health measures—particularly vaccination and sanitation—play an important role in helping reduce antibiotic use. For instance, introduction of pneumococcal conjugate vaccine in the United States resulted in reduced antibiotic consumption and fewer infections caused by antibiotic-resistant strains of *S. pneumoniae* (Kyaw et al., 2006). In countries with a high burden of diarrheal illness, access to clean water and adequate sanitation could dramatically reduce the use of antibiotics for diarrheal illnesses. Improving laboratory capacity in low-resource settings, as well as providing access to point-of-care diagnostic tests, would both reduce antibiotic consumption and improve access to appropriate treatment (Mendelson et al., 2016).

Nowhere is a One Health approach more needed than in combating AMR. As is true in humans, antibiotics are a necessary part of maintaining animal health and need to be available for appropriate veterinary use. However, the use of low-dose antibiotics for growth promotion in food animals and as prophylaxis in fish farming are important contributors to the rise of AMR. Indeed, the use of antimicrobial agents in animals to increase food production greatly exceeds the use of these drugs in humans (WHO, 2012b). In 2006, the European Union banned the use of antimicrobial agents for growth promotion, although they are still widely used for that purpose globally.

Addressing the rise of AMR and ensuring continued access to treatment with effective antimicrobial agents will require global action. In 2015, WHO endorsed an action plan to combat AMR that includes five strategic objectives:

- Improve awareness and understanding of AMR
- Strengthen knowledge through surveillance and research
- Reduce the incidence of infections
- Optimize the use of antimicrobial agents

- Develop the case for sustainable investment and increase investment in the development of new antimicrobial agents (WHO, 2015b)

The way forward will require that we improve surveillance for AMR, decrease human consumption of antibiotics while improving access to appropriate treatment, adopt responsible animal husbandry practices, expand measures to prevent and control infections in humans, and foster innovations such as new medicines, vaccines, and diagnostic tests, as well as sustained political commitment on a global scale. The chapters on *Public Health Infrastructure* and *Pharmaceuticals* provide additional discussion of AMR.

Emergence of New Infectious Disease Threats

The availability of a growing number of antimicrobial agents and vaccines beginning in the 1950s and continuing through the 1970s simultaneously led to the burgeoning infectious disease prevention and control activities described earlier in this chapter and to a widely shared assumption that infectious disease threats to human (and animal) health would diminish over time. A sobering note was injected into this otherwise optimistic conversation with the unexpected emergence of new infectious diseases and the reemergence of previously controlled diseases that became apparent in the 1980s and 1990s. Their appearance made it clear that efforts to control existing infectious diseases needed to be accompanied by an improved global capacity for early detection and rapid response to newly emergent or reemergent infectious diseases. Concern about the possible intentional release of infectious agents in a deliberate effort to frighten, harm, or kill gave added impetus to efforts in this area.

The concept of emerging and reemerging infections, which began receiving prominent attention after the U.S. Institute of Medicine released a report entitled *Emerging Infections: Microbial Threats to Health in the United States* in 1992, encompasses several distinct phenomena that can produce unexpected and sometimes urgent infectious disease threats. Included under the rubric of emerging and reemerging infectious disease threats are diseases caused by microbial agents not previously known to cause illness in humans (e.g., SARS, Nipah virus encephalitis, and H5N1 [avian] influenza in humans), the appearance in a new location of an infectious agent (e.g., the spread of West Nile virus to the United States or Zika virus to South America), the appearance of a new epidemiologic pattern of disease caused by an infectious agent (e.g., epidemic meningococcal meningitis caused by serogroup W-135 *N. meningitidis*), the appearance or spread of new variants of an infectious agent (e.g., multidrug- and extensively drug-resistant *M. tuberculosis*), and the resurgence of an infectious disease previously under good control (e.g., diphtheria in parts of the former Soviet Union).

The 1992 report by the Institute of Medicine, together with a follow-up report in 2003 (Smolinski, Hamburg, & Lederberg, 2003), outlined a number of factors that could promote the emergence or reemergence of infectious disease threats. In addition to microbial adaptation and change in response to selection pressures, numerous human and environmental factors may contribute to this trend—for example, increased human susceptibility to infection; human demographic conditions and behaviors; international travel and commerce; economic development and changes in land use; technological change; climate and ecologic factors; breakdown of public health measures; war and famine; poverty and social inequality; lack of political will; and intent to harm. Individually and collectively, these factors may increase the likelihood that humans will come in contact with various infectious agents, produce a greater susceptibility to infection, enhance and accelerate the spread of infectious agents, and reduce the capacity of communities to detect and respond effectively to infectious disease threats. Although the result can be dramatic outbreaks that command widespread public attention and political response (e.g., SARS, Ebola, and Zika), other equally serious infectious disease threats (e.g., multidrug- and extensively drug-resistant tuberculosis) often go largely unnoticed by the general public and decision makers because they do not produce explosive epidemics.

A dramatic example of an emerging infectious disease threat was the appearance of SARS. This life-threatening form of pneumonia appears to have originated in southern China in late 2002 (CDC, 2003). Before the significance of these cases of pneumonia became apparent, the illness had spread to multiple other parts of Asia and eventually to Europe, North America, and elsewhere. By the middle of 2003, more than 8,400 probable cases of SARS and more than 800 SARS-related deaths had been reported from 30 countries, with China, Hong Kong, and Taiwan bearing the brunt of the epidemic. SARS is caused by a previously unknown member of the Coronaviridiae family that almost certainly originated in one or more animal

reservoirs and initially spread to humans through direct exposure to infected animals in southern China. The virus then proved to be transmissible from person to person, particularly in healthcare settings. Spread of the SARS-associated coronavirus was also documented on commercial airplanes, and the ease of modern travel from one part of the world to another clearly facilitated the rapid dissemination of the virus across the globe.

In addition to the morbidity and mortality it caused, the SARS epidemic had an enormous economic impact. The total cost of this epidemic to Asian economies alone was estimated at approximately $60 billion. In the absence of a vaccine, preventing further spread of the SARS epidemic required stringent isolation of patients, quarantine of exposed individuals, restrictions on travel, and various other measures that were highly disruptive to commerce, travel, and other aspects of life.

Experience with influenza demonstrates many of the challenges related to detecting and responding rapidly to an emergent infectious disease threat. The appearance in Hong Kong in 1997 of human cases of influenza caused by the highly pathogenic avian influenza virus A (H5N1) heralded widespread epizootics (i.e., epidemics in animals) in domestic poultry and widespread infection (often asymptomatic) in many species of wild birds that ultimately reached much of Asia and parts of Africa, Europe, and the Middle East. By 2008, several hundred human infections with H5N1 had been documented in Asia (Vietnam, Thailand, Cambodia, Indonesia, and China), as had a smaller number of infections in Egypt and Turkey (Writing Committee of the Second World Health Organization Consultation on Clinical Aspects of Human Infection with Avian Influenza A [H5N1] Virus, 2008).

The H5N1 influenza virus is highly pathogenic in people. More than 50% of the people with documented illnesses died from their disease, prompting well-justified concerns about a human epidemic or pandemic caused by this virus and resulting in efforts to make and stockpile a safe and effective H5N1 vaccine. To date, however, there have been very few instances of person-to-person transmission of H5N1 virus (almost all human cases are the result of animal-to-human transmission), and it remains uncertain whether this virus is capable of both retaining its high pathogenicity and becoming readily transmissible from person to person.

While public health officials and vaccine manufacturers were preparing for a possible H5N1 influenza pandemic, a novel H1N1 influenza A virus of swine origin arose. Although this H1N1 virus was first detected in ill individuals in southern California and in Mexico in early 2009 (Novel Swine-Origin Influenza A [H1N1] Virus Investigation Team, 2009), its origins remain unknown. By the time the virus was first detected, it undoubtedly had undergone many generations of transmission among humans and had already become widely disseminated, making attempts to contain it futile. Within a short period of time after its discovery, the novel H1N1 influenza A virus was circulating and causing disease throughout North America, Europe, and Asia in the northern hemisphere and causing large epidemics in numerous countries in South America, southern Africa, and Australia and New Zealand in the southern hemisphere. Although a vaccine containing this virus was developed and produced with

EXHIBIT 6-7 Global Outbreak Alert and Response Network

Throughout the 1970s, 1980s, and 1990s, outbreaks of novel or high-impact infectious diseases (e.g., Ebola, cholera, and meningococcal meningitis) in LMICs often led to ad hoc responses by multiple national, international, academic, research, and private-sector organizations. Unfortunately, many of these efforts were uncoordinated and sometimes duplicative or even competing in nature. Although countries often looked to WHO for leadership and technical assistance in such instances, historically this organization has had very limited trained personnel and resources to devote to such efforts, as well as political and legal constraints that could limit its access.

In recognition of these problems, in 2000 WHO created the Global Outbreak Alert and Response Network (GOARN), which has its headquarters in Geneva, Switzerland. GOARN is a network of more than 200 institutions and networks that provides rapid assistance to identify and control infectious disease outbreaks and public health emergencies worldwide. This network has proved useful as SARS, influenza, yellow fever, and other outbreaks have appeared since 2000. Revisions to the International Health Regulations that give WHO improved access when important outbreaks occur should improve the functioning of this system.

exceptional speed, neither the vaccine nor other approaches (e.g., antiviral drugs, isolation and quarantine, and social distancing measures) prevented a pandemic from unfolding.

Fortunately, this influenza A virus proved to be no more virulent than the influenza A and B viruses that cause annual epidemics, although it still produced widespread morbidity and mortality. A more virulent influenza A virus would have exacted a substantially higher human toll, and would have been equally difficult to contain.

As these examples demonstrate, there is an ongoing threat of new infectious agents entering and causing disease in human populations, particularly from animal sources. Even as progress is made in eradicating or controlling historically important infectious diseases, the need persists for vigilance, preparedness, and a high level of international cooperation to detect and respond to new infectious disease threats that might emerge. WHO and others are working to improve global capacity in this area (**EXHIBIT 6-7**).

Global Health Security Agenda

In 2014, the Global Health Security Agenda (GHSA) was launched by multiple partners, including almost 50 countries, diverse international organizations, and various nongovernmental stakeholders, in response to the recognition that substantial parts of the world were not adequately prepared and did not have adequate resources to prevent, detect, and respond to infectious disease threats (Sands, Mundaca-Shah, & Dzau, 2016). GHSA is committed to supporting collaborative capacity-building efforts by helping countries develop and maintain the core animal and human disease surveillance, pandemic preparedness, and outbreak response capacities mandated by WHO's International Health Regulations, the World Organization of Animal Health's Performance of Veterinary Services Pathway, and other global health security frameworks. GHSA, which has received substantial initial financial commitments, is working to improve epidemiologic and laboratory capabilities in dozens of LMICs around the world, through workforce development and training; laboratory improvement and expansion; and enhancement of communications and computing capabilities. Whether it can have a sustained impact will likely depend on whether funding agencies continue to make such efforts a priority, once the initial funds committed to GHSA have been expended (see the *Public Health Infrastructure* chapter for more on GHSA).

Conclusion

The current status of infectious diseases in LMICs reflects both the dramatic progress that has been made in controlling some diseases and the disappointing results to date in controlling others. The eradication of smallpox, the expected imminent eradication of polio, and impressive gains made against measles and neonatal tetanus all demonstrate what can be accomplished, even in the lowest-income countries, with an effective vaccine when concerted efforts are made to ensure that the vaccine reaches those in need. Similar progress in reducing morbidity from dracunculiasis and onchocerciasis demonstrates that, under the right conditions and with available resources, infectious diseases can be controlled through a combination of vector control and avoidance and treatment. At the same time, the reductions in the morbidity and mortality from diarrheal diseases and acute respiratory infections that have been achieved provide clear evidence that a combination of improved knowledge and access to reasonably inexpensive treatment modalities can also be highly effective.

Remarkable progress has been made in substantially reducing the geographic extent of and mortality from malaria, despite the absence of an effective vaccine. Similarly, by making antiretroviral treatment with inexpensive, generic medications widely available, the morbidity and mortality from HIV/AIDS have been reduced in many LMICs. Progress against TB and dengue, however, has proved harder to achieve. Moreover, recent explosive outbreaks of Ebola virus and Zika virus infections have demonstrated how quickly an infectious agent can spread, reinforcing the need for ongoing vigilance in the form of disease surveillance and adequate global preparedness to respond quickly to regional and global infectious disease threats.

The progress made to date in controlling the morbidity and mortality from infectious diseases in LMICs demonstrates that much can be accomplished even in the absence of marked improvements in socioeconomic conditions. Ultimately, though, widespread improvements in education and socioeconomic conditions will be needed if such progress is to be maintained.

The authors acknowledge Christina Phares and Kelly Walblay for their assistance in the preparation of this chapter.

Discussion Questions

1. What are the major types of approaches that have been used to prevent morbidity and mortality from infectious diseases in LMICs?
2. What are the major obstacles that have had, and remain, to be overcome in implementing various approaches to preventing morbidity and mortality from infectious diseases in LMICs?
3. In the current year, which infectious diseases account for the most mortality in LMICs? The most morbidity?
4. If you were working in the Ministry of Health of a low-income country and needed to set priorities concerning resource allocation, how could you go about determining the relative importance of various infectious diseases as causes of mortality in your country? The causes of morbidity/disability?

CHAPTER 7

Nutrition

Christine Stewart, Jessica Fanzo, Keith West, and Robert Black

Introduction

Nutritional concerns in low- and middle-income countries (LMICs) are diverse, ranging from deprivation, hunger, and micronutrient deficiencies that impair health, quality of life, and survival, to a rising tide of obesity and ensuing risks of noncommunicable diseases (NCDs) in every region of the world. Nutritional disorders in early life can have significant health consequences, including increased risk of infectious disease and mortality, poor child cognitive development and performance in school, and increased risk of NCDs in adulthood. Undernutrition, reflected by high prevalence of wasting, stunting, and micronutrient deficiencies, is the predominant form of malnutrition throughout southern Asia and most of sub-Saharan Africa, while overweight and obesity, often in the presence of stunting and micronutrient malnutrition, is now a growing concern globally. Undernutrition and obesity both are problems arising from a complex array of societal, community, and individual risk factors. Food quality and dietary intake are certainly immediate contributors, but so, too, are environmental risks from infectious disease and poor access to health care. From practices within the home to food systems and markets, an individual's nutritional status is influenced by many factors. This presents a challenge for programs to prevent and respond to nutritional problems, as one approach is unlikely to meet all needs in all contexts. Nevertheless, across a wide range of interventions and programs, there is strong evidence of success. Focused, nutrition-specific programs and integrated or multisectoral programs both offer opportunities for improving nutrition, and thereby improving health and well-being throughout life. This chapter covers the burden of malnutrition including who is affected and where, the causes and consequences of malnutrition, and the interventions and approaches to address the disease burden.

Spectrum of Malnutrition and Its Consequences Across the Life Course

Malnutrition may manifest in many forms throughout the life course. Undernutrition in childhood may lead to a pattern of slow, stunted growth and inadequate weight gain. During or prior to pregnancy, undernutrition or inadequate weight gain may have negative health consequences on the mother as well as the developing fetus. These overt patterns of undernutrition may be accompanied by either clinical or subclinical deficiencies in essential micronutrients, described as a form of "hidden hunger." Layered onto this situation in many countries is an increasing problem of excess weight gain leading to overweight and obesity. These problems may co-occur in populations and even within individuals, who may be overweight while

also suffering from a micronutrient deficiency, for example. This has come to be referred to as the "triple burden of malnutrition," reflecting the coexistence of three distinct, but related problems of undernutrition, micronutrient deficiencies, and obesity (Pinstrup-Andersen, 2007).

Undernutrition

Undernourishment comes in many forms. Individuals who are undernourished may have experienced a recent event, such as a food shortage or period of infection that led to an acute period of undernutrition. They may experience periods of wasting, characterized by the loss of muscle and adipose tissue. Sometimes the problem may be longer term in nature, resulting from chronic deprivation, malabsorption in the gut, or chronic illness. Among children, their growth rate may slow or micronutrient deficiencies may develop, as their stored nutrient reserves become depleted. Among pregnant women, undernutrition may lead to poor birth outcomes

Undernutrition in Childhood

The most common first step in detecting undernutrition in childhood is through anthropometric measurements of height, weight, or circumferential measures of the arm or head. To understand whether children are growing well, these measurements need to be compared to a reference population. In 2006, the World Health Organization (WHO) released a set of growth standards that are now used in nearly every country worldwide. The WHO Multicentre Growth Reference Study collected data on approximately 8,500 children representing the regions of North America (United States), Latin America (Brazil), Africa (Ghana), Asia (India), Europe (Norway), and the Middle East (Oman) (WHO Multicentre Growth Reference Study Group, 2006a). Among the resulting standard's advantages are that it reflects patterns of growth among children exposed to healthy environments, such as having been reared in nonsmoking households, provided with appropriate breastfeeding and complementary feeding practices, and rendered standard pediatric care, such as immunizations and care during illness. As such, this standard is considered prescriptive, revealing how child populations should grow, and it firmly establishes the breastfed infant as the model for normative growth and development.

Using the WHO growth standard, weight-for-age, height- or length-for-age, weight-for-length or height, and body mass index (BMI)-for-age growth charts have been created for monitoring children's growth and for comparing populations. For an individual child, measurements can be plotted on the growth chart to monitor trends over time and risk of undernutrition. As examples, three girls are shown in the charts in **FIGURE 7-1**. Child A's weight and length

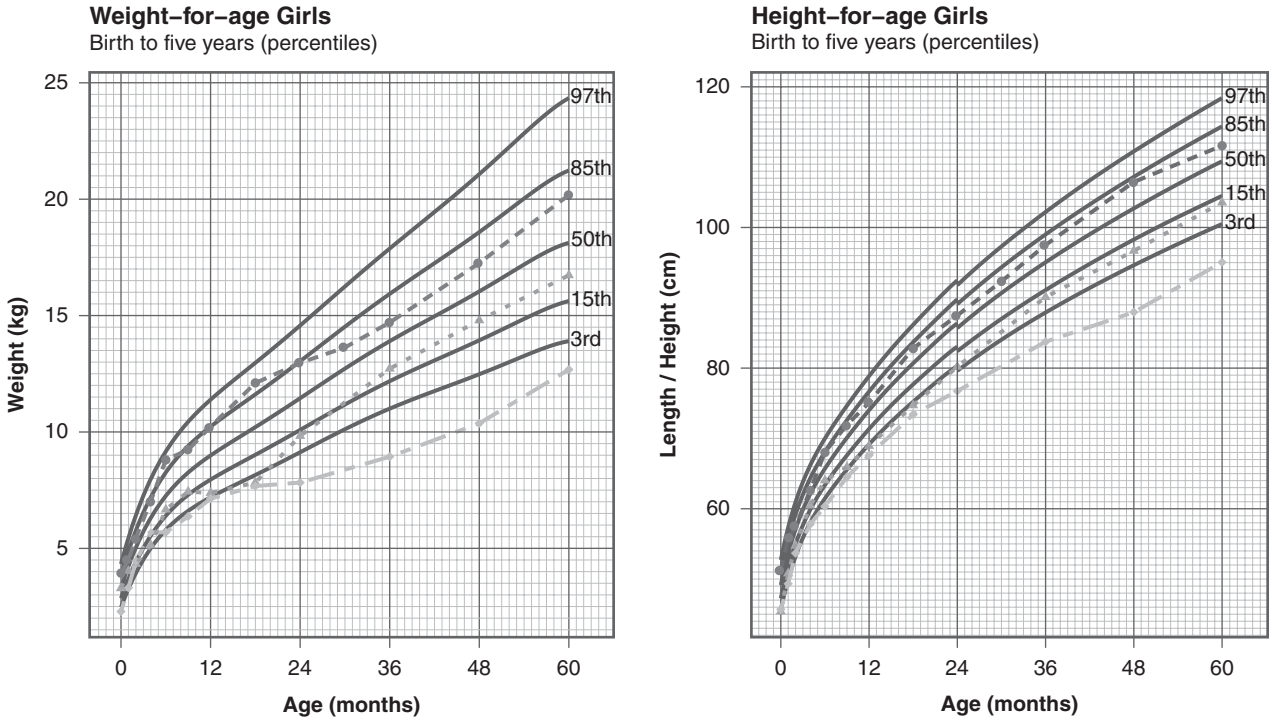

FIGURE 7-1 Weight-for-age and length-for-age growth charts illustrating the growth patterns for three girls. Child A is indicated with a dashed line and circles, Child B with dotted lines and triangles, and Child C with dashed lines and diamonds.

gains roughly track the centile lines, suggesting that she is growing well. In contrast, Child B experienced a period of weight loss at approximately 18 months of age followed by catch-up weight gain due to a short-term event, such as an episode of illness or a period of food deprivation, from which she has recovered. Her length gain over the period was largely unaffected and appears to have stayed on track. Child C, by comparison, has experienced a longer-term problem that is resulting in slower growth in length and weight. Her growth trajectory is crossing the lower centile lines, indicating that she is not growing at the rate that would be expected for her age and sex.

At the population level, *z*-scores are commonly calculated and used for cross-population comparisons or to monitor trends over time. Children who fall below the defined cutoffs of the age- and sex-specific WHO growth standard median would be classified as stunted (low height- or length-for-age), underweight (low weight-for-age), or wasted (low weight-for-length). The degrees of stunting, underweight, or wasting are shown in **TABLE 7-1**. Mid-upper arm circumference (MUAC) is also used as an indicator of wasting, often when access to scales might be limited. Measurements less than 11.5 cm or between 11.5 and 12.5 cm indicate severe or moderate wasting, respectively; these standards are most applicable to children 1 through 4 years, an age when circumferential growth is slow. The WHO Multicentre Growth Study firmly established that populations of children of diverse ethnic and geographic backgrounds with adequate access to health services and nutrition have the same distributions of height and weight (WHO Multicentre Growth Reference Study Group, 2006b). In a healthy population, therefore, we would expect that the median *z*-score of the indicator would be zero and that approximately 2% of children would fall below the –2 cutoff, representing an expected proportion of normal, small children. When the median falls below zero and when population has a high proportion of stunting, wasting, or underweight, that finding is indicative of a significant public health concern. In comparing regional trends in child growth, however, it becomes apparent that sub-Saharan Africa and Asia, and to a lesser degree, Latin America, have evidence of significant population growth faltering (**FIGURE 7-2**) (Victora, de Onis, Hallal, Blossner, & Shrimpton, 2010). These data also reflect that there is increasing severity of stunting with age. Irrespective of region, two key observations are the steadfast decline in attained length through the second year of life, occurring at a rate of approximately –0.10 *z*-score

TABLE 7-1 Interpretation of Anthropometric Indicators in Children

Indicator	Cutoff	Interpretation
Height- or length-for-age *z*-score (HAZ or LAZ)	< –3.0 cm	Severely stunted
	–3.0 < –2.0 cm	Moderately stunted
	–2.0 < –1.0 cm	Mildly stunted
Weight-for-age *z*-score (WAZ)	< –3.0 cm	Severely underweight
	–3.0 < –2.0 cm	Moderately underweight
	–2.0 < –1.0 cm	Mildly underweight
Weight-for-height or length *z*-score (WHZ or WLZ)	< –3.0 cm	Severely wasted
	–3.0 < –2.0 cm	Moderately wasted
	–2.0 < –1.0 cm	Mildly wasted
Mid-upper arm circumference (MUAC)	< 11.5 cm	Severe wasting
	11.5 < – 12.5 cm	Moderate wasting

Data from WHO Multicentre Growth Reference Study Group, 2006a.

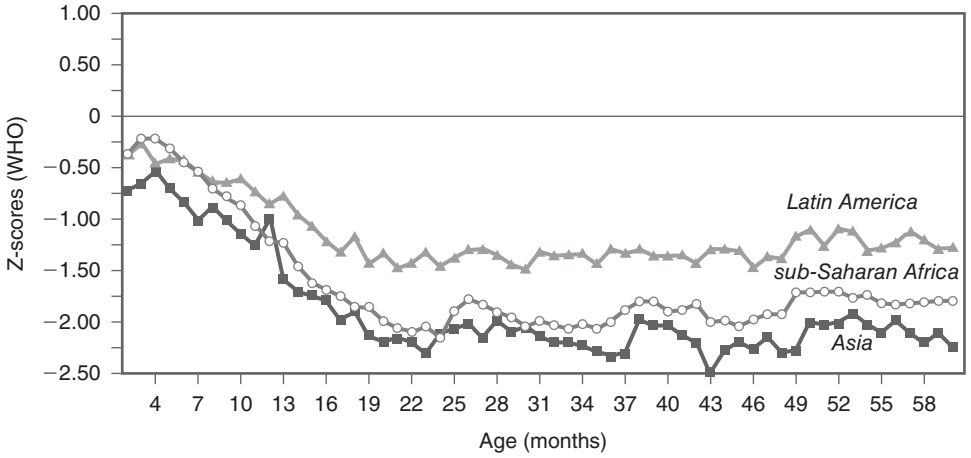

FIGURE 7-2 Mean height-for-age *z*-scores for children 1–59 months relative to the WHO growth standards. Geographic groupings are based on the WHO regions for Latin America and the Caribbean, South Asia, and sub-Saharan Africa.

Data from Victora, C. G., de Onis, M., Hallal, P. C., Blossner, M., & Shrimpton, R. (2010). Worldwide timing of growth faltering: Revisiting implications for interventions. *Pediatrics, 125*(3), e473–480.

per month, and the lack of statural catch-up thereafter. This pattern emphasizes the importance of promoting adequate fetal and postnatal linear growth in children through 2 years of age as critical to resolving lifelong, intergenerational stunting in the developing world.

Although milder stages of undernutrition are often clinically inapparent (**FIGURE 7-3**, left child), severe acute malnutrition (SAM) refers to two clinically distinct presentations, marasmus and kwashiorkor, and a mixed form, marasmic kwashiorkor. *Marasmus*, a term originating from the Greek word *marasmos*, which means "withering," is marked by severe wasting, grossly clinically evident accompanied by a weight-for-height usually less than −3 *z*-scores. In a preschool child, it is diagnosed based on a MUAC less than 11.5 cm, from loss of muscle and adipose; a resultant "baggy" appearance to the skin; moderate to severe stunting from a near cessation of linear growth; soft, sparse hair; absence of edema; alertness; and hunger (Reddy, 1991) (Figure 7-3, right child). *Kwashiorkor* is a term from the Ghanaian language, Ga, for a condition that was initially observed to have developed when an older child was displaced from the breast (Williams, 1933). As implied by the term, children 2 to 3 years of age are at highest risk of this condition. Evidence of kwashiorkor includes edema (an essential feature), milder wasting, reddish hair changes, enlarged liver, frequent dermatosis (flaky paint rash), and a state of misery and disinterest in food (Reddy, 1991). Children with either marasmus or kwashiorkor are at high risk for corneal xerophthalmia due to severe vitamin A deficiency (Sommer & West, 1996). While both conditions are considered to result from severe deficiencies in energy and protein, their distinct clinical and biochemical profiles (Di Giovanni et al., 2016) suggest that this description is an oversimplification, with differences in other nutrient deficiencies and oxidative stress offering potential explanations for their occurrence (Golden, 2002). The case fatality rate for severe acute malnutrition is high (Brown et al., 1981).

FIGURE 7-3 Mild underweight (clinically normal appearance) and marasmus (evident by extreme wasting of limbs and torso) in 1-year-old Bangladeshi fraternal twins. The child on the left is a boy, and the child on the right is a girl.

Undernutrition During Pregnancy

When it occurs during pregnancy, undernutrition has significant consequences for both the mother and her developing fetus. Intrauterine growth restriction (IUGR) may develop in the fetus if the mother begins her pregnancy malnourished or does not gain a sufficient amount of weight during gestation (Institute of Medicine [IOM], 2003). Other factors might also cause IUGR, such as smoking or pregnancy-induced hypertension. IUGR is assessed in a variety of ways. Historically, the primary criteria was low birth weight (LBW; less than 2,500 g), although a lower weight at birth may be due to either IUGR or to earlier gestational age at delivery (Kramer, 1987). Infants born preterm (less than 37 weeks' gestation) may have lower weight at birth, but might not be growth restricted. A child with a weight or length below the 10th percentile of the sex- and gestational age-specific growth reference would be considered small for gestational age (SGA) (Alexander, Himes, Kaufman, Mor, & Kogan, 1996).

Unlike with the child growth standards, there is some debate over whether country- or ethnic-specific fetal growth charts should be used. Two sets of fetal growth standards for international use have been released in recent years. In 2014, an international consortium (INTERGROWTH-21st) released a set of fetal growth standards based on data from 60,000 pregnancies in Europe (Turin, Italy, and Oxford, United Kingdom), Asia (Muscat, Oman; Beijing, China; and Nagpur, India), North America (Seattle, Washington), South America (Pelotas, Brazil), and Africa (Nairobi, Kenya) (Villar et al., 2014). This study found relatively similar patterns of fetal growth across participating countries, supporting the idea that a single growth standard could be used globally. In 2017, however, WHO examined fetal growth patterns using data from 1,387 pregnancies in Europe (Copenhagen, Denmark; Paris, France; Hamburg-Eppendorf, Germany; Bergen, Norway), Asia (Delhi, India, and Khon Kaen, Thailand), South America, (Rosario, Argentina, and Campinas, Brazil), and Africa (Assiut, Egypt, and Kinshasa, Democratic Republic of Congo) (Kiserud et al., 2017). This study found significant heterogeneity in growth patterns between countries that could not be fully explained by differences in maternal height, health during pregnancy, or other factors.

Adequate maternal weight gain during pregnancy is essential for a healthy pregnancy. Weight gain recommendations vary, depending on the prepregnancy maternal BMI (**TABLE 7-2**). These recommendations are based on evidence that women who gain insufficient weight are at a greater risk of adverse birth outcomes, including stillbirth, SGA, and preterm birth (Goldstein et al., 2017; IOM, 2009). In contrast, women who gain too much weight are at risk of developing gestational diabetes mellitus (GDM) and hypertensive disorders during pregnancy, as well as retaining excess weight postpartum. Their infants are at elevated risk of requiring a cesarean delivery and developing obesity in later childhood. Recently, other research groups have evaluated whether these standards are appropriate for use in low-income country settings. A study of healthy pregnant women in Malawi who delivered live-born singleton, normal-weight, term infants reported lower weight gain during pregnancy than recommended by the IOM (Xu, Luntamo, Kulmala, Ashorn, & Cheung, 2014), drawing into question the usage of the North American standard for use in African populations.

TABLE 7-2 Weight Gain Recommendations for Pregnancy

Prepregnancy Weight Category	Body Mass Index (kg/m^2)	Recommended Range of Weight Gain (kg)	Recommended Rates of Weight Gain in the Second and Third Trimesters (range [kg/wk])
Underweight	Less than 18.5	12.5–18	0.44–0.58
Normal weight	18.5–24.9	11.5–16	0.35–0.50
Overweight	25–29.9	7–11.5	0.23–0.33
Obese	30 and greater	5–9	0.17–0.27

Modified from Institute of Medicine. (2009). *Weight gain during pregnancy: Reexamining the guidelines* (Table S-1, pp. 2). Washington, DC: National Academies Press. Copyright 2009 by the National Academy of Sciences.

Population Trends

Estimates of the prevalence of stunting, wasting, and underweight compiled by the United Nations Children's Fund (UNICEF), WHO, and the World Bank suggest that there were nearly 155 million children stunted (HAZ < −2) and 16.9 million severely wasted (WHZ < −3) in 2016 (**TABLE 7-3**). These conditions afflicted nearly 23% and 2.5% of children, respectively. Although the highest prevalence of stunting occurs in Eastern Africa, where 36.7% of children are stunted, the largest number of children who are stunted—61 million—live in South Asia. As an indicator of prenatal

TABLE 7-3 Estimated Prevalence (%) and Number (in millions) of Children Affected by Moderate to Severe Stunting (HAZ < −2) or Severe Wasting (WHZ < −3) by UN Region in 2016

	Stunting		Severe Wasting	
	Percentage Stunted	Number Stunted	Percentage Wasted	Number Wasted

Data from UNICEF, WHO, & World Bank, 2017.

undernutrition, an estimated 15% to 20% of infants are born with low birth weight, although there is considerable uncertainty about this estimate because nearly half of infants are not weighed at birth (WHO, 2014a).

Over the past 30 years, the prevalence of most forms of undernutrition has been declining globally. Notably, the prevalence of stunting declined from 39.5% in 1990 to 22.9% in 2016 (UNICEF, WHO, & World Bank, 2017), resulting in nearly 100 million fewer children stunted. Despite these impressive gains, the average rate of reduction has not been on track to achieve the World Health Assembly targets (**EXHIBIT 7-1**). The declines also have been uneven across regions. The fastest declines have been in Asia, particularly East Asia, where there was a decline from 48% in 1990 to 24% in 2016 (**FIGURE 7-4**). By contrast, the corresponding decline in Africa was from 42% to 32%. This was offset by the overall population growth in the African region, however, which means that there were actually 12.5 million more stunted children in Africa in 2016 than in 1990.

EXHIBIT 7-1 Using Data to Track Progress Towards Achieving Nutrition Goals

Since the launch of the Millennium Development Goals in 2000 and the release of the Sustainable Development Goals in 2015, it has been increasingly recognized that the effective use of data can stimulate global development efforts. In 2012, the World Health Assembly endorsed a set of six global nutrition targets that it aimed to achieve by 2025:

- A 40% reduction in the number of children younger than age 5 who are stunted
- A 50% reduction in anemia among women of reproductive age
- A 30% reduction in low birth weight
- No increase in child overweight
- A 50% increase in the rate of exclusive breastfeeding in the first 6 months
- Maintenance or reduction in child wasting to less than 5% (WHO, 2014b)

At the time that these targets were adopted, few countries were routinely collecting data on all six of these indicators. The Global Nutrition Report, which was launched in 2014, was designed as a mechanism to track countries' progress and hold them accountable to achieving the targets, highlight success stories, and serve as means of advocating for change. In 2016, only 41 of 193 countries were considered to be on track toward meeting the stunting target, but 79 lacked sufficient data to track progress (International Food Policy Research Institute [IFPRI], 2016). Only 36 were on track to meet the exclusive breastfeeding target, but 110 lacked data on this issue. Moreover, despite more complete data with which to monitor trends, only 3 countries were on target to meet the anemia target. Routine data collection on the prevalence of low birth weight has been notably absent in many countries, rendering it impossible to track progress on achieving the goal. In many places, this may be due to a lack of skilled birth attendants or inadequate equipment available to weigh newborns. There is a need for a global data revolution to aid in nutrition monitoring efforts, to track progress at the country level, and to better target policies and programs to the most vulnerable populations that could stand to benefit most.

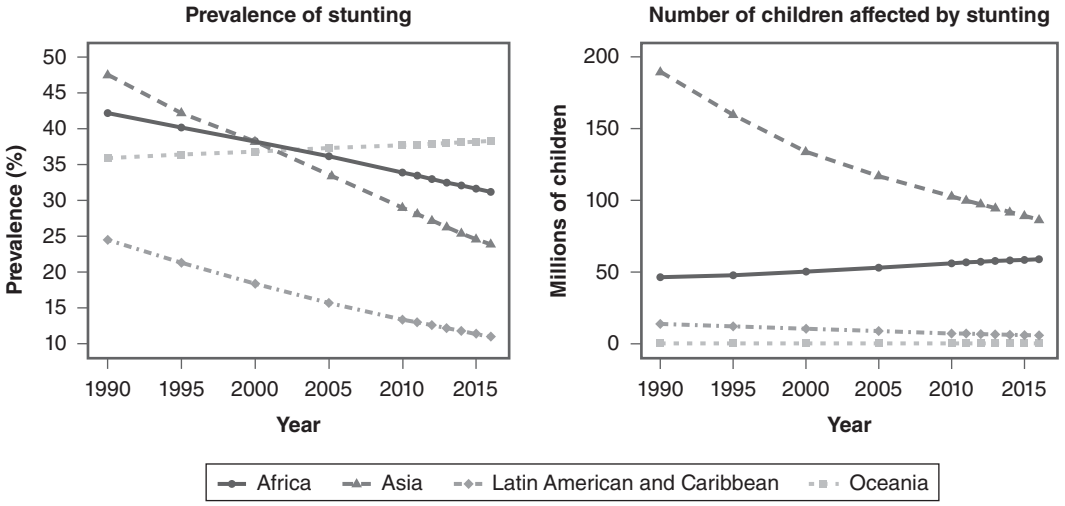

FIGURE 7-4 Trends in the prevalence and number of children affected by stunting from 1990 to 2016.

Data from UNICEF, WHO, & World Bank, 2017.

Health Consequences

Undernutrition is a risk factor for infectious morbidity and associated case fatality among children in low-income countries. Among neonates, given that gestational age and age-adjusted size at birth are often correlated with nutritional status during early childhood, it is appropriate to consider these factors as part of a continuum of risk between nutrition and infection. Nevertheless, studies have generally examined separately the risk of mortality related to status at birth in the neonatal or infant period and the risk related to nutritional status throughout childhood, at least up to age 5 years.

Low Birth Weight: Morbidity and Mortality Risk. To examine the role of nutritional risk factors for morbidity and mortality early in life, it is important to evaluate births that have been subjected to fetal growth restriction, as characterized by their being small for gestational age. There is a larger body of literature on the risks of LBW that does not distinguish whether this condition was due to SGA, to preterm birth, or to both. Although recent analyses do provide the specific effects of SGA, the effects of LBW will also be considered because this metric remains a common measure of birth status when the gestational age of the newborn is difficult to determine.

LBW babies have the largest increase in risk during the neonatal period, and they continue to have additional risk in the post-neonatal period of infancy. In high-income countries, birth weights of 3,500 to 4,500 grams (7 lb, 11 oz to 9 lb, 14 oz) are associated with the lowest risk of neonatal mortality. The relative risk of neonatal mortality increases with birth weights less than 2,500 grams and increases even more for very LBW babies of less than 1,500 grams (3 lb, 3 oz) (Ashworth, 1998). In low-income countries, the data are more limited due to the difficulty of obtaining accurate birth weight measurements for deliveries, which occur predominantly in the home. In these settings, neonatal mortality rates typically range as high as 50 deaths per 1,000 live births, and increase with decreasing birth weight. A pooled analysis of 20 birth cohorts with data on more than 2 million live births from Africa, Asia, and Latin America provides the relative risk of mortality associated with SGA (Katz et al., 2013). The pooled relative risk for babies who were SGA (birth weight in the lowest 10th percentile compared with a reference population) was 1.83 (95% confidence interval [CI], 1.34–2.50) for neonatal mortality and 1.90 (95% CI, 1.32–2.73) for post-neonatal mortality.

Because of the importance of diarrhea and pneumonia as causes of death in children in low-income countries, studies have evaluated whether LBW confers additional risk for deaths from these two causes. In three studies conducted in low-income countries, the increased risk of diarrheal deaths during infancy was 2.5- to 2.8-fold for LBW babies (Ashworth & Feachem, 1985). Likewise, the risk of death from acute lower respiratory infection was increased, but with more variability; the relative risk ranged from 1.6 to 8.0 (Victora et al., 1999).

As might be expected from these studies of infant mortality, LBW has also been shown to be a risk factor for diarrheal and respiratory morbidity (Ashworth & Feachem, 1985; Victora et al., 1999). Studies in Papua New Guinea (Bukenya, Barnes, & Nwokolo, 1991), Thailand (Ittiravivongs, Songchitratna, Ratthapalo, & Pattara-Arechachai, 1991), and Brazil (Victora, Barros, Kirkwood, & Vaughan, 1990) found a relative risk associated with LBW, adjusted for other possible determinants of illness, ranging from 1.6 to 3.9 for acute diarrhea. Studies in China (Chen, Yu, & Li, 1988), Argentina (Cerquerio, Murtagh, Halac, Avila, & Weissenbacher, 1990), and Brazil (Victora et al., 1990; Victora, Smith, Barros, Vaughan, & Fuchs, 1989) found a relative risk ranging from 1.4 to 2.2 for acute lower respiratory infection or pneumonia hospitalization.

Beyond its immediate effects on survival and morbidity, LBW is associated with stunting in later childhood (Christian et al., 2013). Likewise, it is associated with increased risk of chronic diseases in adulthood (Uauy, Kain, & Corvalan, 2011).

Anthropometric Deficits in Children: Morbidity and Mortality Risk. Anthropometric status in early childhood is related to the risk of mortality and subsequent infectious disease. Severe malnutrition clearly carries a high risk of death, but it is the interaction of undernutrition with common infectious diseases in low-income countries that is of greater importance for mortality. This relationship reflects the synergy between undernutrition and infectious diseases in which the combined conditions result in much greater mortality than either would alone (Scrimshaw, Taylor, & Gordon, 1968). Compromised host defenses and more severe infectious diseases in undernourished children may lead to higher case fatality rates, although an increased incidence of infectious diseases may play some role as well.

A review of the observational population studies in a large number of countries clearly reveals a monotonic increase in the risk of mortality at each progressively worse level of anthropometric status compared to the WHO growth standards or other reference populations (Caulfield, de Onis, Blossner, & Black, 2004; Olofin et al., 2013; Pelletier, Frongillo, & Habicht,

1993). In the most recent pooled analysis of 10 prospective studies from Africa, Asia, and South America, all degrees of anthropometric deficits increased the hazards of dying (**TABLE 7-4**) (Olofin et al., 2013).

It is important to note that even mild to moderate undernutrition puts a child at increased risk of mortality. Because the greatest number of undernourished children have mild to moderate undernutrition rather than severe malnutrition, most of the excess risk of death is attributable to the less severe forms of undernutrition. Also important is the observation that with worsening levels of anthropometric status, the mortality rate increases logarithmically. An estimated 14.7% and 12.6% of all childhood deaths have been attributed to stunting and wasting, respectively (Black et al., 2013).

Diarrheal diseases and pneumonia are the two most important infectious causes of death in children

younger than 5 years of age in low-income countries (Liu et al., 2016). These two conditions have a higher case fatality rate in undernourished children compared to those who are well nourished. For example, malnourished children who were discharged from a hospital after treatment for diarrheal illness in Bangladesh had a 14-fold greater risk of dying compared with better-nourished controls (Roy, Chowdhury, & Rahaman, 1983). In a community-based study in rural India, severely wasted children had a 24-fold higher diarrheal case fatality rate compared with better-nourished children (Bhandari, Bhan, & Sazawal, 1992). In Mexico, undernourished children had an 8-fold greater risk of death with severe diarrhea (Tome, Reyes, Rodriguez, Guiscafre, & Gutierrez, 1996). Studies in the Philippines (Tupasi et al., 1990), Papua New Guinea (Shann, Barker, & Poore, 1989), Bangladesh (Rahman et al., 1990), and Argentina (Weissenbacher et al., 1990) of acute lower respiratory infection and pneumonia found a 2- to 3-fold increase in the case fatality rate in undernourished versus better-nourished children. While measles fatality also rises with worsening nutritional status, fatality from malaria does not show this clear trend (Olofin et al., 2013).

Nutritional status has been assessed widely as a risk factor for the severity and incidence of diarrheal diseases. As might be expected with the reported higher case fatality rate in undernourished children, nutritional status has an association with disease severity. One measure of this relationship is the duration of the illness. In studies in several countries, the duration of diarrhea in mildly to moderately malnourished children was shown to be up to 3-fold longer than for better-nourished children (Black, Brown, & Becker, 1984a). Undernutrition is also an important risk factor for the occurrence of persistent diarrhea (Baqui et al., 1993). This relationship has been demonstrated for specific types of diarrhea, such as episodes due to *Shigella* species and enterotoxigenic *Escherichia coli*, in which the illness duration in Bangladeshi children was 2.5-fold longer in undernourished children (Black, Brown, & Becker, 1984b). Poorer nutritional status has also been documented to be associated with an increased rate of stool output in children, leading to an increased risk of dehydration (Black et al., 1984a). These mechanisms likely explain the increased risk for hospitalization and length of hospital stay due to diarrhea in undernourished children (Man et al., 1998; Victora et al., 1990).

The effect of undernutrition on diarrheal incidence has been more variable in different settings. Some studies have not found any increased risk of overall incidence in undernourished children, whereas others have found a 30% to 70% increased risk of incident diarrhea in such children (Black et al., 1984a; Checkley et al., 2002; El Samani, Willett, & Ware, 1986; Guerrant, Schorling, McAuliffe, & de Souza, 1992). Some enteropathogens causing diarrhea, such as *Cryptosporidium parvum*, may be particularly selected as a cause of infection in undernourished children (Checkley et al., 1998).

The role of undernutrition as a risk factor for severity or incidence of acute lower respiratory infections or pneumonia has also been the subject of extensive study. Evidence supports an association between undernutrition and severity of respiratory infection, with such relationships being found in both hospital-based and community-based studies. Undernutrition has been found to increase the likelihood that a child will have bacteremia, pleural effusion, and other complications (Johnson, Aderele, & Gbadero, 1992). Studies in the Philippines, Costa Rica (James, 1972), and Brazil (Fonseca et al., 1996; Victora et al., 1989) found a modestly increased incidence of acute lower respiratory infections in undernourished children. In contrast, studies in Papua New Guinea (Smith, Lehman, Coakley, Spooner, & Alpers, 1991), Uruguay (Selwyn, 1990), and Guatemala (Cruz et al., 1990) did not find any such relationship. A meta-analysis found that underweight status (less than −2 weight-for-age *z*-scores) confers an increased relative risk of pneumonia of 1.86 (95% CI, 1.06–3.28) (Fishman et al., 2004). One study in Gambia found that the development of pneumococcal infection was associated with a history of poor weight gain prior to the illness compared with other children in the community (O'Dempsey et al., 1996).

Early observations reported that malaria was more frequent in those persons with inadequate diets or with undernutrition (Garnham, 1954). Later studies appeared to show that malnutrition could actually be protective against malaria. This contention was based on observational studies (Hendrickse, Hasan, Olumide, & Akinkunmi, 1971) and on interventions such as the refeeding of famine victims (Murray, Murray, Murray, & Murray, 1975) in which an exacerbation of malaria appeared to occur. Animal studies seemed to support the suppressive effects of a poor diet on malaria, leading to the belief that undernourished children are less susceptible to the infection and consequences of malaria. If refeeding a malaria-infected, starved host can reactivate the low-grade infection and lead to more severe disease, antimalarial measures should be included during nutritional rehabilitation of famine victims who are likely to have malaria infection.

In addition to its association with increased risk of infection, chronic undernutrition has insidious effects on brain development and cognitive function, which in turn hinders an individual's capacity to perform well in school and seek economic opportunities in

adulthood (Black et al., 2017). In a systematic review of numerous observational studies, it was estimated that each standard deviation (SD) increase in height-for-age *z*-score among children younger than 2 years is associated with an approximate 0.2 SD increase in cognitive abilities in early childhood—an effect size that largely persists into later childhood (Sudfeld et al., 2015). Longitudinal studies of malnourished children have also found long-term effects on occupational status, economic productivity, and wages (McGovern, Krishna, Aguayo, & Subramanian, 2017). Precise estimates of these effects are difficult to develop because of variations in the measurement of the exposure and outcome in each of the studies, but cross-sectional studies of adults have suggested that each 1 cm increase in stature is associated with a 4% increase in wages among men and a 6% increase in wages among women (McGovern et al., 2017).

Micronutrient Deficiencies

Overview

The term "micronutrients" refers to vitamins and minerals that must be provided in minute amounts in the human diet to support essential cellular and tissue functions of growth, development, maturation, and homeostasis at each stage of life (Ames, 2010; Fenech, 2010; Gernand, Schulze, Stewart, West, & Christian, 2016). Discovered through animal experiments and clinical studies over the past century, micronutrients known to be required from the diet, always or conditionally, to maintain health include four lipid-soluble vitamins (A, D, E, and K) and nine water-soluble vitamins (thiamin, riboflavin, niacin, pyridoxine, folate, and cobalamin [collectively termed "B-complex"], plus vitamin C, biotin, and choline), plus 12 inorganic elements, including iron, zinc, selenium, and copper (IOM, 2005). Guided by the Dietary Reference Intakes (IOM, 2005), which provide age-, sex-, and pregnancy and lactation–specific estimates of nutrient intake adequacy, a diet diverse in vegetables, fruits, whole grains, and animal-source foods (meat, poultry, fish, eggs, milk, and cheese) is usually adequate in micronutrients. Carefully planned vegetarian diets can also meet most vitamin and mineral requirements, except for vitamin B_{12}, for which animal foods are major sources. Micronutrient requirements are assumed to be largely met in the first 6 months of life through adequate breastfeeding by well-nourished mothers (IOM, 2005).

Micronutrient intakes at either extreme may adversely affect health. Deficient intakes are unable to meet normal requirements, perturbing genomic, translational, energetic, and stress response pathways that may adversely affect multiple immune, neural, and metabolic functions and disease risk (Ames, 2010). Consequences of deficiencies range from nonspecific effects (e.g., impaired cognition or growth) to nutrient-specific pathological conditions (e.g., xerophthalmia from vitamin A or goiter from iodine deficiencies), depending on the nutrients involved and their interactions, the duration and severity of the deficiency, life stage, and exacerbating conditions such as inflammation from infection, chronic disease, or toxic exposures (Kutlesic et al., 2017). Evidence is emerging that the gut microbiome, depending on its community structure and interactions, may affect host micronutrient nutriture by enhancing or inhibiting nutrient uptake, synthesizing vitamin intermediates, or otherwise affecting micronutrient metabolic pathways (Biesalski, 2016). Gene mutations that lead to a defect in nutrient uptake or metabolism (e.g., a polymorphism in a beta-carotene cleavage enzyme in the intestine required for conversion to vitamin A [Shete & Quadro, 2013]) are being discovered and may explain deficiencies in some population groups. In contrast, with expanding, overlapping, or poorly regulated micronutrient interventions, the potential exists for some nutrients (e.g., vitamin A) to be excessively consumed, highlighting the importance of both effective and safe prevention. These many factors emphasize the importance of preventing micronutrient deficiencies in the context of local or regional diets, disease risks, and environs.

The global public health community has historically focused on assessing and preventing vitamin A, zinc, iron, and iodine deficiencies due to their known high prevalence, health consequences, and preventability—for example, through supplementation, food fortification, and dietary diversification. In truth, this narrow focus also reflects lack of data on prevalence, health risks, and resources needed to prevent other micronutrient deficiencies. For this reason, micronutrient deficiencies are colloquially known as "hidden hunger" (Ruel-Burgeron et al., 2015), emphasizing the need for more comprehensive and readily available approaches to assessing micronutrient deficiencies in populations (Cole et al., 2013; Lu et al., 2017).

Vitamin A

Vitamin A deficiency is a nutritional burden of impoverishment with public health consequences, especially among preschool-age children, infants, and women of reproductive age in LMICs (Sommer & West, 1996). Estimating its global burden is challenging, as national surveys are infrequent, leaving estimates imprecise (Stevens et al., 2015; Wirth, Petry, et al., 2017); employ a wide range of status indicators,

making direct comparisons difficult; and are conducted against multiple-intervention landscapes (Wirth, Petry, et al., 2017). A study modeling trends in preschool child vitamin A deficiency (serum retinol < 0.70 μmol/L), based on national surveys from 1991–2013, suggests a prevalence of 29%, with the highest rates in South Asia (44%) and sub-Saharan Africa (48%) (**FIGURE 7-5**) (Stevens et al., 2015). These rates are approximately 10% lower than the global, South Asian, and sub-Saharan African rates of 33%, 50%, and 44%, respectively, obtained by WHO for the period 1995–2005 that led, at the time, to a global estimate of 190 million affected children (WHO, 2009). Thus, while still high, the vitamin A deficiency burden may be gradually lessening, possibly resulting from intensified prophylaxis through fortification, biofortification, and vitamin A supplementation under way in more than 80 countries (Wirth et al., 2017).

Data on vitamin A deficiency among older children, adolescents, and women remain sparse. One estimate suggests that 23% of children 5–15 years of age in Southeast Asia are vitamin A deficient, and 2.6% have mild xerophthalmia (Singh & West, 2004). Among pregnant women in LMICs, 8% (nearly 10 million) are estimated to experience night blindness, while some 19 million may be vitamin A deficient (WHO, 2009). Inexpensive, valid indicators of vitamin A status are needed to greatly improve estimation of this burden (Tanumihardjo et al., 2016).

Function, Requirements, and Assessment. Vitamin A comprises a group of molecules called retinoids, known to regulate numerous cell functions. As an aldehyde (retinal) acting with the protein opsin in photoreceptors of the eye, vitamin A enables light detection and transduction in a process known as the visual cycle (Saari, 2016); as a ligand in the cell nucleus, retinoic acid acts via specific receptors to regulate transcription of hundreds of genes (Blomhoff & Blomhoff, 2006), whose protein products mediate cellular differentiation, proliferation, apoptosis, and plasticity (Al Tanoury, Piskunov, & Rochette-Egly, 2013) plus extracellular matrix composition and signaling functions (Barber, Esteban-Pretel, Marin, & Timoneda, 2014). As retinol, vitamin A regulates enzymatic reactions and cellular bioenergetics (Brossaud, Pallet, & Corcuff, 2017). Through these diverse mechanisms, vitamin A nutriture affects the development, shape, and function of tissues beginning in embryonic life, with deficiency exerting adverse effects on vision, innate and adaptive immune mechanisms, neurotransmission, and bone metabolism and growth.

Vitamin A is provided through the diet as preformed esters in foods such as fish or animal liver, milk, dairy products, eggs, and fortified foods (e.g., vegetable oils, flour, or sugar), and as provitamin A carotenoids, comprising pigments found in yellow-orange vegetables (e.g., yellow sweet potato, carrot) and fruits (ripe mango or papaya) and in dark green leaves (e.g., spinach) (IOM, 2005). Certain indigenous foods may

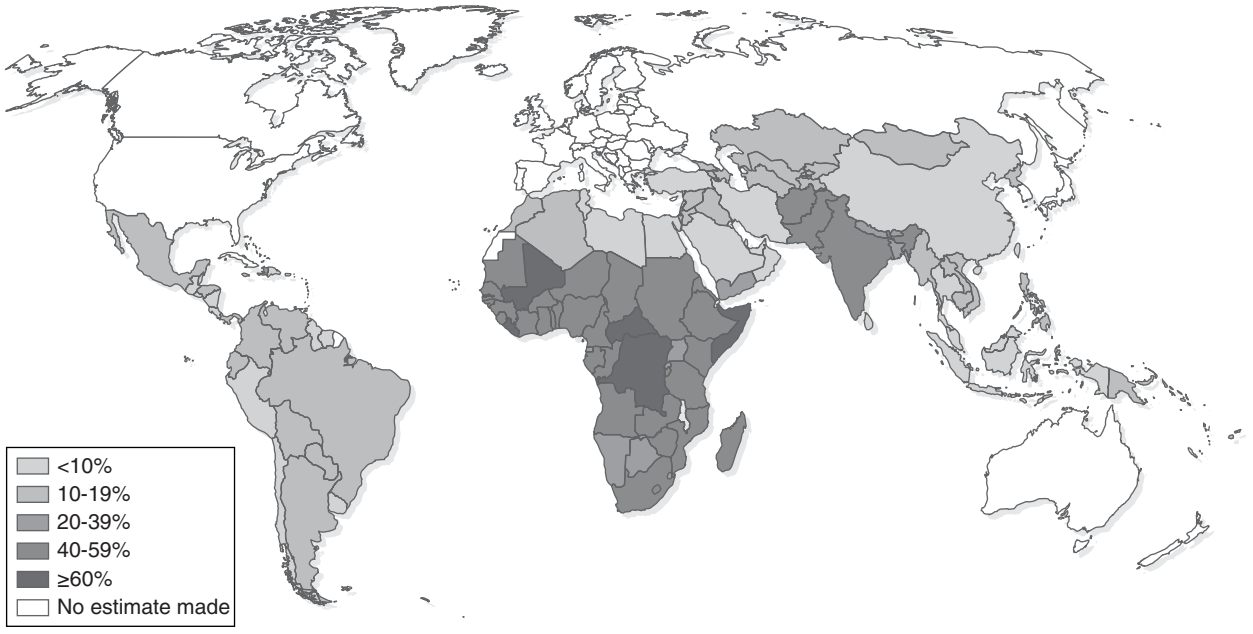

FIGURE 7-5 Estimated prevalence map of vitamin A deficiency among children 6–59 months of age from modeled trends based on serum retinol surveys of 138 countries between 1991 and 2013.

contribute provitamin A to the diet, as illustrated by gac (Aoki, Kieu, Kuze, Tomisaka, & Van Chuyen, 2002), buriti (Mariath, Lima, & Santos, 1989), and pandanus (Engleberger et al., 2006) fruits in Vietnam, Brazil, and the Western Pacific, respectively. Breast milk, which is affected by maternal vitamin A nutriture, provides a critical, protective dietary source of the nutrient to infants through the first 2 years of life (Haskell & Brown, 1999). After 6 months of age, complementary feeding must contribute dietary sources of vitamin A to protect against xerophthalmia and other deficiency disorders (Sommer & West, 1996). As vitamin A is stored in the liver and released into circulation, deficiency typically requires a prolonged period of inadequate intake, during which hepatic stores gradually decrease to low levels; in turn, this leads to low serum (or plasma) retinol concentrations, altered tissue function, and increased risk of impaired health (Tanumihardjo et al., 2016).

Assuring dietary adequacy of vitamin A in children and women of reproductive age is a public health priority, evaluated by comparing intakes, as retinol activity equivalents (RAEs) that combine contributions from preformed and provitamin A food sources (assuming a beta-carotene-to-retinol conversion of 12:1), to age-sex specific Estimated Average Requirements (EARs) and Recommended Dietary Allowances (RDAs) (IOM, 2005) (**TABLE 7-5**). These indices specify intakes at which 50% and 97.5%, (i.e., +2 SD above the EAR), respectively, of a healthy population can meet requirements for vitamin A. When an EAR (and, therefore, RDA) is not computable for an age group, such as infancy, an Adequate Intake (AI) has been derived based on observed intakes in healthy

TABLE 7-5 Dietary Reference Intakes: Estimated Average Requirement and Recommended Dietary Allowances for Vitamin A by Life Stage Group

		Dietary Reference Intakes (IOM, 2006)	
	Sex	EAR[a]	RDA[a]
Life Stage Group		RAE/d[b]	
≤ 6 months	Both male and female		400 (AI)[a]
7–12 months	Both male and female		500 (AI)[a]
1–3 years	Both male and female	210	300
4–8 years	Both male and female	275	400
9–13 years	Male/female	445/420	600/600
14–18 years	Male/female	630/485	900/700
19–70 years or older	Male/female	625/500	900/700
Pregnancy			
≤ 18 years	Female	530	750
19–50 years	Female	550	770
Lactation	Female	900	1,300

Data from IOM. (2006). *Dietary reference intakes: Essential guide to nutrient requirements* (Vitamin A Chapter, Table 1, pp. 170). J. J. Otten, J. P. Hellwig, & L. D. Meyers (Eds.). Washington, DC: National Academies Press. Copyright 2006 by the National Academy of Sciences.

populations. The RDA for vitamin A is 300 to 600 μg RAE/day for children up to 13 years of age, and 700 to 900 μg RAE/day thereafter for both sexes, including for women during pregnancy, but increases to 1,300 μg/day during lactation. Intakes that are chronically below the EAR by age and sex can be expected to place populations at risk of vitamin A deficiency.

Vitamin A status is commonly assessed by clinical, biochemical, and functional indicators. Serum (plasma) retinol concentration remains the most commonly measured biochemical indicator, with a concentration less than 0.70 μmol/L being indicative of deficiency (Tanumihardjo et al., 2016) and prevalences of 10% or greater and 20% or greater reflecting WHO cut-offs marking moderate public health concerns and severe public health concerns, respectively (WHO, 2011a).

Although usually maintained within a normal range when adequately nourished, serum retinol falls progressively with depletion of body stores. It also declines in response to inflammation—for example, with infection. This latter response, which is attributed largely to retinol binding protein (RBP; the major transport protein) being sequestered in the liver, suggests that serum retinol may be stratified (or adjusted) by biomarkers of inflammation, such as C-reactive protein and α_1-acid glycoprotein, in affected populations. Because these biomarkers respond to severity and duration of inflammation, their use allows fractions of low serum retinol to be potentially explained by stages of infection versus nutritional deficiency (Thurnham, Mburu, Mwaniki, & De Wagt, 2005).

Although serum retinol remains the most common population indicator of vitamin A status, other approaches include measurements of serum RBP, breast milk and dried blood spot retinol concentrations, relative response tests following administration of a small oral dose of vitamin A (approximating liver store relative adequacy), stable isotope dilution (to estimate total body vitamin A stores), and functional tests of dark adaptation (Tanumihardjo et al., 2016). Each of these approaches has its own strengths, limitations, and costs that guide its use.

Health Consequences

Xerophthalmia. Ocular manifestations of vitamin A deficiency include night blindness and Bitot's spots (**FIGURE 7-6A**), each of which may affect 1% to 5% of preschoolers in a high-risk population. A far less common manifestation is the potentially blinding keratomalacia ("softening of the cornea"; **FIGURE 7-6B**).

Night blindness (designated XN), the mildest symptom, results from a depletion of vitamin A in the rod photoreceptors of the eye and inability to see under low-light conditions (Sommer, 1995). Night blindness is often detectable by history, using a local term that may refer to *twilight or evening blindness* or *chicken eyes* (chickens' eyes lack rods, so these animals are night blind). Pregnant women may become night blind in the latter half of pregnancy due to gestational demands in the context of an inadequate diet (Christian, 2002). XN usually disappears in both children and mothers within 24–48 hours following vitamin A treatment per WHO guidelines (Sommer, 1995).

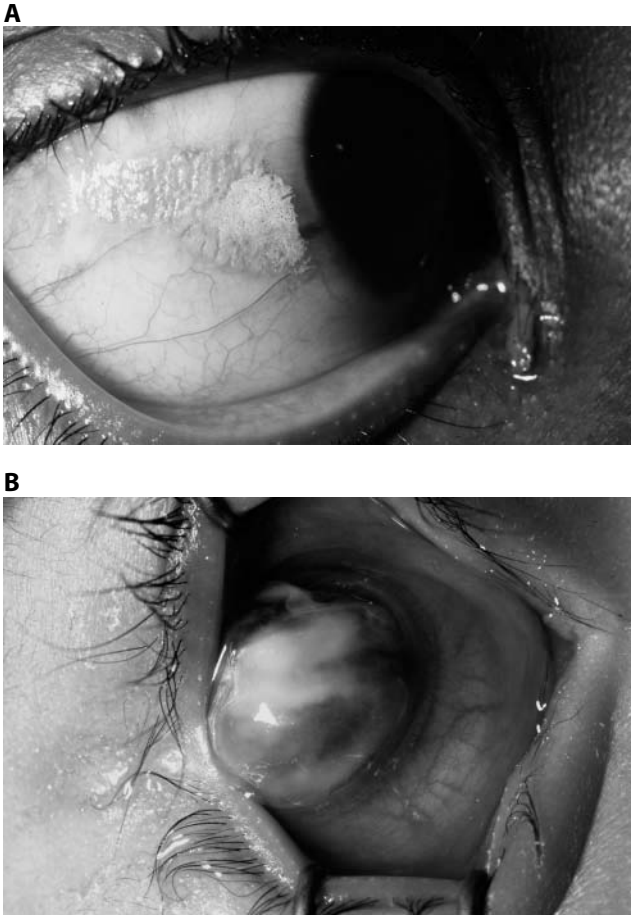

FIGURE 7-6 A. Bitot's spot. **B.** Keratomalacia.

Reprinted with permission of Oxford University Press, Inc. Photos courtesy of Randy Whitfield and Alfred Sommer.

Bitot's spots (X1B), the next most severe clinical stage, appear on the conjunctiva as cheesy or foamy patches of keratinized, sloughed cells. X1B does not affect vision and regresses following vitamin A treatment over a period of weeks, although it may not always disappear. While representing mild ocular disease, XN and X1B reflect moderate-to-severe systemic vitamin A deficiency, evident by their positive association with morbidity and mortality in young children (Sommer, Hussaini, Tarwotjo, & Susanto, 1983) and (for XN) pregnant women (Christian et al., 2000).

Keratomalacia (X3) represents a blinding stage of xerophthalmia. It is associated with a high risk of fatality, with death usually precipitated by measles or other severe infections. Vitamin A therapy will heal the cornea in patients with X3, but may not preserve vision, depending on the extent and severity of corneal destruction (Sommer & West, 1996).

Morbidity. Vitamin A supplementation has been shown to reduce severity of infections, including diarrhea or dysentery (Stevens et al., 2015), measles (Fawzi, Chalmers, Herrera, & Mosteller, 1993), malaria (Shankar et al., 1999), and other infectious illnesses. In addition, it can reduce hearing loss associated with purulent ear discharge (Schmitz et al., 2012), an effect likely explained by effects of the vitamin in maintaining normal epithelial barrier (Sommer & West, 1996) and by innate and adaptive immune function (Beijer, Kraal, & den Haan, 2013), including tolerance and the capacity to resolve infections (Mora & Iwata, 2015). While animal studies reveal vitamin A deficiency may also compromise lung defenses and, in human studies, be associated with an increased risk of respiratory infection (Sommer & West, 1996; Thornton, Mora-Plazas, Marin, & Villamor, 2014), vitamin A supplementation does not appear to reduce risk of lower respiratory infections (Nacul et al., 1998; Vitamin A and Pneumonia Working Group, 1995), for reasons that remain unclear.

Mortality. Vitamin A deficiency increases the risk of mortality among preschool-age children, including infants, in underserved and undernourished regions. Large community trials in South Asia and Africa, designed and implemented to test the efficacy of supplementation, have shown that vitamin A, delivered as a high oral dose every 4–6 months (200,000 IU for children 12 months or older, half-dose at age 6–11 months), or as a weekly small dose (15,000 IU), or provided as a fraction of an RDA daily via food fortification, can reduce preschool child mortality by 23% to 34% (Beaton et al., 1993; Fawzi et al., 1993; Sommer & West, 1996) (**FIGURE 7-7**). Embedded in this decline in all-cause mortality are likely strong effects of vitamin A in reducing the case fatality of measles, which has been documented in both community (Rahmathullah et al., 1990; West et al., 1991) and hospital-based trials (Barclay, Foster, & Sommer, 1987; Coutsoudis, Broughton, & Coovadia, 1992; Hussey & Klein, 1990), and in decreasing the severity of diarrhea and dysentery (Arthur et al., 1992; Banajeh, 2003; Stevens et al., 2015) and *Plasmodium falciparum* malaria (Shankar et al., 1999). Evaluations of vitamin A programs may yield estimates of impact that are higher, if accompanied by other interventions that enhance child survival (Thapa, Choe, & Retherford, 2005). Conversely, such estimates may be lower if design, implementation, and resource constraints affect the quality of either the program or its evaluation (Awasthi et al., 2013; West, Sommer, Palmer, Schultink, & Habicht, 2015).

Early neonatal vitamin A supplementation (oral 50,000 IU dose) has been evaluated for efficacy in reducing infant mortality. An early, positive trial from Indonesia (Humphrey et al., 1996) was followed by 10 additional trials across the Southeast Asian, Eastern Mediterranean, and African regions to assess the effect on mortality in the first 6 months of life (**TABLE 7-6**). While no effects were observed in Africa (Malaba

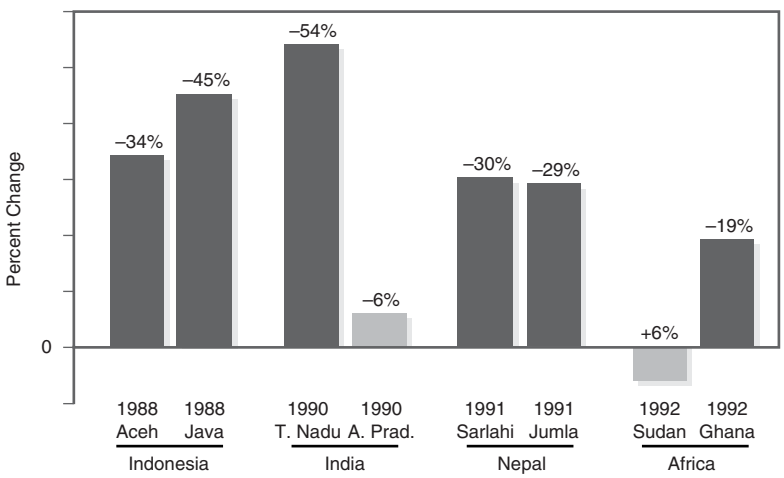

FIGURE 7-7 Summary of percent change in all-cause mortality of children (approximately 6 months or older to 72 months) receiving vitamin A versus no vitamin A (controls) in eight field intervention trials. Black bars represent statistically significant reductions; white bars indicate nonsignificant change. Total *N* (across trials) >165,000 children. Meta-analyses showed overall 23% to 34% reductions in mortality with vitamin A.

[1] Mortality rate ratios reported per 1,000 infant-years

[2] Reported value is an odds ratio

et al., 2005; Benn et al., 2008, 2010, 2014; Edmond et al., 2014; Masanja et al., 2014), or Eastern Mediterranean (Soofi et al., 2017) regions, 10% to 64% reductions in all-cause mortality (relative risks of 0.90 to 0.36) were reported from trials in Southeast Asia (Humphrey et al., 1996; Klemm et al., 2008; Rahmathullah et al., 2003; Mazumder et al., 2014). The stark regional differences may be partly explained by more pronounced gestational vitamin A deficiency in Southeast Asia (Rotondi & Khobzi, 2010). In South India, where morbidity was monitored, fatality related to diarrhea and fever was reduced 45% and 37%, respectively (Tielsch et al., 2007). Animal vitamin A repletion experiments in the puerperium support strengthened intestinal mucosal immune responses (Liu et al., 2014) and less colitic inflammation (Reifen et al., 2002) in vitamin A–replete versus vitamin A–deficient offspring as plausible mechanisms of action. Newborn vitamin A receipt was also associated with delayed pneumococcal colonization of the respiratory tract at 2–4 months of age in India (Coles et al., 2001), suggesting an additional possible pathway of effect.

Effects of antenatal vitamin A supplementation on pregnancy outcome and maternal mortality have been examined in South Asia and West Africa. In Nepal, where maternal night blindness was associated with increased morbidity, anemia (Christian et al., 1998), and mortality through 2 years postpartum (Christian et al., 2000), weekly, maternal low-dose vitamin A or beta-carotene supplementation reduced pregnancy-related mortality by approximately 40% (West et al., 1999), but had no overall effect on infant mortality (Katz et al., 2000). However, offspring of vitamin A–supplemented mothers followed to pubescence exhibited greater lung (Checkley et al., 2010) and innate immune (Palmer, Schulze, Khatry, De Luca, & West, 2015) capacity. In rural Bangladesh, a similar weekly vitamin A or beta-carotene regimen revealed no effect on materno-infant mortality (West et al., 2011), although risk of maternal bacterial vaginosis was reduced (Christian et al., 2011). In Ghana, where maternal night blindness is rare, weekly vitamin A during pregnancy also had no effect on mortality (Kirkwood et al., 2010), suggesting that levels of maternal vitamin A deficiency may influence health outcomes of this intervention.

Poor Growth and Anemia. Vitamin A is required for mammalian growth. Children with mild xerophthalmia (XN or X1B) are more likely to be stunted than children who do not have xerophthalmia (Sommer & West, 1996). Nevertheless, growth responses to population-based vitamin A supplementation have revealed mixed results, with most studies finding either no effect (Ramakrishnan, Aburto, McCabe, & Martorell, 2004) or seasonal, subgroup, sex-specific, or anthropometry-specific effects (Sommer & West, 1996).

Vitamin A regulates erythropoiesis, modulates iron metabolism and mobilization, and influences immune functions, providing plausible pathways by which vitamin A deficiency could lead to an increased risk of anemia (Christian et al., 1998; Semba & Bloem, 2002). Where deficiency is endemic, there is moderate evidence from meta-analyses that vitamin A supplementation during pregnancy may reduce maternal anemia by one-third (odds ratio [OR], 0.64; 95% CI, 0.43–0.94) (McCauley, Van Den Broek, Dou, & Othman, 2015).

Iron Deficiency and Anemia

Iron is essential in the body for oxygen transport and cellular respiration—functions that are especially critical in red blood cells, brain, and muscle (Beard, 2001). Iron deficiency is considered the most common micronutrient deficiency in the world; anemia, characterized by abnormally low blood hemoglobin concentration, is its major clinical manifestation. Although anemia is not specific to iron deficiency, the two conditions are closely linked in most malnourished populations, making anemia the most frequently reported clinical index of iron deficiency in low-income countries (WHO, 2007).

Anemia has both nutritional and non-nutritional causes. Major non-nutritional causes of red cell mass loss or destruction and consequent anemia include hookworm, schistosomiasis, trichuris, malaria, or HIV infections (Thurnham & Northrop-Clewes, 2007) as well as inherited hemoglobin disorders such as sickle cell or thalassemia (Engle-Stone et al., 2017). The term *nutritional anemia* goes beyond iron deficiency and includes the anemia due to deficiencies in other nutrients, particularly vitamin A, folate, riboflavin, and vitamin B_{12} (Fishman, Christian, & West, 2000), and trace elements that participate in erythropoiesis (Olivares, Hertrampf, & Uauy, 2007; Semba, 2007). Approximately half of the global burden of anemia appears to be responsive to iron supplementation (Gera, Sachdev, Nestel, & Sachdev, 2007). At the same time, iron deficiency may occur without the development of anemia (Engle-Stone et al., 2017; Wirth et al., 2017). The relative degree to which the distributions of anemia and iron deficiency overlap varies by the underlying burden of infection and by the prevalence of nutritional deficiencies. In many low-income populations, where the burden of infectious disease is high and micronutrient deficiencies are common, it is difficult to determine which of these factors may be the primary cause of anemia; in turn, multiple strategies might be needed to address these conditions.

An estimated 800 million children and women of reproductive age are anemic and 153 countries are classified as having anemia prevalence of moderate to severe public health significance (WHO, 2015a). In the period between 1995 and 2011, there was a modest reduction in the prevalence of anemia worldwide; however, due to population growth, the absolute numbers of women and children affected have increased (Stevens et al., 2013). Pregnant women, infants, and young children are at highest risk of anemia. On average, an even higher percentage of preschool-age children are anemic than pregnant women or other women of reproductive age (**TABLE 7-7**). The condition affects 42% of children, or an estimated 273 million worldwide. Africa and Southeast Asia have the highest burden of anemia, and presumably iron deficiency: An estimated 54% to 62% of young children and 46% to 48% of pregnant women in those regions have anemia. However, the largest number of people with anemia live in Southeast Asia, where roughly 97 million children, 11 million pregnant women, and 191 million nonpregnant women are estimated to suffer from anemia.

Function, Requirements, and Assessment. In the body, iron is found in metabolically active "functional" and "storage" pools, accounting for approximately 75% and 25% of total body iron, respectively (Lönnerdal & Hernell, 2013). Approximately 80% of functional iron complexes with hemoglobin during erythropoiesis, where it plays a central role in oxygen transport to cells. Ten percent of this metabolic iron pool is incorporated into intracellular myoglobin, where oxygen is stored for use during muscle respiration and contraction. In addition, iron serves as a cofactor in more than 200 heme and nonheme enzymes involved in cellular respiration, division, neurotransmission, immunity, and growth (Beard, 2001). It plays a catalytic role in numerous metabolic oxidation–reduction (redox) reactions due to the ability of ferrous (Fe^{2+}) and ferric (Fe^{3+}) iron to donate and accept electrons, respectively. However, excess iron can promote the formation of reactive oxygen species that can cause damage to DNA, proteins, or lipids within cells (Coffey & Ganz, 2017).

During pregnancy, there is an additional iron requirement for maternal red blood cell expansion and fetal growth and development (Cao & O'Brien, 2013). During the fetal and infant periods, iron is essential for the developing brain through its role in neurogenesis and differentiation, neurotransmitter synthesis, and energy metabolism in the brain (Beard, 2008; Lozoff et al., 2006). Iron also plays an important role in the human innate immune system, such that deficiency of this mineral may result in thymic atrophy, a depression

of T-lymphocyte production and decreased neutrophil function (Jonker, Te Poel, Bates, & Boele van Hensbroek, 2017). These ubiquitous functions highlight the importance of adequate iron nutriture in achieving health benchmarks as diverse as normal physical performance, pregnancy, and motor and cognitive function.

The metabolic and functional pathways of iron in the body provide the basis for the indicators used to assess iron status. The total body iron balance is largely regulated at the point of absorption because humans lack a mechanism for controlled iron excretion (Coffey & Ganz, 2017). Human diets contain iron in two forms: (1) heme iron, derived mainly from hemoglobin and myoglobin found in meat, poultry, and seafood; and (2) various forms of inorganic non-heme iron, typically from plant sources. A higher proportion of heme iron is absorbed, making this the more bioavailable source of iron, yet non-heme iron is the predominant form of iron in most diets. When iron status is adequate, the hormone hepcidin will block the release of iron from enterocytes in the small intestine, causing excess iron to be lost when enterocytes are sloughed off into the intestinal lumen (Coffey & Ganz, 2017). During periods of iron deficiency, hepcidin expression is reduced, thereby allowing a greater proportion of iron to be transported into the plasma.

Newly absorbed iron as well as endogenous iron released from normal degradation of senescent red blood cells is transported to tissues by plasma transferrin. Although almost all cells require iron, the majority of transferrin-bound iron is delivered to bone marrow for red blood cell production—a process mediated by expression of a specific transferrin receptor that reflects tissue iron need (Coffey & Ganz, 2017; Knutson, 2017). Transferrin will also serve to deliver iron to ferritin, the major body iron storage protein, found primarily in the liver (Gibson, 2005).

During prolonged dietary deficit, iron is released from intracellular ferritin into the circulation via transferrin to support hematopoiesis, which has the effect of decreasing iron stores. As iron depletion progresses, transferrin carries and delivers a diminishing supply of iron to the marrow and other tissues. This stage of iron deficiency without anemia is reflected by increased transferrin receptor expression on cell surfaces, a low level of transferrin being saturated with iron, and increased amounts of circulating erythrocyte protoporphyrin, a protein that accumulates in red blood cells lacking iron. If the iron deficit continues, iron-deficiency anemia develops as hemoglobin concentration falls and red cells become smaller in size (microcytic) and more pale in color (hypochromic) (Gibson, 2005).

Several indicators may be used to track these changes in iron status, only a few of which are commonly used. Assessment of hemoglobin or hematocrit concentrations and evaluation of their distributions against conventional cut-offs by age, life stage, and gender (**TABLE 7-8**) is the standard approach for diagnosing and estimating the prevalence of anemia (WHO, 2011b). Hemoglobin concentrations are affected by altitude and smoking status, so adjustments should be made to account for those factors (Gibson, 2005). Simple diagnostic tools available to assess anemia in primary care settings include the clinical diagnosis of pallor (palmar, tarsal conjunctival, and nail bed), which can be used to identify severe anemia (hemoglobin less than 50 to 70 g/L or hematocrit less than 15%) with approximately 10% to 50% sensitivity and 90% to 100% specificity (Kalter et al., 1997; Luby et al., 1995). If facilities allow, assessment of additional hematologic measures is recommended, such as the mean cell volume (MCV), mean cell hemoglobin (MCH), and mean cell hemoglobin concentration (MCHC), all of which will be low in the presence of iron-deficiency anemia (Gibson, 2005). Assessing hemoglobin response to supplementation provides another, more accurate, but complex approach to estimating the extent of iron-deficiency anemia in populations (Gera et al., 2007).

TABLE 7-8 Commonly Used Indicators of Anemia in Various Life Stage Groups

	Anemia	
	Hemoglobin[a] (g/dL)	Hematocrit (%)
Children 0–5 years	<11.0	<33.0
Children 5–11 years	<11.5	<34.0
Nonpregnant women	<12.0	<36.0
Pregnant women		
First trimester	<11.0	<33.0
Second trimester	<10.5	<32.0
Third trimester	<11.0	<33.0
Men	<13.0	<39.0

[a] Hemoglobin cut-offs are for individuals residing at sea level.
Data from Cao & O'Brien, 2013; Gibson, 2005; WHO, 2011b.

Serum ferritin and transferrin receptors are more specific indicators of iron deficiency. Although the majority of ferritin is intracellular, serum ferritin concentrations are reflective of iron stores and will decline as the individual becomes deficient in iron. Concentrations less than 12 μg/L are indicative of iron deficiency. In contrast, serum transferrin receptors will be expressed in greater concentrations as cells signal the need for more iron, with concentrations greater than 8.3 mg/L being indicative of iron-deficient erythropoiesis (Rohner et al., 2017). Serum ferritin and, to a lesser degree, transferrin receptors are both sensitive to inflammation, making interpretation of their values in the presence of infection challenging. Various methods have been proposed to adjust ferritin and transferrin receptor estimates by measuring two inflammatory cytokines, C-reactive protein (CRP) and alpha-1 acid glycoprotein (AGP) (Namaste et al., 2017; Rohner et al., 2017; Thurnham et al., 2010). New multiplex, rapid immunoassays are being developed that include concurrent measurements of ferritin, CRP, and AGP, along with other micronutrients (Lu et al., 2017).

Other indicators of iron status that are useful, albeit less commonly used in resource-limited settings, include the measurement of zinc protoporphyrin, serum iron, total iron-binding capacity, and transferrin saturation. The latter three are useful for differentiating between iron-deficiency anemia and anemia due to chronic infections, inflammation, or neoplastic diseases (Gibson, 2005). For individual assessment and when resources allow, it is recommended that multiple iron status and red blood cell indices be measured to more specifically determine the likely cause of anemia or degree of iron deficiency (Gibson, 2005).

Health Consequences. The highest-risk groups, in terms of both probability of becoming anemic from iron deficiency and suffering its consequences, are women of reproductive age, especially during pregnancy; infants; and young children.

Pregnancy-Related Outcomes. Women are at high risk of anemia due to periodic menstrual blood loss and because of increased requirements during pregnancy due to expanded red blood cell mass and accretion of iron in fetal tissue and the placenta. In a multicountry study of severe adverse pregnancy outcomes, the most common risk factor for maternal death was severe anemia, which was present in 50% of cases (Lumbiganon et al., 2014). While no experimental trials have been undertaken to demonstrate that iron supplementation reduces maternal mortality, plausible causes associated with moderate to severe anemia include puerperal cardiac failure or hemorrhage (Allen, 1997). A meta-analysis suggests there is a continuous reduction in maternal mortality risk, reflected by a protective odds ratio of 0.75 (95% CI, 0.62–0.89), with each 1 g/dL increase in blood hemoglobin concentration (Stoltzfus, Mullany, & Black, 2004).

Risks of preterm delivery, low birth weight, fetal malformations, and fetal deaths have been found to follow a U-shaped curve with respect to maternal hemoglobin levels measured early in pregnancy, with an elevated hemoglobin level presenting as much or more risk of an adverse outcome as a lower hemoglobin concentration (Cao & O'Brien, 2013). Inadequate plasma volume expansion may explain some of the excess risk among those pregnant women with high hemoglobin concentrations, but the causal mechanisms yielding these risks are not well understood.

Maternal iron-deficiency anemia may also place newborns at risk of low iron stores during infancy (Cao & O'Brien, 2013). Iron supplementation during pregnancy has been found to reduce the risk of anemia at term and increase maternal hemoglobin levels at 6 weeks postpartum, although the protective effects on low birth weight and preterm delivery were somewhat weak and not statistically significant (LBW: relative risk [RR], 0.84; 95% CI, 0.69–1.03; preterm birth: RR, 0.93; 95% CI, 0.84–1.03) (Pena-Rosas, De-Regil, Garcia-Casal, & Dowswell, 2015).

Child Health Outcomes. Late infancy and early childhood is a high-risk period for iron deficiency and anemia because of the high iron supplies needed to support rapid growth coupled with low dietary intake of often poorly bioavailable iron (Dewey, 2013). Although some studies have noted an association between iron-deficiency anemia and stunted growth (Chwang, Soemantri, & Pollitt, 1988), meta-analyses of iron supplementation trials have failed to find an overall effect on child growth (Pasricha, Hayes, Kalumba, & Biggs, 2013; Thompson, Biggs, & Pasricha, 2013).

A meta-analysis of epidemiologic studies in Africa revealed that for each 1 g/dL increase in hemoglobin, there was an associated 24% reduction in the odds of child mortality (OR, 0.76; 95% CI, 0.62–0.93) (Scott, Chen-Edinboro, Caulfield, & Murray-Kolb, 2014). There is a complex relationship between iron status and morbidity, however. As described earlier, iron is required for many pathways in cellular immunity. Yet, iron is also required by most pathogenic bacterial, viral, and parasitic organisms, which sets the stage for a competition between the host and the pathogen for access to iron (Drakesmith & Prentice, 2012). For this reason, there may be some benefit for the host to create a state of functional iron deficiency, by reducing iron absorption and sequestering iron

from circulation during periods of infection (Jonker et al., 2017). Iron supplementation during a period of acute infection, such as with malaria, may provide limited benefit because the individual cannot absorb iron efficiently during that time, so the intervention may actually increase the risk and severity of infection (Jaramillo et al., 2017; Sazawal et al., 2006).

Iron-deficiency anemia is also associated with poorer cognitive outcomes and school performance in children (Prado & Dewey, 2014), with associated long-term consequences on economic opportunity (Horton & Ross, 2007). Iron is essential for neurogenesis and differentiation of brain cells and regions. Deficiency likely disturbs the developing brain via at least three iron-dependent pathways: (1) disruption of oligodendrocytes, the cells responsible for producing myelin; (2) disruption of neurotransmitter synthesis and metabolism; and (3) regulation of energy metabolism in the brain (Beard, 2008). Longitudinal studies of children who had been anemic prior to age 2 years have consistently demonstrated long-term deficits in cognition and school achievement from 4 to 19 years of age (Lozoff et al., 2006), although observational studies may be confounded other risk factors for poor child development common among children living in poverty (Black et al., 2017; Prado & Dewey, 2014). A number of randomized controlled trials of iron supplementation for infants or children have examined developmental outcomes. There is evidence of weak, but positive effects on motor development, cognitive/language development, and socio-emotional development, although the few long-term follow-up studies that have been conducted have not demonstrated persistent effects into later childhood (Pasricha et al., 2013; Prado & Dewey, 2014; Thompson et al., 2013).

Iodine Deficiency

Iodine is an essential component of thyroid hormones that control cellular metabolism and neuromuscular tissue growth and development. Deficiency in iodine and consequent thyroid hormone production during critical periods of organogenesis can damage the brain and nervous tissue, causing irreversible mental retardation and other developmental abnormalities. The spectrum of mild through severe health consequences causally linked to iodine deficiency at different stages of life is collectively known as iodine-deficiency disorders (IDD) (Delange, 1994; Li & Eastman, 2012), a concept that has led to greater understanding of the multiple health and societal consequences of this nutrient deficiency. Informative treatises exist on the histories of goiter and cretinism—the two most notable clinical syndromes of iodine deficiency (Hetzel, 1989).

Iodine adequacy of plant and animal sources of food grown in a general locale depends on adequacy of the nutrient in soil, which can vary by region of the world. Most iodine is found in the world's oceans, such that the highest soil concentrations have historically been found in coastal areas (Eastman & Zimmermann, 2017). More recently, recent epidemiologic studies of IDD have revealed the problem to extend beyond inland and mountainous regions to include island nations (Li & Eastman, 2012). In some cultures, insufficient iodine intake is augmented by routine consumption of goitrogenic substances, such as linamarin, a cyanide-containing compound found in the root of cassava (Delange, 1994; Rohner et al., 2014). Thiocyanates, which result from detoxification of linamarin in the liver, decrease iodine uptake by the thyroid gland and suppress circulating thyroid hormone, leading to secondary iodine deficiency.

As of the 1990s, an estimated 1.6 billion persons, or nearly 30% of the world's population, were thought to be at risk of iodine deficiency (WHO, 1993), based on documented prevalence and sizes of affected populations living in iodine-depleted regions. Despite successes in improving iodine status via salt iodization, iodine deficiency remains a significant public health problem in 32 countries (Andersson, Karumbunathan, & Zimmermann, 2012). Revised estimates of the extent of iodine deficiency obtained from WHO's global database for the 193 member-states of the United Nations suggest that nearly 2 billion people, including 30% of school-age children, have iodine intakes below the required amounts (**TABLE 7-9**), including 76 million children in Southeast Asia and nearly 58 million children in Africa. However, the highest proportions of children with inadequate iodine intake live in the European (43%) and Eastern Mediterranean (39%) regions. In contrast, iodine intakes may be excessive in 47 countries, emphasizing the importance of regular monitoring of national IDD prevention initiatives.

Function, Requirements, and Assessment. Iodine, ingested as either iodide or iodate, is an essential constituent of thyroid hormones. Once in circulation, approximately 80% of total body iodine is stored in the thyroid gland, where it is oxidized, bound to tyrosine amino acids, and catalyzed by an iron-containing peroxidase to form the thyroid hormones, T_3 (triiodothyronine), and T_4 (tetraiodothyronine, or thyroxine) (Li & Eastman, 2012). T_3 and T_4 are stored in the thyroid gland in association with the glycoprotein thyroglobulin. During periods of low dietary intake, thyroid-stimulating hormone (TSH) is secreted from the anterior pituitary gland, which leads to reduced renal clearance of iodine and increased breakdown of

TABLE 7-9 Number of Countries, Proportion of Population, and Number of Individuals with Insufficient Iodine Intake in School-Age Children (6–12 Years) and in the General Population (All Age Groups), by WHO Region in 2011

		Insufficient Iodine Intake (UI < 100 µg/L)			
		School-Age Children		General Population	
WHO Region[a]	Countries (number)	Proportion (%)	Total Number (millions)[b]	Proportion (%)	Total Number (millions)[b]
Africa	10	39.3	57.9	40.0	321.1
Americas	2	13.7	14.6	13.7	125.7
Southeast Asia	0	31.8	76.0	31.6	541.3
Europe	11	43.9	30.5	44.2	393.3
Eastern Mediterranean	4	38.6	30.7	37.4	199.2
Western Pacific	5	18.6	31.2	17.3	300.8
Total	32	29.8	240.9	28.5	1881.2

[a] Comprising 193 WHO member-states.

thyroglobulin (Li & Eastman, 2012). In this process, T_3 hormones are secreted and T_4 is preferentially converted to T_3 in peripheral tissues. As iodine concentrations become progressively depleted, hypothyroidism develops and hyperplasia of the thyroid epithelial cells may lead to the development of goiter.

During gestation, both maternal- and fetal-derived T_3 and T_4 contribute to the regulatory thyroxine pool that, in concert with other hormones (e.g., growth hormone, insulin), directs fetal tissue function, growth, and development. In particular, thyroid hormones are required for normal neuronal migration and myelination of the brain during fetal and early postnatal life and play a role in regulating fetal and infant growth (Eastman & Zimmermann, 2017; Rohner et al., 2014). Paradoxically, excess buildup of iodine in the thyroid gland can suppress the release of T_3 and T_4 and cause goiter, particularly if there is an overcorrection for prior deficiency (Eastman & Zimmermann, 2017). High iodine intake after prolonged deficiency may also lead to iodine-induced hyperthyroidism.

Iodine status can be assessed through clinical and biochemical means. Urinary iodine concentration, goiter rate, serum TSH, and serum thyroglobulin are four methods generally recommended for assessment (Rohner et al., 2014). They provide a complementary picture of iodine status, with urinary iodine representing a sensitive indicator of recent iodine intake, thyroglobulin responding to a change in status over a period of weeks to months, and the goiter rate usually reflective of longer-term iodine nutrition over a period of months to years (Zimmermann & Andersson, 2012). Indicators with suggested cut-offs, target populations for assessment, and criteria related to severity of iodine deficiency as a public health problem have been published by WHO, UNICEF, and the International Council for the Control of Iodine Deficiency Disorders (ICCIDD) (2007) (**TABLE 7-10**).

Virtually all goiter occurring in iodine-deficient areas can be attributed to iodine deficiency; thus, goiter prevalence can serve as a useful population indicator of risk. The size of the thyroid gland changes inversely in response to change in iodine intake. Nevertheless, there are practical limitations for assessing goiter where iodine deficiency is mild or in very young age groups because of the challenges in palpating the smaller thyroid gland. High-resolution ultrasonography is a feasible option for assessing goiter, but has limited use due to its expense and training requirements (Zimmermann & Andersson, 2012).

Urinary iodine (UI) excretion over 24 hours and measurement of UI concentration, alone or preferably

TABLE 7-10 Epidemiologic Criteria for Assessing the Severity of Iodine-Deficiency Disorders Based on Urinary Iodine or the Total Goiter Rate in School-Age Children and Pregnant Women

	Urinary Iodine		Total Goiter Rate	
Population Group	**Median Concentration (μg/L)**	**Interpretation**	**Proportion (%)**	**Interpretation**
School-age children	<20	Insufficient: severe iodine deficiency	>30	Severe
	20–49	Insufficient: moderate iodine deficiency	20.0–29.9	Moderate
	50–99	Insufficient: mild iodine deficiency	5.0–19.9	Mild
	100–199	Adequate	0.0–4.9	None
	200–299	Above requirements	5.0–19.9	Mild
	≥300	Excessive		
Pregnant women	<150	Insufficient		
	150–249	Adequate		
	250–599	Above requirements		
	≥500	Excessive

in relation to creatinine excretion, serve as conventional, biochemical means of determining the current iodine intake and status of a population. However, because collecting 24-hour samples can be impractical (Zimmermann & Andersson, 2012) and measuring creatinine is challenging, UI concentration (in μg/L) is commonly reported. With a large number of samples, day-to-day variations in hydration and intake average out so that, across population groups, median concentrations correlate well with medians from 24-hour collections and creatinine-corrected concentrations (Zimmermann & Andersson, 2012). A median UI value of more than 100 μg/L urine is considered to reflect a normal (average) iodine intake of 150 μg or more per day) and adequate status in the community (WHO, UNICEF, & ICCIDD, 2007).

Additional iodine status indicators include serum, whole blood, or whole blood spot TSH and serum thyroglobulin concentrations. Although TSH concentrations among adults are not sensitive to deficiency, TSH measurement is recommended for screening neonates for hypothyroidism (Eastman & Zimmermann, 2017). Thyroglobulin concentration, reflecting turnover of thyroid cells, is reflective of iodine nutrition over a period of months or years. A dried blood spot assay, suitable for field assessment, now exists for thyroglobulin, making this indicator easier to measure in field settings (Zimmermann & Andersson, 2012).

Health Consequences. IDDs range from severe and life-threatening to mild disorders of lifelong consequence. Fetal and neonatal hypothyroidism, due to gestational iodine depletion, permanently alters the structure and function of the brain as well as other nervous tissues, giving rise to permanent neurologic and developmental abnormalities (Hetzel, 1994; Stein, 1994). Severe maternal iodine deficiency can also result in spontaneous abortion, stillbirth, and congenital abnormalities (Eastman & Zimmermann, 2017). Postnatal iodine deficiency perpetuates thyroid failure that, depending on its duration and severity, leads to hypothyroidism, growth

retardation, sexual immaturity, and impaired cognition and motor development (Halpern, 1994).

Cretinism (**FIGURE 7-8**) represents the most severe clinical spectrum of the IDD, usually manifested as severe mental and growth retardation, paraplegia, rigidity, deaf–mutism, and facial disturbances (Hetzel, 1994). Central nervous system defects of cretinism can be linked to severe iodine deficiency in the second trimester of pregnancy (DeLong et al., 1994; Halpern, 1994), a period when the cerebral cortex, basal ganglia, and cochlea undergo rapid growth and development. Normal amounts of thyroid hormone are needed for neuronal migration and myelination of the fetal brain—processes that are irreversibly damaged if inadequate iodine is available (Zimmermann, 2012). Severe fetal hypothyroidism gives rise to neurologic cretinism, whereas severe postnatal iodine deficiency can lead to myxedematous cretinism, marked by severe growth retardation, neurologic damage, sexual delay, and musculoskeletal deformity (Boyages, 1994). For these reasons, iodine deficiency is known as the most common preventable cause of mental retardation (Walker et al., 2007).

FIGURE 7-8 Cretinism.

Mild, biochemical, or noncretinous hypothyroidism is a major public health concern due to its frequency in infancy and early childhood. Children living in iodine-deficient regions, who usually exhibit one or more IDDs, tend to have lower intelligence quotients (IQs) and perform more poorly in cognition, motor function, and school achievement tests than their iodine-sufficient peers. For example, a meta-analysis of findings from 37 Chinese publications found that children growing up in iodine-deficient areas had average IQs 12.5 points below those of children being raised in iodine-sufficient areas (Qian et al., 2005). Another meta-analysis of studies among children younger than 5 years of age found that iodine deficiency during pregnancy or childhood was associated with a reduction in IQ of 6.9 to 10.2 points (Bougma, Aboud, Harding, & Marquis, 2013).

Recognition and quantification of this subclinical "base of the IDD iceberg" have been key in motivating programs to prevent iodine deficiency (Hetzel, 1989). Globally, it has been estimated that IDDs account for 2.6 million disability-adjusted life years (DALYs) lost, primarily due to cognitive and motor impairment and hearing loss associated with deficiency (Black et al., 2008).

Goiter is an enlarged thyroid gland and is the most commonly observed clinical manifestation of iodine deficiency. Goiter size can range from barely palpable with the neck extended to grotesquely visible from a distance. The health risks posed by an enlarged thyroid due to iodine deficiency have not been well delineated. Nevertheless, hypothyroidism associated with goiter may cause lethargy, cold sensitivity, weight gain, weakness, depression or memory impairments (Chaker, Bianco, Jonklaas, & Peeters, 2017).

Zinc Deficiency

Zinc is essential for many metabolic functions, growth, and survival; in turn, zinc deficiency has many serious consequences (Hambidge & Krebs, 1999; Keen & Gershwin, 1990; Solomons, 1999). Even so, zinc deficiency has been one of the least "visible" micronutrient deficiencies. Evidence of some of the clinical abnormalities due to human zinc deficiency became clear in the 1960s (Prasad, 1985), but the prevalence of this deficiency has proved difficult to ascertain due to absence of adequate, nationally representative data on zinc status (Administrative Committee on Coordination/Sub-Committee on Nutrition [ACC/SCN], 2000). This uncertainty, which is attributed to a lack of reliable indicators or lack of consensus with respect to their use, interpretation, and target groups

to assess (Black, 1997), coupled with the limited experience with prevention programs (Gibson & Ferguson, 1998a), may have been factors that led to the near exclusion of zinc on the global micronutrient agenda until recently (Trowbridge et al., 1993).

Extensive evidence accumulated in the last two decades, primarily from randomized, controlled trials of zinc supplementation in children in low-income countries, has conclusively demonstrated the importance of zinc deficiency in these settings in regard to growth, risk of infectious disease morbidity and mortality, and other outcomes. This evidence, coupled with new estimates indicating that zinc deficiency is highly prevalent in LMICs (Wessels & Brown, 2012), has resulted in a better appreciation of the magnitude of this problem.

Function, Requirements, and Assessment. Zinc, which is found in all cells, serves as a constituent of more than 200 enzymes and numerous transcription proteins (as a "zinc finger") that regulate nucleic acid synthesis; metabolism of proteins, lipids, and carbohydrate; and cell differentiation (Cousins & Hempe, 1990; Stipanuk, 2000). These functions confer on zinc important roles in organogenesis, tissue growth, functional development, and immunity (Shankar & Prasad, 1998; Stipanuk, 2000). Such broad involvement in metabolism virtually assures zinc an important role in maintaining health.

Zinc is absorbed both by passive diffusion across a concentration gradient and by energy-dependent processes when intake is low (Stipanuk, 2000). Specific transporter proteins may facilitate its absorption (McMahon & Cousins, 1998). In mixed diets, the efficiency of this absorption can vary widely, from practically nil to 40%, with the lowest absorption associated with high grain and plant consumption and the highest absorption with human milk and meat consumption. Absorption rates tend to be higher in individuals with zinc deficiency (Solomons, 1999). Uptake into tissues appears to be regulated in some fashion, although the mechanisms involved are poorly understood.

Approximately 85% of total body zinc resides in skeletal muscle, calcified bone, and marrow; it is mostly bound to the storage protein known as metallothionein. This leaves only a small exchangeable body pool that can respond to short-term variations in zinc intake. Less than 1% of body zinc is found in circulation (Cousins & Hempe, 1990). Although the body lacks reserves of zinc in the conventional sense, bone may serve as a passive reserve, with zinc being made available from this source during normal turnover.

Recommended Dietary Allowances for zinc in healthy individuals have been available from WHO and were updated with new values developed by the Institute of Medicine (2005) in the United States. Many experts considered the IOM values to be too low for grain-based, low-meat diets, leading to the development of different recommendations by the International Zinc Nutrition Consultative Group (Hotz & Brown, 2004). For children, these values range from 3 to 14 mg per day depending on age, weight, sex, and the bioavailability of dietary zinc. For adults, the recommended intakes range from 8 to 15 mg per day depending on sex and physiologic state (i.e., pregnancy or lactation). Because zinc is lost during diarrhea and may be used more rapidly during infections, such conditions may increase the need for dietary zinc.

Zinc status may be assessed by a combination of clinical, biochemical, test-response, and dietary methods (Gibson, 2005; Gibson & Huddle, 1998). Clinical signs of moderate to severe zinc deficiency, including marked growth retardation, dermatitis and other skin changes, poor appetite, and mental lethargy, are either rare or lack sufficient specificity to be useful for population assessment. Diagnosis of more prevalent mild zinc deficiency usually rests on determining serum or plasma zinc concentration. Although unreliable for individual assessment, the distribution of serum zinc concentrations or responsiveness of the lower end of the distribution to interventions can identify groups at risk (Hotz & Brown, 2004). Serum zinc concentration varies by time of day, largely related to food ingestion, and can be lowered by infection because of cytokine-mediated shifts into the liver. Extensive recent work has resulted in suggested lower cut-offs for the assessment of serum zinc concentration depending on time of day, fasting state, age, sex, and pregnancy (**TABLE 7-11**) (Hotz & Brown, 2004).

Dietary assessment can provide valuable insight with respect to the bioavailable dietary zinc from local food resulting from concurrent estimation of zinc and phytate content, but by itself this approach cannot determine the status of an individual or population (Gibson & Ferguson, 1998b). Extensive guidelines on conducting and interpreting dietary surveys to assess the adequacy of dietary zinc intake have been published (Hotz & Brown, 2004).

Other possible measures of zinc deficiency in a population are the functional responses to zinc supplementation, such as improved growth and reduced infections, which will be considered in the following "Health Consequences" section. Because of the association of zinc deficiency with growth stunting (low height-for-age) as well as dietary inadequacy, the International Zinc Nutrition Consultative Group has developed a composite index consisting of the percentage of preschool-age children who are stunted

TABLE 7-11 Suggested Lower Thresholds for Mean Serum Zinc Concentrations (μg/dL)[a] to Classify Populations at Risk of Zinc Deficiency

	Age Group		
		10 Years or Older	
Time of Day of Blood Sample	Younger Than 10 Years	Nonpregnant Females	Males
Morning, fasting	Unknown	70 (10.7)	74 (11.3)
Morning, other	65 (9.9)	66 (10.1)	70 (10.7)
Afternoon/evening	57 (8.7)	59 (9.0)	61 (9.3)

[a] Values in parentheses represent thresholds in μmol/L. 1 μmol/L= 6.54 μg/dL.

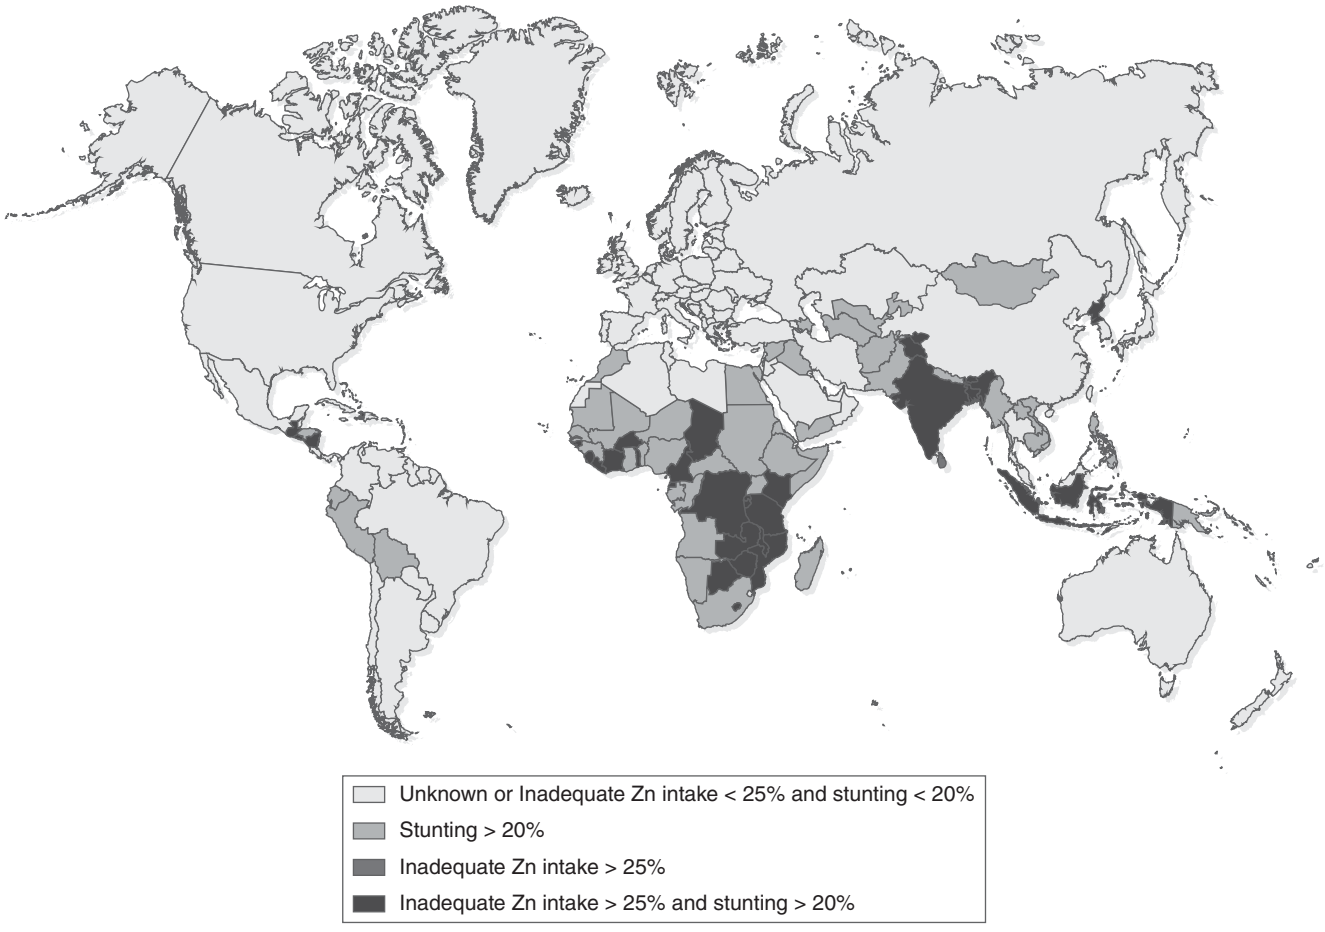

FIGURE 7-9 National risk of zinc deficiency based on the prevalence of childhood stunting and the estimated prevalence of inadequate zinc intake.

Reproduced from Wessells, K. R., & Brown, K. H. (2012). Estimating the global prevalence of zinc deficiency: Results based on zinc availability in national food supplies and the prevalence of stunting. *PLoS One, 7*(11), e50568. doi:10.1371/journal.pone.0050568

and the percentage of individuals at risk of inadequate zinc intake (from national food balance sheets) to classify countries based on their risk of zinc deficiency (**FIGURE 7-9**) (Wessels & Brown, 2012).

Health Consequences. Preschool-age children who exhibit low serum zinc levels are more likely to develop diarrhea and experience more severe episodes of diarrhea or acute respiratory infection than

children with adequate zinc status. The causality of this association has been examined by quantifying the impact of zinc supplementation on the incidence, duration, and severity of infectious diseases.

Diarrhea. Evidence for a role of zinc in reducing the incidence, severity, and duration of diarrhea is strong; 26 trials included 35 comparisons of zinc versus no zinc with 15,042 study subjects who had been provided with zinc as sulfate, gluconate, or methionate in daily or weekly supplements in doses generally of 5–15 mg per day for periods of weeks to more than a year to preschool children (Mayo-Wilson et al., 2014). Overall, there was a 13% reduction in the incidence of diarrhea (RR, 0.87; 95% CI, 0.85–0.89). There was no benefit (RR, 1.0; 95% CI, 0.96–1.05) in the subgroup of trials in which zinc was given with iron (compared to receipt of iron alone), but a significant benefit was found when zinc was given alone (compared to placebo) (RR, 0.82; 95% CI, 0.80–0.82). Zinc supplementation has also been found to be safe and to reduce the incidence of diarrhea in HIV-positive children in South Africa (Bobat et al., 2005; Siberry, Ruff, & Black, 2002).

Zinc has been successfully used in therapy of acute diarrhea. A systematic review identified 104 trials, including 18,882 study subjects, in which oral zinc was given in addition to fluids for therapy of acute watery diarrhea (Lamberti, Walker, Chan, Jian & Black, 2013). The meta-analysis of results from all trials found a 26% (95% CI, 20%–32%) reduction in the relative risk of the episode lasting more than 3 days. In those studies with pertinent data available, statistically significant benefits were found for average episode duration, duration of hospitalization, diarrhea lasting more than 7 days, and diarrhea stool frequency. Beneficial effects were similar for diarrhea associated with rotavirus infection and diarrhea for which the etiology was unknown. Of additional interest is the finding that zinc supplements given for 2 weeks during and following diarrhea have been shown to reduce the incidence of diarrhea in the subsequent 2 to 3 months (Zinc Investigators' Collaborative Group, 1999).

Respiratory Infection. A number of studies have evaluated the effects of zinc on prevention of acute lower respiratory infection. A meta-analysis of 12 zinc trials found a reduction in the incidence of lower respiratory infections (rate ratio, 0.92; 95% CI, 0.85–0.99) (Aggarwal, Sentz, & Miller, 2007). However, further analysis of these trials demonstrated that acute lower respiratory illnesses defined by specific clinical criteria were reduced to a greater degree (incidence rate ratio, 0.65; 95% CI, 0.52–0.82) (Roth, Richard, & Black, 2010).

Zinc has also been shown to have benefits as an adjunctive therapy given along with antibiotics for pneumonia. Studies in Bangladesh and India found that children with severe pneumonia who received zinc had a shorter duration of illness and a lower rate of failure for the initial antibiotic therapy (Brooks et al., 2004; Mahalanabis et al., 2004). Another study in India failed to find such a therapeutic benefit of zinc, however (Bose et al., 2006).

Malaria. Experimental zinc deficiency impairs host defenses against malarial infection (Shankar & Prasad, 1998). *Plasmodium falciparum* parasitemia has also been negatively associated with measures of zinc status or intake in Africa (Gibson & Huddle, 1998) and Southeast Asia (Gibson et al., 1991).

The public health impact of this association has been tested in four randomized, double-masked field trials (2,407 participants). A meta-analysis of these trials did not find a significant effect on the incidence of malaria (RR, 1.05; 95% CI, 0.95–1.15).

Mortality. Given the mounting body of evidence showing that adequate zinc nutriture can reduce the incidence and severity of infections, it is plausible that child mortality could be reduced by preventing even "mild" zinc deficiency through supplementation or dietary enhancement, including fortification. Several trials have provided evidence suggesting that zinc supplementation may lead to a large reduction in child mortality. One trial in full-term SGA Indian infants, who received daily zinc supplements from 1 to 9 months of age, found a reduction by two-thirds in deaths in the group compared to infants receiving a control supplement without zinc (Sazawal et al., 2001). Large randomized controlled trials of zinc supplementation in preschool-age children were also conducted in Pemba, Zanzibar, and Nepal (Sazawal et al., 2007; Tielsch et al., 2007). Although neither trial showed a benefit of zinc in children 1 to 11 months of age, both trials found a similar 18% reduction in mortality in older children (combined result RR, 0.82; 95% CI, 0.70–0.96).

In a large trial in Bangladesh, 50% fewer deaths were noted in preschool-age children who received a zinc supplement along with oral rehydration therapy for diarrhea compared to children receiving oral rehydration alone (Baqui et al., 2002). Another large effectiveness trial in India found that zinc given for diarrhea treatment reduced hospitalizations for diarrhea (OR, 0.69; 95% CI, 0.50–0.95) and pneumonia (OR, 0.29; 95% CI, 0.15–0.54) (Bhandari et al., 2008).

Poor Growth. A recent overview has clarified the extent and type of growth response that may occur when prepubescent children are given zinc on a daily basis. Thirty-three controlled trials were included in a meta-analysis that examined the effect of giving children younger than 12 years doses of 1 to 20 mg zinc

daily for periods ranging from 8 weeks to 15 months (mean of approximately 7 months) (Brown, Peerson, Rivera, & Allen, 2002). Differences in ponderal and linear growth were expressed as an "effect size" ([mean change in treatment group – mean change in control group] ÷ pooled standard deviation of the difference between groups), weighted by sample size, expressed as a standard deviation. The analysis revealed modest but statistically significant increases in weight (0.31 SD, $p < 0.001$) and height (0.35 SD, $p < 0.0001$), with larger effects seen for weight in children with lower weight-for-age and for height/length in more stunted children (Brown et al., 2002).

Reproductive Health. Zinc is required for normal maternal health, fetal growth, and development and parturition (Caulfield, Zavaleta, Shankar, & Merialdi, 1998). Experimental zinc deficiency leads to poor pregnancy outcomes (Apgar, 1985; Bunce, Lytton, Gunesekera, Vessal, & Kim, 1994). In a recent meta-analysis of 16 trials (7,637 participants) in which pregnant women either did or did not receive zinc supplements, there was a statistically significant reduction in preterm (less than 37 weeks' gestation) births (RR, 0.86; 95% CI, 0.76–0.97) (Ota et al., 2015). There was a similar, but not statistically significant, reduction in low birth weight (RR, 0.93; 95% CI, 0.78–1.12), but no reduction in stillbirths or births that were small for gestational age.

Zinc plays a known role in mammalian cell differentiation and turnover, ontogeny of mammalian systems, and thymic and other lymphoid tissue development and function (Cousins & Hempe, 1990). These effects could, for example, predispose individuals deprived of essential zinc *in utero* to permanent impairment in immunity and host resistance (Beach, Gershwin, & Hurley, 1982). Evidence from trials of zinc supplementation in pregnancy supports a beneficial effect on neonatal and infant infectious disease morbidity (Osendarp et al., 2001).

Micronutrient Frontiers

Public health frontiers exist in addressing micronutrient deficiencies. For example, current mapping of hidden hunger globally is modeled on indicators of only three nutrients (Ruel-Bergeron et al., 2015), signaling a need for more comprehensive, rapid, and affordable approaches to assess micronutrient status, establish population risk, and guide interventions (Cole et al., 2013). In particular, there are needs in the following areas:

- Articulate plausible pathways by which micronutrients protect health and prevent disease, illustrated by the apparent roles of periconceptional folate in one-carbon metabolism in preventing birth defects (Nazki, Sameer, & Ganaie, 2014).
- Clarify nutrient and disease interactions of public health importance, illustrated by the interplay of iron with pathogens affecting health (Mwangi, Prentice, & Verhoef, 2017) and the likely mediating effects of the gut microbiome in influencing status for some micronutrients (Biesalski, 2016).
- More clearly link micronutrient status to healthy eating patterns to guide dietary recommendations, requiring improvements in dietary data and regional food composition tables (World Food Programme [WFP], 2017).
- Conduct better-equipped and -informed epidemiologic studies and trials to establish public health importance of, to date, largely ignored micronutrients. For example, other B-complex vitamins in addition to folate, vitamins D (Roth et al., 2017) and E (Shamim et al., 2015), and selenium (Perkins & Vanderlie, 2016) are gaining public health recognition for their roles in materno-fetal health (Gernand et al., 2016), while supplemental antenatal intake of multiple micronutrients may affect cognitive development of offspring (Prado et al., 2012).

Obesity and Overweight

The following sections identify trends in overweight and obesity rates as well as the lifelong, detrimental effects caused by excess body weight and diet-related noncommunicable diseases.

Population Trends

Overweight and obesity are defined as abnormal or excessive fat accumulation on the body that may impair health outcomes (WHO, 2016c). Both conditions are rapidly increasing on a global scale: Worldwide, obesity has more than doubled since 1980. Measured using body mass index (BMI) cut-offs, a calculation of mass and height, an estimated 2 billion adults suffer from one or both of the conditions: 600 million adults are obese, while 462 million adults are overweight (Ng et al., 2014; WHO, 2017). Among children younger than age 5, undernutrition is still the most prevalent form of malnutrition. In contrast, among adults, overweight and obesity are the primary malnutrition burden. Global estimates indicate overweight and obesity are now responsible for more deaths among adults than underweight (WHO, 2016c).

In the last three decades, high-income countries such as the United States, the United Kingdom, and Australia have experienced rapid increases in obesity

among adult men and women (Ezzati et al., 2015). However, overweight and obesity are increasingly affecting both children and adults in LMICs as well, not only in urban centers but also in peri-urban and rural areas (Prentice, 2005). More than half of the world's obese population lives in just 10 countries, but the countries' income classifications vary widely. From the largest to smallest shares of the obese population, and classified by the World Bank as having either high-income (H), middle-income (M), or lower-middle-income (LM) economies, these countries include the United States (H), China (M), India (M), Russia (H), Brazil (M), Mexico (M), Egypt (LM), Germany (H), Pakistan (LM), and Indonesia (LM) (Ng et al., 2014).

Childhood obesity rates continue to rise in countries of all income levels (Ells et al., 2015; Kelly et al., 2013). In 2013, the prevalence of overweight and obese children and adolescents in high-income countries was 23.8% for boys and 22.6% for girls. In LMICs, this prevalence was 12.9% for boys and 13.4% for girls (Ng et al., 2014). Asian and African countries have almost half of the burden of all overweight children younger than age 5 (UNICEF et al., 2017).

Health Consequences

Data from 195 countries spanning 25 years show that excess BMI contributes to an estimated 4 million deaths (7.1% of all deaths) and accounts for 120 million DALYs (4.9% of all DALYs among adults) (Afshin et al., 2017).

Overweight and obesity are considered major risk factors for NCDs, a group of comorbidities that include cancer, cardiovascular disease (CVD), chronic respiratory diseases, and diabetes (Lozano et al., 2013; WHO, 2014b). NCDs (covered in the *Chronic Diseases and Risks* chapter, are currently the most common cause of death and disability worldwide, accounting for more than 60% of global mortality and two of every three deaths (Islam et al., 2014), with increased rates of NCD-related deaths being found in all regions of the world (Ezzati & Riboli, 2013). NCD-related deaths occur at younger ages in LMICs, with 30% of NCD-related deaths occurring before the age of 60 as compared to 13% of such deaths in high-income countries (Harikrishnan, Leeder, Huffman, Jeemon, & Prabhakaran, 2014; WHO, 2014b). CVD alone is a significant cause of premature death and the primary driver of morbidity for all NCDs, the largest burden of which occurs in LMICs (Zoghbi et al., 2014). Diabetes prevalence among adults increased 81% from 1980 to 2014, with this disease now affecting an estimated 422 million adults (NCD Risk Factor Collaboration, 2016; Korat et al., 2014).

Causes of Malnutrition

Poverty and Food Insecurity

Malnutrition is rooted in environments characterized by poverty and food insecurity. Food security, as defined by the Food and Agriculture Organization (FAO, 2017a), "exists when all people have physical, social, and economic access to sufficient, safe, and nutritious foods that meet their dietary needs and food preferences for an active and healthy life." There are four dimensions of food security: availability, economic and physical access, utilization, and stability over time. Food production, international trade, transport networks, and food storage conditions facilitate food availability within markets, while household incomes, poverty, and food prices influence household access to foods. Food utilization refers to how foods are prepared, used, and distributed within the home, and to how efficiently individuals are able to absorb and metabolize the nutrients from those foods. Individuals with frequent or chronic infections may have impaired absorption of nutrients, hindering their ability to efficiently utilize the foods that they consume. Finally, stability is influenced by environmental factors, such as weather or seasonal patterns; political factors, such as stable governance structures and trade agreements; and economic factors, such as unemployment or fluctuating food prices.

Tracking food insecurity is done in a variety of ways—through household surveys assessing access or food purchases over a given period, by monitoring food production and food prices, or through monitoring of population nutritional status. At the national level, the FAO (2017a) tracks the prevalence of undernourishment, which is defined as the proportion of the population whose dietary energy consumption is lower than that required to meet a basic need for light activity levels. This metric is constructed using national-level data from food balance sheets, which estimate the food availability within a country by summing the food production and imports and subtracting the exports, foods not used for human consumption, and food wastage. Using the population demographic structure and their known caloric requirements, one can estimate the degree to which the food energy availability within a country meets the needs of that country's population. Finally, household surveys are used to estimate the degree of inequity in access to foods within a population (FAO, 2017a).

The undernourishment metric is used for cross-country comparisons and for tracking trends over time. Since 1990, there have been substantial reductions in the prevalence of undernourishment

worldwide, which dropped from 18.6% in 1990 to 11% in 2016 (FAO, 2017a). This corresponds to a reduction from 991 million to 815 million people affected—a dramatic decrease considering the overall increase of 2 billion persons in the total global population over that same time period. Progress has been uneven between and even within regions, however, and 2017 marked the first time in 15 years in which the undernourished population has increased. The prevalence of undernourishment has declined rapidly in Latin America and Central, East, and Southeast Asia, but has remained intractable in South Asia and sub-Saharan Africa.

Food security is highly correlated with poverty, although economic growth is not sufficient by itself to eliminate food insecurity and hunger. Within many countries, inequalities exist between urban and rural areas, across regions, or between various ethnic groups. Although inequities in intra-household food allocation within a household can themselves lead to nutritional vulnerabilities (e.g., for female children or adult women in some cultures), variations in undernutrition can usually be traced to chronic food insecurity at the level of the household, the community, or larger aggregates of society. Broad economic development initiatives may fail to have an impact on food security because very poor households or communities may lack investment capital or the education or skills necessary to participate in new employment opportunities (FAO, 2017b). It is also apparent that financial crises that lead to sustained rises in food prices, losses of jobs, and lower real income initially create short-term adjustments and asset losses, which may then be followed by extended nutritional consequences (Alderman, 2010). Food insecurity is also significantly more likely in areas with acute or protracted crises arising from conflict or natural disasters (FAO, 2017b). These complex patterns of causation highlight the utility of conceptualizing food insecurity and malnutrition in present and intergenerational contexts.

Climate change poses an emerging threat to food security worldwide. Changes in the climate have already begun to negatively affect agricultural productivity. Wheat and maize yields have declined and cereal grain prices have increased following climate extremes in critical production regions (Intergovernmental Panel on Climate Change [IPCC, 2014]. In contrast, production of cassava, an important staple crop for many populations in Africa, is projected to increase, because this crop thrives in warmer temperatures and responds positively to CO_2 increases. Increased CO_2 will also affect the nutritional quality of major staple grains, with models suggesting a decrease in iron, zinc, and protein content in these foods with climate change (Myers et al., 2014, 2015, 2017). Less is known about other effects of climate change on horticultural crops or livestock production system. Marine fisheries have been impacted to varying degrees. Coral reef ecosystems provide food and other resources to 500 million people worldwide, but reef degradation has led to a decline in the abundance of fish and invertebrate species (IPCC, 2014).

The increasing incidence and frequency of extreme climate events will likely affect food security in unpredictable ways. The 2010 heat wave in Russia and floods in Pakistan led to an embargo on grain exports, creating fear of shortages and leading to subsequent price spikes (Nelson et al., 2010). Projections of the effects of climate change through 2050 suggest relatively modest global average declines on food production capacity, but after that point, grain yields may decline by 14% to 29% in the second half of the century (Nelson et al., 2010).

Conceptual Models

Two conceptual models in common use help to visualize the continuum from food insecurity to undernutrition, the causal factors involved, and the consequences of such failure to provide full nutrition and the ways in which health is affected.

One conceptual model (**FIGURE 7-10**), put forth in a series of papers in *The Lancet* focused on maternal and child nutrition, links the societal, underlying, and immediate contributors to optimal nutrition with its immediate and long-term health effects (Black et al., 2013). Building on an older undernutrition framework developed by UNICEF (1998), this model highlights that there is no single cause of optimal nutrition, but rather a set of contributing factors that vary in intensity, duration, specificity, and proximity to the undernourished individual. At the immediate level, optimal infant and young child feeding, care practices within the home, and low burden of infectious disease are immediate supporting factors. Underlying conditions of food security, caregiving resources, functioning health systems, and clean environments are necessary support systems. All of these assets are shaped by social and economic conditions, buoyed by leadership and financial resources, and backed by positive political governance structures. This conceptual model goes further than the UNICEF framework, however, by linking causes of undernutrition to potential programmatic actions that could be employed at multiple levels.

The second model illustrates the interconnectedness of nutrition across the various stages of life, from generation to generation (**FIGURE 7-11**). If individuals have access to adequate diets, reside in healthy environments, and have access to health care, they are able to achieve their health and developmental potential.

In the absence of this, infants may be growth restricted and developmentally delayed at birth, due to maternal undernutrition. Subsequently, they then face a sequence of nutritional, health, and developmental insults, mediated by socioeconomic constraints, which stunt their growth throughout early life. These factors may lead to an increased risk of infection and mortality in the short term as well as developmental delays that may affect the individual's potential to succeed in school and go on to achieve economic opportunities upon reaching adulthood. These exposures may continue through adolescence and the reproductive years. If they occur among women, they can affect both the women themselves and their offspring. Stunted, undernourished women are at greater risk of complications during pregnancy and delivery (Black et al., 2013). Their offspring are at greater risk of intrauterine growth restriction, preterm delivery, and later growth faltering (Kozuki et al., 2015; Martorell & Zongrone, 2012). Nutritional factors in childhood and young adult life also set the stage for long-term chronic health conditions, such as cardiovascular disease and type 2 diabetes (Barker, 1998). This model is meant to illustrate the value of nutrition and health inputs throughout the life course and suggest opportunities for effective and timely intervention.

Dietary Patterns Across the Life Course

A requisite for health throughout life is a diet that is adequate in quantity (calories), quality (nutrient density), diversity (variety of foods), and safety (hygienic) (Forouzanfar et al., 2015). Further, an adequate diet must be affordable (i.e., reasonably priced foods), accessible (i.e., in physical proximity; comprise foods that can be prepared and cooked), and culturally appropriate (i.e., considering local norms and traditions) (High Level Panel of Experts [HLPE], 2017). No one "ideal" diet exists for optimal health, nutrition, or environmental benefit, as these vary based on geographic location, season, and cultural context.

Infant and Young Child Diets

The infant-to-child feeding continuum should be viewed as a process, involving first breastfeeding and then gradual transitional feeding, that results in adequate nourishment to support normal growth, health, and development from birth through early childhood. The process of initiating and establishing breastfeeding, followed by phasing in complementary feeding and the eventual transition to family foods, is illustrated in **FIGURE 7-12**. Under optimal circumstances, a young infant will be fed only breast milk for a period of 6 months after birth. "Exclusive breastfeeding" is therefore defined as feeding only breast milk, excluding any solids or other liquids, including water (WHO, 2008a). Complementary feeding begins as infants are first introduced to other foods, typically soft or semi-solid transitional foods. Gradually, infants will gain the abilities to consume solid foods and eating more from the family pot. During this time, breastfeeding frequency will wane with concurrent declines in the proportion of calories and nutrients from breast milk until the young child fully transitions to family foods.

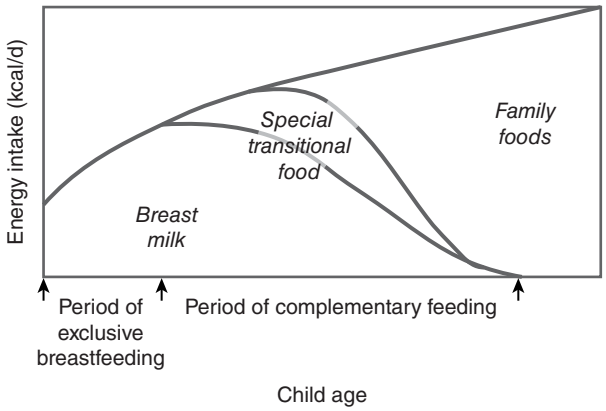

FIGURE 7-12 The sequential phases of early childhood feeding.

Reprinted from Brown, K. H., Dewey, K., & Allen, L. (1998). *Complementary feeding of the young children in developing countries: A review of current scientific knowledge.* Geneva, Switzerland: World Health Organization.

Striking differences in infant and young child feeding practices can occur both across and within regions. Patterns of breastfeeding initiation, introduction of complementary foods, and graduation to a household diet, as observed in four countries, are illustrated in **FIGURE 7-13** (WHO, 2008b). The data from Rwanda (Panel A) reveals a pattern in which more than 90% of infants exclusively breastfeed shortly after birth, with a high proportion continuing to exclusively receive human milk through age 6 months. Beyond that age, most infants begin to receive solid, semi-solid, or soft foods with human milk. In contrast, in Burkina Faso (Panel B), fewer than 20% of infants are exclusively breastfed at birth. In this culture, most young infants receive either plain water or other non-milk liquids in addition to regular breastfeeding during the first 6 months of life, beyond which solid, semi-solid, or soft foods are introduced while breastfeeding continues. South and Southeast Asian mothers tend to partially breastfeed their infants for a longer duration, indicated by a prevalence of any breastfeeding of 50% to 80% during the third year of life (Panel D), whereas a more rapid transition to the family diet is evident in Latin America (Panel C).

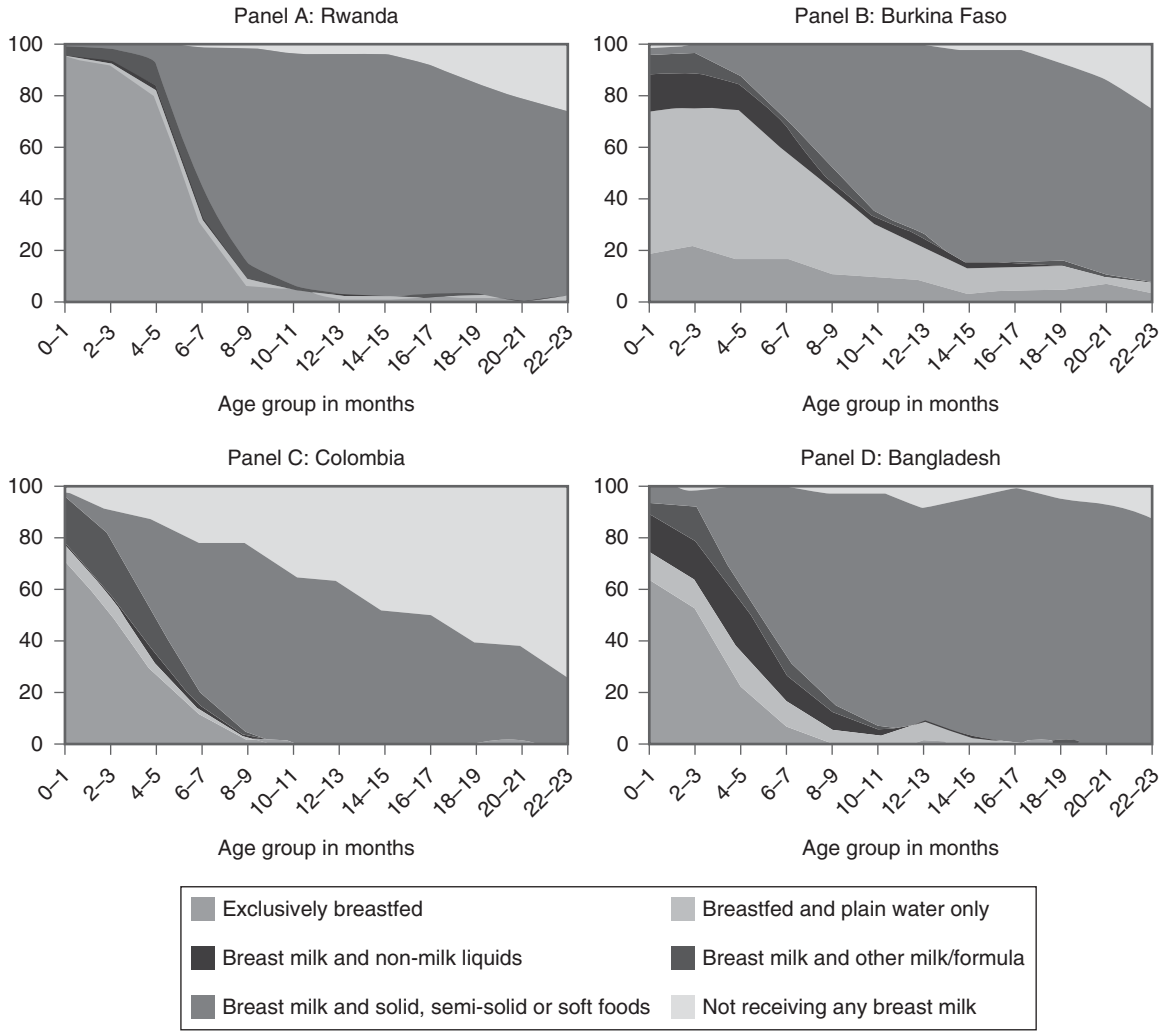

FIGURE 7-13 Distribution of breastfeeding and complementary feeding practices in Rwanda **(Panel A)**, Burkina Faso **(Panel B)**, Colombia **(Panel C)**, and Bangladesh **(Panel D)**.

Optimal breastfeeding and complementary feeding start with the initiation of breastfeeding, ideally within the first hour after birth (Debes, Kohli, Walker, Edmond, & Mullany, 2013). This ensures that the newborn will be exposed to the mother's colostrum, the thick, yellowish, immunologically rich first fluid produced by the mammary gland. While the amounts of calories or nutrients provided by the colostrum on the first 2–3 days of life are low, colostrum provides a form of an early inoculation for the infant, delivering maternal antibodies and immune factors such as secretory immunoglobulin A (IgA), lactoferrin, and leukocytes that protect the newborn as it transitions to life outside the womb (Ballard & Morrow, 2013). In a study in Nepal and Ghana, initiating breastfeeding more than 24 hours after birth was associated with a 2.4- to 3-fold increased risk of neonatal mortality compared to breastfeeding within 24 hours. The lowest risk of mortality was observed among infants breastfed within the first hour of birth (Debes et al., 2013). Globally, however, only about half of newborns are breastfed within the first hour (Victora et al., 2016).

Early initiation of breastfeeding also supports the establishment of healthy breastfeeding thereafter. WHO recommends that exclusive breastfeeding be practiced for the first 6 months of life, based on the consensus view that, on average, breastfeeding can provide adequate energy, nutrients, and fluid; protect against infection; permit normal growth for infants through this age; and reduce the risk of neonatal and infant mortality (WHO, 2013a). During the first 6 months of life, average human milk intakes for populations of infants have been noted to range between 700 and 800 mL per day in both low-income and higher-income countries (Brown, Dewey, & Allen, 1998; Dewey & Brown, 2003); this amount is adequate to meet the average child's nutritional needs.

Unlike infant formula, the composition of human milk is variable, varying within a feed, diurnally, over the course of lactation, between women, and across populations (Ballard & Morrow, 2013). The energy and protein content of human milk are relatively well conserved, even under conditions of maternal undernutrition (Prentice, 1995). The fat content of human milk is the most variable of the macronutrients, with 2–3 times higher concentrations of fat being found in the hindmilk, which is expressed later in a feed, as compared to the initially produced foremilk (Ballard & Morrow, 2013). The concentrations of long-chain polyunsaturated fatty acids, such as docosahexaenoic acid (DHA), are strongly influenced by the maternal diet (Smit, Koopmann, Boersma, & Muskiet, 2000; Urwin et al., 2013). Micronutrient quality of the breast milk is less well understood. Concentrations of certain nutrients, such as folate, calcium, iron, copper, and zinc, appear to be largely unaffected by maternal intake or nutritional status, while other nutrients—notably thiamin, riboflavin, vitamin B_6, vitamin B_{12}, choline, retinol, vitamin A, vitamin D, selenium, and iodine—are affected by maternal depletion or low intake (Allen, 2012).

Beyond its nutritive properties, human milk is a bioactive fluid that supports optimal infant health. It contains a variety of growth factors that promote tissue growth as well as maturation and repair of the intestinal mucosa (Ballard & Morrow, 2013). It also contains bioactive compounds that confer immunologic protection to the infant, as well as regulate the inflammatory response to infection. Human milk oligosaccharides (HMOs) support a healthy microbiota—the complex community of bacteria that live within the gut, promoting proliferation of healthier gut flora, and reducing susceptibility to pathogenic bacteria (Bode, 2015).

Despite the protections conferred by breast milk, young infants are at significantly elevated risk of morbidity and mortality when other liquids are introduced early in their diets. In many low-income settings, contaminated water sources serve as a primary route of exposure to enteric pathogens for young infants. Even predominant breastfeeding among infants younger than 6 months, wherein the infant receives primarily breast milk with only the addition of water, tea, or juice, is associated with a nearly 50% increased risk of mortality compared to exclusive breastfeeding (Sankar et al., 2015). By contrast, nonbreastfeeding among infants in this age is associated with a 14-fold increased risk of mortality, driven in large part by diarrhea-specific mortality.

The benefits of breastfeeding extend beyond child survival. This feeding practice has been associated with a reduction in the incidence of diarrhea and respiratory infections, increases in child intelligence scores in later life, and probable reduction in risk of overweight (Victora et al., 2016).

At roughly 6 months of age, the energy provided by breast milk is no longer adequate to meet the growing infant's needs. Unlike the strong, clear evidence that supports the benefits of breastfeeding, evidence about the benefits of specific complementary feeding practices have been mixed (Dewey & Adu-Afarwuah, 2008). Complementary feeding practices are, by contrast, a more complex set of behaviors, influenced by the diversity of locally available foods.

The total energy requirements for healthy, breastfed infants are roughly 600 kcal/day for 6- to 8-month-olds and increasing to 900 kcal/day for 12- to 23-month-olds (Dewey & Brown, 2003). While breastfeeding by itself is not sufficient to provide this amount of energy for children beyond 6 months of age, much of this energy need can be met by human milk. The added energy requirements from complementary foods for infants with "average" human milk intakes are 200 kcal/day at 6 to 8 months of age, rising to 550 kcal/day at 12 to 23 months of age (Dewey & Brown, 2003). The energy density of many complementary foods in low-income countries is low, however, because infants often consume watery porridges. To meet their energy requirements, a child needs to be fed at least 2–3 times per day from 6 to 12 months and 3–4 times per day from 12 to 24 months with food of sufficient energy density, at least 0.8 kcal/g. Protein requirements are estimated to be 1 g/kg of body weight per day for 6- to12-month-olds and 0.87 g/kg/day for 1- to 3-year-olds (IOM, 2005). Protein is rarely a limiting nutrient in infant diets, except when the overall intake of complementary foods is low (Arsenault & Brown, 2017).

Dietary diversity is associated with improved micronutrient quality of the diet and a greater likelihood of meeting the nutrient requirements for infants and young children in low-income countries (Khor, Tan, Tan, Chan, & Amarra, 2016; Moursi et al., 2008; Wondafrash, Huybregts, Lachat, Bouckaert, & Kolsteren, 2016). Animal-source foods, such as meat, fish, eggs, and dairy products, are particularly important sources of iron, zinc, calcium, and vitamin A in the diet. Dark green leafy vegetables as well as orange and yellow fruits and vegetables offer beta-carotene, a pro–vitamin A carotenoid. These nutrients tend to be limited in the diets of children in low-income settings, because their higher costs put these nutrient-rich foods out of reach for many poor families. However, even in dietary optimization studies, in

which theoretical optimal diets are constructed from locally available foods, infants would still not be able to meet their nutrient requirements from diet alone (Hlaing et al., 2016; Santika, Fahmida, & Ferguson, 2009; Tharrey, Olaya, Fewtrell, & Ferguson, 2017). Critical gaps in iron, zinc, calcium, and some vitamins still exist, even in these "optimal" diets. Micronutrient supplementation or food fortification approaches are needed to fill those gaps.

Diets of Adolescent Girls

Adolescent girls are at high risk of malnutrition due to rapid growth in body mass (skeletal, fat, and fat-free body mass) and nutrient loss through the onset of menstruation. To meet their increased nutrient needs, adequate amounts of iron, folate, calcium, and zinc are required in their diets (Salam & Bhutta, 2015).

Throughout the world, adolescent diets are often characterized by limited dietary diversity, with cereals accounting for the majority of the diet while fruit and vegetable intake is low (Ochola & Masibo, 2014). In many urban areas, adolescents have high consumption of energy-dense, nutrient-poor snacks and beverages (Ochola & Masibo, 2014). A systematic literature review of diets in LMICs found that more than 50% of adolescent girls 10 to 20 years old had inadequate levels of zinc, calcium, vitamin D, folate, thiamine, and riboflavin—micronutrients that are necessary to support growth and positive pregnancy outcomes for both mother and child (Elliot, Lutter, Lamstein, Koniz-Booher, & Caulfield, 2015).

A variety of social and cultural factors influence the diet adequacy of adolescent girls, spanning issues related to body image in some countries to early marriages and social status in others. Adolescence is a critical window of opportunity to form independent food habits (Salam & Bhutta, 2015).

Diets of Women

Menstruation, pregnancy, and lactation increase women's dietary needs throughout the life cycle. Women may consume enough calories for their daily energy needs (i.e., high-quantity diet), yet do not obtain adequate quantities of micronutrients such as vitamin A and iron (i.e., low-quality diet) (Arimond et al., 2010). In 24-hour food recall surveys in six sub-Saharan African countries, a majority of women reported consuming starchy staples, but fewer than half of those surveyed consumed legumes and nuts, vitamin A-rich fruits and vegetables, dairy products, or eggs (Kothari, Abderrahim, Colie, & Cheng, 2014).

The state of women's high-quantity/low-quality diets around the world is likely exacerbated by social inequities, whereby household resource allocation (i.e., food, water, sanitation, and health care) may limit women's access to nutritious foods or inhibit nutrient absorption. In some settings, women's and children's food intake—particularly animal-source foods—may reflect their social valuation to the community and economic contribution to the household (Gittelsohn & Vastine, 2003). Men often have greater access to fats, protein, and micronutrient-rich foods than do women (Messer, 1997). Given the domestic and work demands and constraints placed upon women, their social status can have intergenerational nutritional consequences.

How Diets Change

Substantial longitudinal data confirm that significant changes in consumer preferences, dietary habits, and micronutrient deficiency or excess have occurred throughout the last three decades (Mozaffarian, 2016). From 1990 to 2013, consumption of "healthy foods," or nutrient-rich foods with some evidence of health benefit, generally grew in all regions (Global Panel for Agriculture and Food Systems, 2016). However, some important differences in the types of food groups consumed are notable. Fruit consumption increased throughout the world, while vegetable consumption increased in only four of the seven regions. Consumption of whole grains rose substantially only in Southeast Asia, while consumption of omega-3 fatty acids declined in three of the seven regions.

By contrast, changes in consumption of "unhealthy foods," referring to nutrient-poor foods that should be consumed in moderation, have been varied. Red meat consumption declined throughout the world except in East Asia, where it rose by nearly 40%. Consumption of processed meat also increased in all regions, a trend that has been linked to certain cancers such as colorectal cancer (Micha, Wallace, & Mozaffarian, 2010). Changes in salt and sodium consumption have been minimal in all regions. Sugar-sweetened beverage consumption has risen in more than half of the regions, with the largest increase occurring in North America.

Changing dietary trends reflect a variety of shifting conditions. The nutrition transition refers to shifts in dietary patterns as populations undergo demographic transformations, including urbanization, globalization, shifting age distributions, and economic development. These shifts subsequently

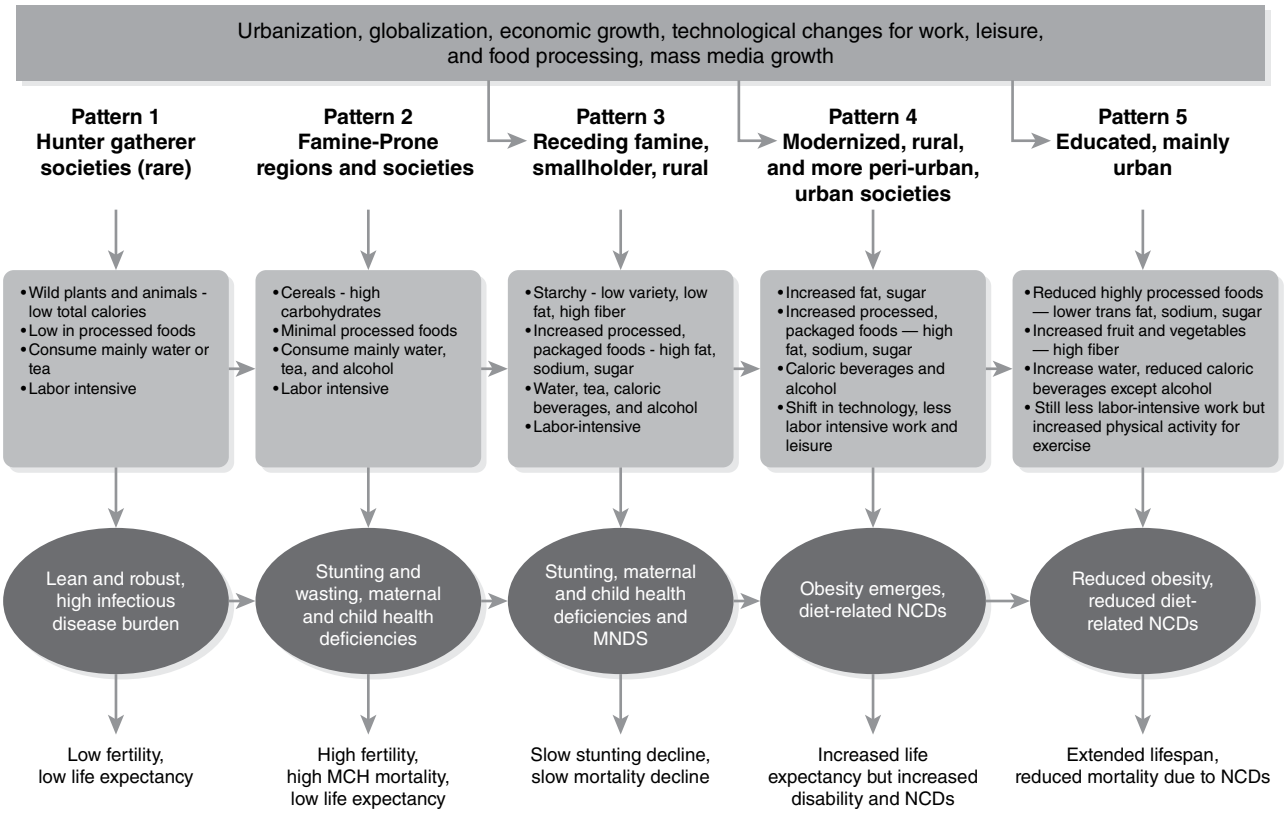

FIGURE 7-14 The five patterns of the nutrition transition.

Modified from Drewnowski, A., & Popkin, B. M. (1997). The nutrition transition: New trends in the global diet. *Nutrition Reviews, 55*(2), 31–43.

influence epidemiologic, dietary, and lifestyle patterns (Drewnowski & Popkin, 1997; Popkin, 2006). As illustrated in **FIGURE 7-14**, five nutrition transitions characterize changing food environments and food systems.

The first pattern in Figure 7-15, often called the *Paleolithic pattern* for its link to hunter–gather societies or subsistence rural communities, facilitates a local, somewhat nutritious but limited diet (Cordain et al., 2005). Individuals need to travel substantial distances to hunt game or gather wild foods, though diets contain little to no processed foods (Frassetto, Schloetter, Mietus-Synder, Morris, & Sebastian, 2009). They tend to be physically strong, but are vulnerable to infectious diseases, undernutrition, maternal and child mortality, and other health outcomes that result in a relatively short life expectancy. While some of these traditional societies still exist in the world, their livelihoods are largely threatened by globalization and climate change.

The second and third patterns reflect both the emergence of modern agriculture and periods of famine or "hunger seasons." These societies are often rural, producing food for their own consumption, though some subsistence farmers also produce food to sell. For some communities, local, traditional foods (e.g., leafy green vegetables, agroforestry foods, legumes and pulses, traditional grains and tubers) remain important components of the diet, but may be insufficient to fill nutrient gaps, initiating a state of high-quantity/low-quality diets. These populations often have a high prevalence of wasting and stunting, maternal and child mortality, and shorter life spans.

The fourth and fifth patterns represent the majority of the global population today. With urbanization, globalization, and trade liberalization, food supply chains are longer and more complex, offering access to new and diverse foods throughout the year, expanding food choices, and modifying dietary preferences. With 3 billion more people expected to enter the middle class by 2030, urbanization will affect income, gender relations, and technological development (Ranganathan et al., 2016; Seto & Ramankutty, 2016). These shifts also affect food preferences and dietary patterns. Urban consumers tend to consume more processed, convenient, street and fast foods (International Panel of Experts on Sustainable Food Systems, 2017). Highly processed foods have a longer shelf life, and are often more palatable, affordable, convenient, and easy to cook—but often lack key micronutrients and/or contain excess calories and sodium (Monteiro et al., 2017; Moreira et al., 2015; Moubarac, Batal, Louzada, Martinez Steele, & Monteiro, 2017; WHO, 2015b). Higher-income consumers in urban areas also demand greater quantities of animal source foods (Gaiha & Young, 1989; Tilman & Clark, 2014;

Timmer, Falcon, & Pearson, 1983). Changes in diet and physical activity patterns coincide with reduced rates of undernutrition and infectious diseases, but also initiate increased rates of overweight, obesity, and diet-related NCDs (Popkin, 2006).

In the fifth pattern, recognition of the poor health outcomes in the fourth pattern triggers behavioral change (e.g., reducing consumption of processed food, increasing physical activity) that can reverse the preceding negative health outcomes—although this is currently rare, even in high-income countries (Popkin, Adair, & Ng, 2012). Such behavioral changes may reflect increased education or higher-quality healthcare services.

Contributions of Infection to Undernutrition

Infectious morbidity—particularly diarrheal disease—has an important effect on physical growth and rates of malnutrition. The negative effect of diarrhea on weight and often height gain of children during and after an episode of acute diarrhea has been documented in diverse low-income country settings. Nevertheless, the magnitude of the effect on growth faltering has varied widely in these studies (Black, Brown, & Becker, 1983). Some studies, such as those conducted in Guatemala (Martorell, Yarbrough, Lechtig, Habicht, & Klein, 1975), Mexico (Condon-Paoloni, Joaquin, Johnston, deLicardi, & Scholl, 1977), and Bangladesh (Black et al., 1983) have reported that 10% to 24% of the growth faltering could be explained statistically by the prevalence of diarrhea. By comparison, studies in other countries such as Uganda (Cole & Parkin, 1977), Gambia (Rowland, Cole, & Whitehead, 1977), and Sudan (Zumrawi, Dimond, & Waterlow, 1987) have reported that diarrhea could explain as much as 40% to 80% of observed faltering. In nearly all instances, these percentages of growth faltering explained by diarrhea were higher than those explained by other infectious diseases, demonstrating the quantitative importance of the diarrhea–growth faltering relationship. In a pooled analysis of data from 9 community-based studies, Checkley et al. (2008) determined the effects of diarrhea prior to 24 months of age on stunting at 24 months: 25% of all stunting at 24 months of age was attributable to having at least 5 episodes of diarrhea in the first 2 years of life.

Infectious diseases can result in poorer weight gain or weight loss, which may be due to loss of appetite (Brown, Black, Robertson, & Becker, 1985) or increased metabolic demands related to inflammation. With diarrhea, there may also be intentional withholding of food, as well as malabsorption of ingested food in the damaged intestine (Behrens, Lunn, Northrop, Hanlon, & Neale, 1987; Lunn, Northrop-Clewes, & Downes, 1991). Variation in these factors may explain some of the differences in the magnitude of effect in various low-income country settings, but it also is necessary to consider factors such as the etiology of diarrhea, the age pattern of infection, the feeding pattern and dietary intake, treatment practices, and the length of the convalescent period.

To date, relatively few studies have examined the differential effect of diarrhea due to specific etiologic agents on growth. In Bangladesh, enterotoxigenic *Escherichia coli* and *Shigella* species were found to have the strongest effects on growth, whereas rotavirus and other enteropathogens, in part due to their lower prevalence, did not have a significant effect (Black et al., 1984b). In Peru, researchers had similar findings regarding these pathogens (Lee et al., 2014). The seasonal pattern of particular enteropathogens causing diarrhea may explain part of the seasonality in growth seen in some low-income country settings.

In regard to clinical syndromes, dysentery (bloody diarrhea) and persistent diarrhea (defined by WHO as an episode lasting 14 days or more) have particularly important adverse effects on the growth of children (Black, 1993). As one might expect, the magnitude of the weight deficit is inversely related to the duration of the diarrheal episode. Persistent diarrheal episodes usually occur in children who also have a higher burden of diarrhea, so that both the persistent episodes and the high prevalence of diarrhea adversely affect growth.

Both asymptomatic and symptomatic infections can have an adverse effect on growth. Infection with *C. parvum*, with or without illness, in Peruvian children was associated with a reduction in weight gain, after controlling for other variables (Checkley et al., 1998). Even though the effect size was smaller with asymptomatic infections than with symptomatic ones, because of their higher prevalence asymptomatic infections had a greater overall impact on growth compared to symptomatic infections. After experiencing an illness, children have the potential to grow more rapidly than they were growing previously; this phenomenon is known as "catch-up growth." Children with a *C. parvum* infection in the first 6 months of life did not have catch-up growth, such that this disease had a long-lasting adverse effect on linear growth, whereas children with infections at an older age did show some catch-up growth. A study in seven LMIC populations found that *Campylobacter* infection in early childhood was associated with growth shortfalls, increased intestinal permeability, and local and systemic inflammation (Amour et al., 2016).

Asymptomatic infection in the small intestine, as occurs in the disorder referred to as environmental enteric dysfunction or environmental enteropathy, may have a substantial effect on the growth of children (Keusch et al., 2014). This disorder is characterized by inflammation, increased intestinal permeability, and malabsorption. The continuous ingestion of large quantities of fecal bacteria in settings with poor sanitation and hygiene may be critical in the pathogenesis of tropical enteropathy. An accelerated immune response triggered by the increased small bowel permeability may divert nutrients to the production of proteins involved in the response to infection and other immune factors instead of supporting the child's growth (Campbell, Elia, & Lunn, 2003). Reduced nutrient absorption, along with a poor-quality diet, may also contribute to growth faltering in this disorder (Humphrey, 2009).

The feeding practices of a child at the time of illness can modify the effect of diarrhea on growth. Infants who are exclusively or predominantly breastfeeding tend to experience fewer adverse effects of diarrhea (Launer, Habicht, & Kardjati, 1990). This relationship may arise because breastfeeding ameliorates the severity of the illness or because breastfeeding generally seems to be continued without reduction in most circumstances during illness (Brown et al., 1985; Hoyle, Yunus, & Hen, 1980), whereas other foods may be reduced due to medical or cultural practices or anorexia because of the illness. Children in the first 6 months of life who are exclusively or predominantly breastfed may have less severe consequences of diarrhea or other infectious diseases (Khin-Maung-U et al., 1985; Launer et al., 1990; Rowland, Rowland, & Cole, 1988). Conversely, if very young children get diarrhea, they may experience long-term height deficits—effects that may be greater than if they developed diarrhea at an older age (Checkley, Epstein, Gilman, Cabrera, & Black, 2003).

Diarrhea has a lesser effect on growth among children whose usual dietary intake is greater or of better quality (Brown et al., 1988) and among children who receive food supplements, compared to children with poorer diets or those not receiving food supplements in the same setting (Lutter et al., 1989). Catch-up growth after a diarrheal episode is usually possible without specific supplementary feeding, due to the child's increased consumption of available food. However, the opportunity for catch-up growth may be limited by the duration of the healthy period between illnesses. Studies in Bangladesh (Black et al., 1983) and Zimbabwe (Moy, Marshall, Choto, McNeish, & Booth, 1994) have shown that, following a diarrhea episode, children take approximately 2 weeks to recover to their pre-illness weight and approximately 4 weeks to reach the weight that would have been expected if these children had continued their rate of growth prior to the illness. If another illness occurs during this month-long convalescent period, it may result in insufficient time for catch-up growth to occur and could add further nutritional insult (Richard, McCormick, Miller, Caulfield, & Checkley, 2014). The net effect in the long term is a reduction in both ponderal and linear growth.

Appropriate treatment of diarrheal illnesses may reduce the adverse effects of diarrhea on growth. The replacement of fluid and electrolytes with oral rehydration therapy may restore appetite and improve bowel function. Also, continued feeding during the illness results in improved weight gain in comparison to partial withholding of food during the acute phase (Brown et al., 1988). While antibiotics are not necessary for most cases of acute diarrhea, appropriate antibiotic treatment of dysentery would be expected to shorten the illness and, therefore, minimize the period of adverse effects on growth. The administration of zinc orally in treatment of diarrhea has been shown to reduce the severity and duration of diarrheal episodes, which would be expected to reduce the corresponding negative effects of diarrhea on growth (Sazawal et al., 1995). Zinc supplementation for 10 to 14 days in therapy of diarrhea is recommended by both WHO and UNICEF (WHO, 2006).

Acute respiratory infections—predominantly upper respiratory infections—have a high prevalence worldwide. Children in low-income countries, while having a similar prevalence of upper respiratory infections as children in higher-income countries, demonstrate a substantially higher rate of acute lower respiratory infections or pneumonia (Graham, 1990). Most of the studies of the effects of acute respiratory infections on growth have included both upper and lower respiratory infections and have generally not found that the illnesses alter growth patterns. In a Gambian study, children younger than 2 years of age with acute lower respiratory infections diagnosed by a pediatrician lost 14.7 g of weight per day of illness, an loss slightly, but not significantly, greater than the weight reduction observed with diarrheal diseases (Rowland et al., 1988). However, the prevalence of diarrhea was much higher than the prevalence of acute lower respiratory infections, so that diarrheal diseases explained half and respiratory infections only one-fourth of the observed weight deficit. Other studies in the Philippines (Adair et al., 1993), Papua New Guinea (Smith et al., 1991), Guatemala (Cruz

et al., 1990), and Brazil (Victora et al., 1990) have also shown that acute lower respiratory infections adversely affect growth.

Acute respiratory illnesses are associated with a 10% to 20% reduction in food intake, possibly due to a reduction in the child's appetite (Brown et al., 1985; Mata, Cromal, Urrutia, & Garcia, 1977). As with other illnesses, catabolism may also play a role. Further studies are required to assess the magnitude of the adverse effects of acute lower respiratory infections on growth and to document whether modifying factors, like those found with diarrheal diseases, exist.

A few studies have attempted to document whether malaria has an adverse effect on growth in children in low-income countries. In Gambia, malaria prevalence was shown to adversely affect weight gain but not linear growth (Rowland et al., 1977). Subsequent studies in Uganda (Cole & Parkin, 1977) and Gambia (Rowland et al., 1988) were not able to demonstrate any effect of malaria on the growth of children. A review of 12 studies that examined the relationship of malaria and stunting found mixed evidence among observational studies, but none of the randomized controlled trials of malaria interventions found an effect on stunting (Jackson & Black, 2017).

Although it has been believed for many years that measles causes a reduction in growth, this relationship has proved difficult to document on a population basis. This difficulty arises in part because of the low incidence of measles found in prospective studies, which in some cases was due to the administration of measles vaccine in the study cohort. Older studies suggest that children with measles lose weight or have reduced growth velocity (Reddy, 1991). Nevertheless, measles has been best recognized as an illness that precipitates severe clinical forms of malnutrition. In children with previous undernutrition, measles can precipitate kwashiorkor or marasmus (Morley, 1964) as well as xerophthalmia (Sommer, 1982).

Intestinal helminthic infections in children in LMICs have been associated with poor growth (Rousham & Mascie-Taylor, 1994). However, systematic reviews of trials of anti-helminth treatment of infected children or mass-deworming of infected populations have not found a consistent benefit for growth in children (Taylor-Robinson, Maayan, Soares-Weiser, Donegan, & Garner, 2015; Welch et al., 2017). This apparent inconsistency may be due to the effect of helminth infection on growth being limited to children with heavy worm infection, who constitute a very small proportion of these included in mass-deworming programs. (The *Infectious Diseases* chapter includes further information on such illnesses.)

Policies and Programs to Address Malnutrition in All Its Forms

As illustrated in the framework in Figure 7-11, policies and programs to address the determinants of malnutrition may operate at the immediate causal level, by addressing the quality of foods available and provided, care practices, or infectious disease risk. Alternatively, they may address underlying determinants of malnutrition, such as food insecurity, feeding and caregiving resources, or access to health services and water and sanitation systems. If effectively scaled and utilized, *nutrition-specific interventions* can significantly reduce stunting, wasting, micronutrient deficiencies, and even overweight and obesity. These interventions target the immediate causes of malnutrition. They largely focus on the most nutritionally vulnerable and underserved populations, such as women, and in particular, pregnant or lactating women and children younger than 2 years of age (Bhutta et al., 2013; Black et al., 2013). Examples of nutrition-specific interventions include micronutrient supplementation and exclusive breastfeeding counseling.

A growing area of research, *nutrition-sensitive approaches* address the underlying and basic determinants of malnutrition. Nutrition-sensitive approaches can serve as delivery platforms for nutrition-specific interventions. Because many of these interventions fit within multisectoral approaches, little research has identified the ways in which individual interventions contribute or interact with larger multisectoral collaborations, as well as the most efficient and systematic measurements when considered as a "package" (Reinhardt & Fanzo, 2014).

Nutrition-Specific Intervention Programs

Breastfeeding and Complementary Feeding Promotion

Although the benefits of breastfeeding have been recognized for decades, a high proportion of infants are not breastfed optimally in the first 2 years of life. Breastfeeding promotion and support programs have been shown to improve breastfeeding practices (Rollins et al., 2016). If these interventions could be scaled up where needed, it has been estimated that improved

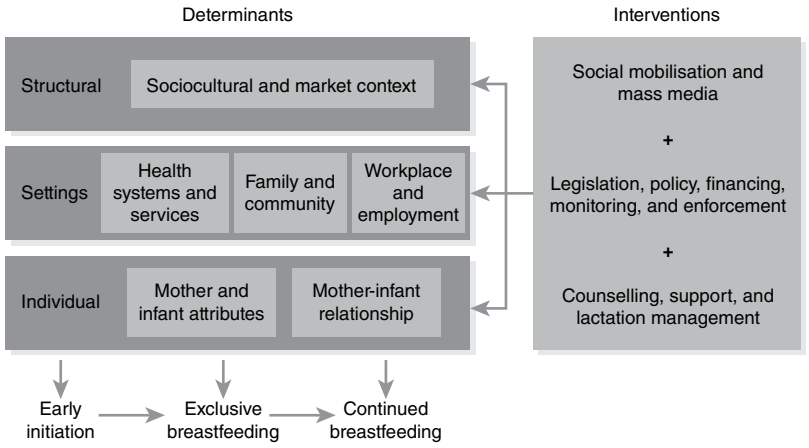

FIGURE 7-15 The components of an enabling environment for breastfeeding—a conceptual model.

breastfeeding practices would prevent an estimated 823,000 deaths in children younger than 5 years and could protect against about half of all diarrheal infections and about one-third of all respiratory infections in young children (Victora et al., 2016). Interventions have been developed and evaluated in a variety of contexts to promote, protect, and support breastfeeding practices among new mothers (**FIGURE 7-15**). For example, they have included mass-media and social mobilization programs; legislation and policy reform; and counseling, support, and lactation management services for mothers.

Within the health system, the most widely implemented and evaluated program is the "Baby-Friendly Hospital Initiative," developed and promoted by WHO and UNICEF (2009). A hospital can be certified as "Baby Friendly" when it does not accept free or low-cost human milk substitutes, feeding bottles, or teats and has implemented the 10 steps to support successful breastfeeding (**EXHIBIT 7-2**). A meta-analysis of this program and its components found that the intervention increased exclusive breastfeeding by 49% (95% CI, 33%–68%) and any breastfeeding by 66% (95% CI, 34%–107%) (Rollins et al., 2016). Since the program was launched in 1991, more than 20,000 hospitals in 156 countries have been designated as "Baby Friendly" and are implementing the program (WHO & UNICEF, 2009).

A common reason for cessation of exclusive breastfeeding is the need for women to return to work after delivery of their infant and a lack of workplace protections to support lactating mothers (Rollins et al., 2016). Only half of all countries globally have maternity protection legislation mandating at least 14 weeks of maternity leave and, even among these, protections may not be available to women working in informal sectors (International Labor Organization, 2014).

EXHIBIT 7-2 Ten Steps to Successful Breastfeeding

Every facility providing maternity services and care for newborn infants should:

1. Have a written policy that is routinely communicated to all healthcare staff.
2. Train all healthcare staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within a half-hour of birth.
5. Show mothers how to breastfeed, and how to maintain lactation even if they should be separated from their infants.
6. Give newborn infants no food or drink other than human milk, unless medically indicated.
7. Practice rooming-in (i.e., allowing mothers and infants to remain together 24 hours a day).
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

Although only a few studies have evaluated workplace supports for breastfeeding, studies evaluating maternity leave policies have shown that provision of lactation rooms at work and paid break time for lactation are associated with significantly higher rates of exclusive and continued breastfeeding (Rollins et al., 2016).

In community-based settings, one-on-one program intervention methods have included peer counseling, community health worker interventions, lactation counselors, or other healthcare worker counseling methods. These types of programs have generally succeeded in improving exclusive breastfeeding rates by 48% (95% CI, 32%–66%). Group counseling or community-based social mobilization, with or without mass-media promotion, has increased exclusive breastfeeding rates by 20% (95% CI, 3%–39%). For example, an evaluation of two large-scale infant and young child feeding promotion programs in Bangladesh and Vietnam found that there were significant improvements in exclusive breastfeeding practice for infants residing in communities targeted with intensive interpersonal counseling coupled with mass-media promotion of breastfeeding (Menon et al., 2016). In Bangladesh, the prevalence of exclusive breastfeeding in intervention communities improved by 36 percentage points (95% CI, 21.0–51.5) compared to communities not exposed to the program. In Vietnam, the increase was nearly 28 percentage points (95% CI, 17.7–38.1). In India, a randomized evaluation of a program implemented by Anganwadi workers, traditional birth attendants, and other local providers reported a 17-fold increased odds of exclusive breastfeeding to 6 months of age and a 30% lower prevalence of diarrhea at 3 months of age in communities that received the intervention (Bhandari et al., 2003).

Marketing practices by breast milk substitute manufacturers significantly undermines breastfeeding promotion and support programs. Compelling case studies in the 1970s drew attention to these marketing practices and the associated risk of infants becoming sick, malnourished, or dying from contaminated or diluted breast milk substitutes (Muller, 1974). This recognition led to the adoption of the International Code of Marketing of Breastmilk Substitutes at the 34th World Health Assembly in 1981. This code outlines the responsibilities of governments, health systems, and companies in the marketing and manufacture of breast milk substitutes. As of 2016, 135 countries had enacted legislation containing all or many provisions of the International Code (WHO, UNICEF, & International Baby Food Action Network [IBFAN], 2016), which represents significant progress in recent years at building an enabling environment to support breastfeeding. However, enforcement of these policies remains a challenge in many countries, and only 6 countries reported having dedicated funding to support monitoring and enforcement.

Complementary feeding intervention programs target infants and young children between the ages of 6 and 24 months, at the time when they transition from exclusive breastfeeding to solid foods and their family diets. Interventions to improve complementary feeding practices have been diverse, differing in their approach to addressing key behaviors and types of foods or supplements promoted (Dewey & Adu-Afarwuah, 2008). Most intervention programs have implemented some or all of the key recommendations in the Guiding Principles of Complementary Feeding (**EXHIBIT 7-3**; Pan American Health Organization [PAHO], 2003), focusing on either providing education or behavior change recommendations, providing supplement packets that could be used for "home fortification" of complementary foods, or providing foods to improve the diversity or nutrient quality of the infant diets.

Education and counseling interventions have been found to have a modest effect on improving linear growth (mean effect size, 0.20; range, 0.04–0.64) and intake of iron-rich foods (Dewey & Adu-Afarwuah, 2008). Interventions with the largest effect sizes were those that stressed the importance of animal-source foods for young children (Guldan et al., 2000; Penny et al., 2005). More recently, large-scale evaluations of social and behavior change interventions in Bangladesh, Vietnam, and Ethiopia have been reported. While these programs have been largely effective at improving reported complementary feeding practice, notable improvements in child growth have not been observed (Kim et al., 2016; Menon et al., 2016; Rawat et al., 2017). The intervention in Bangladesh did, however, report significant improvements in child language and motor developmental outcomes (Frongillo et al., 2017). In general, these types of programs have not been as effective for food-insecure communities as the provision of food supplements or fortified food products (Dewey & Adu-Afarwuah, 2008), likely because of lack of access to high-quality, nutrient-dense foods among poorer households.

A few trials have examined the effects of interventions designed to improve responsive feeding behaviors. Responsive feeding is rooted in responsive parenting practices more broadly, reflecting the reciprocal interactions between parents and children (Black & Aboud, 2011). Interventions have focused on helping parents to navigate the progression of infant feeding development, responding appropriately to infant hunger and satiety cues, and creating a pleasant and supportive environment during feeding. In settings where underweight is a substantial public health concern, interventions have been found to improve

EXHIBIT 7-3 Guiding Principles of Complementary Feeding

1. Practice exclusive breastfeeding from birth to 6 months of age, and introduce complementary foods at 6 months of age while continuing to breastfeed.
2. Continue frequent, on-demand breastfeeding until 2 years of age or beyond.
3. Practice responsive feeding, applying the principles of psychosocial care.
4. Practice good hygiene and proper food handling by washing caregivers' and children's hands before food preparation and eating, storing foods safely and serving foods immediately after preparation, using clean cups and bowls when feeding children, and avoiding the use of feeding bottles.
5. Start at 6 months of age with small amounts of food and increase the quantity as the child gets older, while maintaining frequent breastfeeding.
6. Gradually increase food consistency and variety as the infant gets older, adapting to the infant's requirements and abilities.
7. Increase the number of times that the child is fed complementary foods as he or she gets older. For the average healthy breastfed infant, meals of complementary foods should be provided 2–3 times per day at 6–8 months of age and 3–4 times per day at 9–11 and 12–24 months of age, with additional nutritious snacks offered 1–2 times per day, as desired.
8. Feed a variety of foods to ensure that nutrient needs are met. Meat, poultry, fish, or eggs as well as vitamin A–rich fruits and vegetables should be eaten daily. Vegetarian diets cannot meet nutrient needs at this age unless nutrient supplements or fortified products are used.
9. Use fortified complementary foods or vitamin–mineral supplements for the infant, as needed.
10. Increase fluid intake during illness, including more frequent breastfeeding, and encourage the child to eat soft, varied, appetizing, favorite foods. After illness, give food more often than usual and encourage the child to eat more.

feeding practice, but effects on weight gain have been mixed (Black & Hurley, 2017). In settings where overweight is of concern, the interventions have similarly improved feeding practice and some studies (though not all) have found lower rates of weight gain in the intervention group (Black & Hurley, 2017).

Three randomized controlled trials have evaluated the impact of providing animal-source foods on young children's growth. A study conducted in Zambia, the Democratic Republic of Congo, Guatemala, and Pakistan evaluated the efficacy of daily consumption of meat in comparison to a micronutrient-fortified corn–soy blend for infants 6–18 months of age. The authors reported no significant differences between groups in growth, anemia, or iron status between groups (Krebs et al., 2012). A second study evaluating the efficacy of daily consumption of caterpillar cereal for infants 6–18 months of age also reported no significant benefits on growth, though the prevalence of anemia was significantly reduced (Bauserman et al., 2015). In contrast to the meat trial, the comparison group received their usual diet, which was unlikely to be fortified with micronutrients. A third efficacy trail in the highlands of Ecuador evaluated the impact of the daily provision of eggs for infants 6–15 months of age in comparison to a control group consuming their usual diet (Iannotti et al., 2017). In this trial, the researchers reported significant improvements in child growth and a nearly 50% reduction in the prevalence of stunting between groups. While these findings are promising, the study warrants replication in other settings to determine if the effects can be generalized more broadly.

Even with the best available foods, it is very challenging for families to meet the micronutrient requirements for infants and young children, such that nutrient gaps tend to persist, particularly in iron, zinc, calcium, and vitamin A (Arsenault, Hijmans, & Brown, 2015; Ferguson, Chege, Kimiywe, Wiesmann, & Hotz, 2015). Food supplementation interventions have often offered some type of fortified food products, such as a fortified cereal/legume blend, fortified milk powder, or a fortified lipid-based nutrient supplement. The effects of these types of interventions on growth have varied, but efficacy trials have reported generally modest effects on linear growth of approximately 0.3 standard deviation (Dewey & Adu-Afarwuah, 2008). The effects on anemia and iron status have been more consistently positive, with a mean reduction in the prevalence of anemia of 13 percentage points across all studies (Dewey & Adu-Afarwuah, 2008). Since the publication of a systematic review in 2008, many studies have sought to evaluate the efficacy of fortified lipid-based nutrient supplements (LNS) for the prevention of stunting.

While there is some variation in their composition, these supplements typically provide 100–200 kcal/day and are fortified with approximately 1 RDA of most vitamins and minerals. They are often made from a peanut or soy protein base, with added milk powder and oil (Arimond et al., 2015; Chaparro & Dewey, 2010). While some results are still pending, most studies have reported modest improvements in growth and anemia status (Abbeddou et al., 2017; Adu-Afarwuah et al., 2008; Christian et al., 2015; Dewey et al., 2017; Hess et al., 2015; Iannotti et al., 2014; Maleta et al., 2015).

Fortified cereal/legume blends and lipid-based nutrient supplements have also been evaluated as methods of preventing or treating moderate acute malnutrition, defined as a weight-for-length *z*-score between −2 and −3 (Lazzerini, Rubert, & Pani, 2013). If the problem is left unaddressed, children may progress to severe wasting, requiring more intensive treatment protocols (described in the next subsection). Acute malnutrition may occur in emergency situations, seasonally, and endemically, so it is likely that both short-term and long-term programs addressing the immediate needs as well as the underlying determinants of wasting, such as food insecurity and poor-quality water, sanitation, and hygiene, are needed (de Pee et al., 2015).

Management of Severe Acute Malnutrition

Although it affects only a small fraction of all undernourished children, severe acute malnutrition (SAM) has received programmatic attention because of its high case fatality rate without timely treatment. Severe wasting, the largest component of SAM, has an attributable fraction for child deaths of 7.4%, compared to 12.6% for moderate and severe wasting together and 44.7% for all undernutrition (Black et al., 2013).

For programmatic purposes, SAM is defined as a weight-for-height that is more than 3 standard deviations below the WHO growth standard median (considered severe wasting or marasmus), or bilateral pitting edema (edematous malnutrition or kwashiorkor), or a mid-upper arm circumference of less than 115 mm in children 6–59 months of age (WHO, 2013b). It is preferable to assess both weight-for-height and MUAC because these measurements may identify different children at risk. When screening populations of children for SAM, it is easier to use MUAC, since color-coded measurement tapes can be administered by workers with limited training. These two forms of SAM may occur together when a child with marasmus develops edema; marasmic kwashiorkor has the highest case fatality rate of the three forms of SAM. The proportion of SAM accounted for by kwashiorkor varies by world region, being high in southern Africa and lower elsewhere (Trehan & Manary, 2015).

In programs providing treatment for SAM, it is essential that the child be assessed for clinical complications that would require inpatient therapy—for example, dehydration, high fever, respiratory distress, lethargy, or severe anemia. In addition, it is important to assess anorexia by providing a test feeding of ready-to-use therapeutic food (RUTF). Specific diseases that need treatment, such as HIV/AIDS or tuberculosis, should also be considered.

For children with SAM with complications who are admitted to a health facility, WHO (1999, 2013b) has published a standard protocol for treatment. It includes initially treating infections, generally with intravenous antibiotics. A two-phase feeding approach with two therapeutic formulas, milk F75 and milk F100, is used, with the formulas gradually being replaced by solid foods. A blended food supplement, such as corn–soy or wheat–soy, or an RUTF can be used after the acute phase to continue the nutritional rehabilitation. Children can be transferred to outpatient care when their medical complications and edema are resolving and the child is alert and has a good appetite (WHO, 2013b). Vitamins and minerals should be provided in the food or as supplements. The availability of RUTF has allowed the shortening of the inpatient period from previously 30 days to only 5 to 10 days (Collins et al., 2006).

Children with SAM without complications can enter a feeding program based on the community management of acute malnutrition (CMAM) model. With active surveillance for SAM, a large proportion of cases will be identified early in the illness without complications and, therefore, will be eligible for community management. Children beginning treatment may benefit from oral antibiotics for 7 days (Trehan et al., 2013). CMAM is based on provision of RUTF, the most common form of which is a peanut paste fortified with macronutrients and micronutrients to meet standards set by WHO (WHO, World Food Programme, UN System Standing Committee on Nutrition, & UNICEF, 2007). Children can be provided with a 1- to 2-week supply of RUTF at a dose of about 150–200 kcal/kg/day (Trehan & Manary, 2015). Frequent evaluation of the child every 1 to 2 weeks is important. Treatment should continue until weight-for-height is at least −2 SD or MUAC is greater than 125 mm, depending on which enrollment criterion

was used. Although some children may meet these criteria sooner, treatment can take 10 to 12 weeks.

In well-managed programs that combine inpatient care if needed and CMAM with active surveillance for SAM, two-thirds to three-fourths of cases can be treated in the community, with the overall case fatality rate during treatment being kept as low as 5% (Collins et al., 2006). A systematic review of studies of treatment outcomes and a Delphi process was used to derive benchmarks for outcomes of treatment (Lenters, Wazny, Webb, Ahmed, & Bhutta, 2013). For inpatient treatment of complicated SAM, the estimated CFR was 14% (range, 5%–30%) and the recovery rate was 71% (range, 25%–95%). For CMAM, the CFR was estimated at 4% (range, 2%–7%) and the recovery rate at 80% (range, 50%–93%).

Because most SAM treatment programs follow children only until discharge criteria are met or for a short period thereafter, little is known about longer-term outcomes. The existing studies show substantial rates of relapse to SAM and of death, possibly due to return to impoverished and food-insecure households or to underlying disease, such as HIV/AIDS (Bhandari et al., 2016; Kerac et al., 2014). These findings emphasize the need to provide economic, nutritional, and medical support post discharge to the family through social protection and health programs.

Micronutrient-Deficiency Prevention Programs

As micronutrient deficiencies often occur where dietary quality is poor and lacking in variety, micronutrient deficiency prevention programs have historically utilized three complementary approaches: (1) supplementation; (2) fortification, extended to include biofortification of staple crops and micronutrient powders for home use (WHO, 2016b); and (3) dietary diversification, achieved by education, homestead food production, or other approaches, as detailed later in this section. The choice of strategy should be guided by the mix, extent, and severity of deficiencies, and the potential reach of programs to effectively cover those persons in need.

Supplementation. Supplementation programs are widely used to address micronutrient deficiencies. WHO recommends the supplement interventions listed in **TABLE 7-12**, based on reviews of the evidence demonstrating efficacy or effectiveness at preventing micronutrient deficiencies and reducing morbidity or mortality.

Pregnancy. In high-risk populations, current WHO guidelines suggest that women be supplemented with iron–folic acid (IFA) throughout pregnancy, as this intervention is estimated to reduce risks of anemia by 70% and iron deficiency by 57% (Pena-Rosas et al., 2015). While questions exist about whether to supplement women with iron in malaria-endemic areas, to date there is not strong evidence that IFA supplementation is associated with adverse risks in these settings (Mwangi et al., 2017), indicating it is prudent to both supplement and treat malaria as indicated during pregnancy. WHO also recommends use of calcium supplements during pregnancy. Preeclampsia and eclampsia are a leading cause of maternal mortality and preterm birth, and it has been estimated that calcium supplementation may reduce these risks by 20% and 24%, respectively (Hofmeyr, Lawrie, Atallah, Duley, & Torloni, 2014).

Many countries have adopted IFA and calcium supplementation recommendations as part of their national antenatal care guidelines, although low attendance, coverage, and stock-outs are frequent problems (Sununtnasuk, D'Agostino, & Fiedler, 2016). In such settings, facility-based IFA distribution has been complemented by community health workers who may reach women earlier in pregnancy and be less vulnerable than facilities to stock-outs (Kavle & Landry, 2017). There are also challenges to adding calcium supplements to IFA, which should be taken as three or four divided doses per day, preferably with food and apart from IFA supplements. Social support from family members and peers has been reported to improve IFA and calcium supplementation adherence (Martin et al., 2017), although more work needs to be done to improve adherence while delivering these interventions at scale.

Given that multiple micronutrient deficiencies typically coexist in poorly nourished populations, it is rational to consider replacing IFA with a multiple-micronutrient supplement during pregnancy that, although a higher-cost product, addresses a broader spectrum of nutritional deficiencies and utilizes the same delivery systems as IFA supplements. Multiple-micronutrient supplements have been compared to IFA in large field trials in Indonesia (SUMMIT Study Group, 2008) and Bangladesh (West et al., 2014), and in smaller trials in a dozen other countries. These studies reveal overall reductions of 8% to 15% in low birth weight, preterm birth, and stillbirth; some evidence of a reduction in risk of infant mortality; and a smaller but significant reduction in SGA infants (Smith et al., 2017). Benefits of multiple-micronutrient supplementation have been

TABLE 7-12 WHO Recommended Micronutrient Supplementation Interventions

Recommendation	Dosage	Rationale	Reference
Women of Reproductive Age			
Intermittent iron and folic acid supplementation	60 mg iron + 2,800 µg folic acid taken weekly	Prevention of anemia	(WHO, 2011c)
Pregnancy			
Iron–folic acid tablets	60 mg elemental iron + 400 µg folic acid taken daily	Prevention of anemia and iron deficiency	(WHO, 2016b)
Calcium	1,500–2,000 mg taken daily	Prevention of preeclampsia	(WHO, 2016b)
Infants and Children			
Semi-annual vitamin A supplementation	100,000 IU (6- to 11-month-olds) 200,000 IU (12- to 59-month-olds)	Prevention of vitamin A deficiency and child mortality	(WHO, 2011d)
Zinc supplementation	20 mg per day for 10–14 days (Treatment) 5–10 mg per day (Prevention)	Treatment and prevention of diarrhea	(WHO, 2006)
Multiple micronutrient powders for 6- to 23-month-olds and 2- to 12-year-olds	10–12.5 mg elemental iron + 300 µg retinol + 5 mg zinc + additional micronutrients to achieve 100% of the RNI taken at a target of 90 sachets over a 6-month period	Prevention of anemia and iron deficiency	(WHO, 2016a)
Iron supplements	10–12.5 mg elemental iron (6- to 23-month-olds) 30 mg elemental iron (24- to 59-month-olds) 30–60 mg iron (5- to 12-year-olds) Taken daily and in conjunction with malaria management strategies in malaria-endemic areas	Prevention of anemia and iron deficiency	(WHO, 2016a)

particularly noted when begun early in pregnancy (West et al., 2014), and among infants born to undernourished or anemic women (Smith et al., 2017).

Infancy and Childhood. High-potency vitamin A supplementation is the most common, direct strategy to prevent health consequences attributable to vitamin A deficiency in preschoolers. It is typically delivered as a 200,000-IU oral dose (half-dose to infants 6–11 months of age) in a gelatinous capsule or as an oily syrup every 4 to 6 months. While improving serum retinol concentrations for only a few months, this intervention's protection against xerophthalmia and child mortality can last for 6 to 12 months (Palmer, West, Dalmiya, & Schultink, 2012).

Scaled-up vitamin A supplementation programs, which were launched in the 1970s and expanded globally in the 1980s and 1990s, exist in more than 80 countries (Wirth et al., 2017). Supplementation typically exists as a stand-alone (vertical) activity or is packaged with other child health interventions,

such as deworming, immunizations, growth monitoring, and nutritional screenings. On average, such programs reach approximately 65% of the targeted beneficiaries (Klemm, Palmer, Greig, Engle-Stone, & Dalmiya, 2016). Supplementation should be shifted to other preventive strategies when hyporetinolemia (less than 0.70 μmol/L) is less than 5% in the target population, coupled with supportive evidence of an adequate dietary vitamin A intake in high-risk populations (Palmer et al., 2012).

Extensive evidence indicates that zinc supplementation started during diarrhea can reduce the severity and duration of illness (Lazzerini & Wanzira, 2016), supporting a recommendation that zinc supplements be provided with oral rehydration therapy for diarrhea (WHO, 2006). To date, zinc supplementation coverage has been low due to inconsistent zinc tablet supplies, inadequate healthcare provider knowledge, and lack of public demand (Lamberti, Fischer Walker, Taneja, Mazumder, & Black, 2015; Lamberti et al., 2015). These problems require greater focus on supply chain management, training of providers, and community-based advocacy to raise awareness, promote demand, and realize the public health impact of this efficacious intervention. Modest, consistent benefits of longer-term supplementation on child growth, morbidity, and survival have been observed (Mayo-Wilson et al., 2014), but have not led to recommendations for universal supplementation.

Iron supplements have long been recommended to prevent iron-deficiency anemia in children. However, a long-standing debate over whether prophylactic iron may be contraindicated where malaria is endemic was fueled by the findings of a randomized trial in a *falciparum* malaria-endemic area of Zanzibar; in that study, preschool-child iron supplementation significantly increased the risk of severe illness leading to hospitalization, death, and adverse clinical events due to malaria (Sazawal et al., 2006). Stratification in a subsample suggested that these adverse effects may have been restricted to non-anemic children. Given these findings, for a period of time, WHO had recommended that universal iron supplementation not be implemented in malaria-endemic areas without screening individuals for iron deficiency (World Health Organization Secretariat, 2007). Routine iron-deficiency screening proved challenging due to lack of simple, easily interpretable iron biomarkers for use in community settings. Thus, the net effect of this recommendation was that iron supplementation programs were halted for nearly 10 years. Updated guidance now encourages iron supplementation in both nonmalarial and malaria-endemic settings in tandem with the prevention and treatment of malaria (WHO, 2016a).

Like pregnant women, children in low-income settings are likely to have multiple micronutrient deficiencies. The previously mentioned supplement regimens target only a single nutrient deficiency, leaving unaddressed the challenge of multiple micronutrient deficiencies. Two supplemental approaches have been proposed: (1) multiple-micronutrient powders, which are single-serving sachets of a microencapsulated nutrient mix designed to be added to a child's meal (also known as point-of-use fortification), and (2) lipid-based nutrient supplements, also provided in single-serving sachets, usually combined in an approximately 100-kcal paste made from peanut, soy, and/or milk powder to which micronutrients are added as fortificants.

In several field trials in low-income countries, multiple-micronutrient powders have been found to reduce anemia and iron deficiency as effectively as iron syrups or drops (De-Regil, Suchdev, Vist, Walleser, & Pena-Rosas, 2011; Salam, MacPhail, Das, & Bhutta, 2013) and a multiple-micronutrient supplement (Adu-Afarwuah et al., 2008). Micronutrient powder delivery has been implemented in at least 22 countries, through health facilities and community distribution (UNICEF & Centers for Disease Control and Prevention [CDC], 2013). The sachets each cost approximately $0.03, or $2.70 for a 90-day course. Recent trials with LNS have also found that these lipid-based products offer significant benefits in preventing anemia and reducing iron deficiency (Abbeddou et al., 2017; Siega-Riz et al., 2014).

Fortification. Food fortification offers a potentially sustainable approach to combat micronutrient deficiencies. Foods that are fortifiable include sugar, salt, vegetable oil, flour, staple cereals, and condiments such as soy sauce, fish sauce, and bouillon cubes. Large-scale fortification has the potential to effectively replete populations with one or more deficient nutrients without significantly changing dietary behavior. Fortification is achieved by adding nutrient premixes to food items, typically at the point of production, in a controlled and regulated manner. An alternative approach, known as biofortification, involves selective breeding of staple grains, tubers, and beans to incorporate more micronutrients; it is increasingly becoming available as a means to increase micronutrient consumption and status (Bouis & Saltzman, 2017).

Globally, the oldest, most widespread, and most successful fortification program has been universal salt iodization. Salt iodization involves dry mixing or spraying food-grade salt with potassium iodate or iodide (Mannar & Dunn, 1995), targeting an iodine

concentration of 20 to 40 parts per million (ppm) to deliver, on average, 150 μg of iodine per person per day (WHO, UNICEF, & International Council for Control of Iodine Deficiency Disorders [ICCIDD], 2007). Prior to 1990, 130 countries were classified as iodine deficient, but by 2011 salt iodization programs had been scaled up to reach two-thirds of the world's population, reducing the number of deficient countries to 32 (Hodge, 2016). Despite successes, coverage remains sub-optimal or intermittent in many regions (Knowles et al., 2017), which can lead to a rapid increase in the prevalence of iodine deficiency (Zimmermann, 2004).

Vitamin A fortification has been under way in low-income countries since the 1970s, starting with an effective national program to fortify sugar in Guatemala, which was later expanded into Central America, Africa (Zambia), and Southeast Asia (Philippines). Fortification of monosodium glutamate (a flavor enhancer added to side dishes) with vitamin A was highly effective in reducing deficiency in Indonesia and the Philippines, but never scaled up due to a change in the retail product's color that raised marketing concerns with the producers (Sommer & West, 1996). The most extensive vitamin A fortification strategy to date has occurred with vegetable oil; it has reached an estimated 75% of the populations in eight countries in West Africa (Sablah et al., 2012) and is rapidly expanding into Southern Asia. Notwithstanding, effectiveness relies on numerous legislative, quality control, quality, and market coverage factors. Indeed, 97% of home-sampled vegetable oils were found to contain the prescribed 8 mg/kg of vitamin A in Abidjan (Cote d'Ivoire) (Rohner et al., 2016), but only 11% of tested sugar samples in a rural Zambian market met the statutory level of 10 mg of vitamin A per kg (Green, Kabaghe, Musonda, & Palmer, 2017).

Presently, wheat flour fortification is mandated in approximately 85 countries worldwide. (Hoogendoorn, Luthringer, Parvanta, & Garrett, 2016). While it is technically possible to fortify flours with several micronutrients, the most common fortificants are folic acid and iron, with the former intended to prevent occurrence of neural tube defects. A meta-analysis of eight population-based observational studies of folic acid–fortified flour programs concluded that these programs led to a 46% reduction in the incidence of neural tube defects, which translated into a 13% decrease in the number of neonatal deaths attributable to congenital abnormalities (Blencowe, Cousens, Modell, & Lawn, 2010). There have been few evaluations of the effectiveness of flour fortification on anemia or iron deficiency, but available data suggest this approach broadly improves iron status (Pachon, Spohrer, Mei, & Serdula, 2015).

Biofortification strategies are currently designed to enhance the iron, zinc, or vitamin A–precursor carotenoid content of staple crops such as sweet potato, cassava, maize, beans, rice, and pearl millet to provide 30% to 100% of the estimated average requirements for these nutrients (Bouis & Saltzman, 2017). Evaluation trials have demonstrated significant improvements in micronutrient status, reflected by improved iron status indicators following consumption of iron-fortified beans among women in Rwanda (Haas et al., 2016) and consumption of iron-fortified pearl millet by children in India (Finkelstein et al., 2015). Likewise, consumption of carotenoid-biofortified orange-fleshed sweet potatoes raised the vitamin A status of young children in Mozambique (Low et al., 2007). While controlled orange maize trials in Zambia have shown minimal effects of carotenoid fortification on serum retinol in children, intake was accompanied by improved (estimated) liver vitamin A reserves (Gannon et al., 2014) and function, indicated by dark-adapted pupillary responsiveness to light (Palmer et al., 2016), suggesting that consuming biofortified maize provided a broad dietary safety net in a population with marginal vitamin A status.

Regardless of the nutrients or vehicles used, fortifying a population's food supply to prevent micronutrient deficiencies requires legislation, political commitment, collaboration with industry, adherence to quality control, a plan for financial solvency, sustained market penetrance, societal engagement, and routine product monitoring under ambient conditions of use (Luthringer, Rowe, Vossenaar, & Garret, 2015).

Dietary Diversification. Micronutrient deficiencies emerge from a diet chronically lacking in nutritious food. In its quest to prevent chronic diseases across the course of life, to which micronutrient deficiencies may contribute, the WHO has long advocated a diet rich in diversity, including vegetables and fruits (Nishida, Uauy, Kumanyika, & Shetty, 2004). Population studies in low-resource settings over the past 30 years have consistently revealed low intakes of multiple micronutrients among women of reproductive age (Lee, Talegawkar, Merialdi, & Caulfield, 2012; Torheim, Ferguson, Penrose, & Arimond, 2010) and diets with low dietary diversity among children. Yet population evidence remains exceedingly sparse associating the usual dietary nutrient intakes with risk of multiple micronutrient deficiencies in women and children. Evidence exists that both (1) nutrition

counseling, social marketing, and behavior change efforts that promote nutrient-rich foods and (2) small-scale, homestead food production strategies that target poor, rural households can increase household availability or intakes of dark green leaves (Smitasiri, Attig, & Dhanamitta, 1992), eggs (de Pee et al., 1998), and other carotenoid-rich foods (Sommer & West, 1996; Talukder, Islam, Klemm, & Bloem, 1993). In terms of effects on status, while iron- and vitamin A–fortified complementary feeding in a small number of trials involving young children have generally reduced anemia and hyporetinolemia, respectively, zinc-fortified foods have not affected plasma zinc concentration (Dewy & Adu-Afarwuah, 2008). Nor have nutrition education trials generally lowered the risk of anemia, although in one setting (Burkina Faso), a 2-year integrated agriculture and behavior change intervention may have marginally improved hemoglobin levels in young children (Olney, Pedehombga, Ruel, & Dillon, 2015). Otherwise, virtually no trials exist that have tested the effects of dietary diversification on micronutrient status or risk of deficiencies in women or children, revealing both gaps in the literature and areas that are ripe for further research.

Choice of Interventions

Economic optimization models have been developed to help choose the most efficient strategy for a country, given regional variations in dietary intakes (Brown, Engle-Stone, Kagin, Rettig, & Vosti, 2015; Vosti, Kagin, Engle-Stone, & Brown, 2015). Population monitoring and evaluation are essential to improve program coverage of designees and assure efficient use of resources. There are also risks associated with the large number of intervention possibilities. Uncoordinated program delivery may lead to undesirably high intakes of certain micronutrients in some groups (Klemm et al., 2016). Nonetheless, intervention and monitoring options have never been greater, and will continue to increase, for optimizing micronutrient deficiency prevention in the future.

Obesity Prevention Programs

The NOURISHING framework for obesity reduction includes interventions in food environments, food systems, and behavioral change communication (BCC) (**TABLE 7-13**; Roberto et al., 2015). Most LMICs lack obesity-prevention policies due to the

TABLE 7-13 World Cancer Fund Research International NOURISHING Framework for Obesity Prevention

NOURIS	H	ING
Food Environment	**Food System**	**Behavior Change Communication**
Policy Area		
N	Nutrition label standards and regulations on the use of claims and implied claims on food	
O	Offer healthy food and set standards in public institutions and other specific settings	
U	Use economic tools to address food affordability and purchase incentives	
R	Restrict food advertising and other forms of commercial promotion	
I	Improve nutritional quality of the whole food supply	
S	Set incentives and rules to create a healthy retail and food service environment	
H	Harness food supply chain and actions across sectors to ensure coherence with health	
I	Inform people about food and nutrition through public awareness	
N	Nutrition advice and counseling in healthcare settings	
G	Give nutrition education and skills

higher prioritization accorded to both treatment and prevention of undernutrition (Dietz et al., 2015). For instance, one review found that only 12% of LMICs (14 of 116) had proposed a policy that addressed all four of the WHO's NCD diet-related risk factors (salt consumption, fat consumption, fruit and vegetable intake, and physical activity), and 25% addressed only one risk factor (Lachat et al., 2013). Further, only one low-income country and one LMIC implemented at least one of five policy actions on the consumption of sugar sweetened beverages in 2014 (Popkin & Hawkes, 2016). As a result, much of the evidence base on obesity prevention policies and programs reflects high-income contexts (IFPRI, 2017).

Some studies suggest behavioral change communication (BCC) is viewed as the most valuable and acceptable policy action for obesity-reduction strategies (Holdsworth et al., 2013). As a result, most interventions to reduce childhood obesity are school-based programs targeting BCC among children 6 to 12 years old (Mead et al., 2017; Waters et al., 2011). In LMICs, school-based interventions have been associated with significant decreases in childhood BMI and fast-food eating behavior scores, along with increases in healthy food consumption and time spent being physically active (Verstraeten et al., 2012).

Several Cochrane reviews have examined obesity prevention and its impacts on different groups in different settings. One review (Waters et al., 2011) examined 55 studies (of which 50 were from high-income countries) on childhood obesity prevention in children age 6 to 12 years; the researchers found that, although there was significant heterogeneity of studies, some programs clearly had an impact on adiposity (measured as BMI). Program components that had beneficial effects included improving the nutritional quality of school meals, integrating healthy eating into school curriculums, promoting physical activity, providing parent support and home activities that improve diets and focus less on screen-based activities, and improving school food environments (Waters et al., 2011). Two additional Cochrane reviews summarized the results of 114 studies involving more than 13,000 children and young people in middle- and high-income countries/regions including Europe, the United States, Canada, New Zealand, Australia, Japan, and Malaysia. A combination of diet, physical activity, and behavioral change interventions was found to potentially reduce weight in children age 6 to 11 years and in adolescents age 12 to 17 years, though there were limitations in the studies and variation in the results. In children, these interventions (which were mainly school-based) may have small, short-term effects in reducing children's weight and BMI *z*-scores (Mead et al., 2017). In adolescents, some evidence suggested that the combined interventions could reduce adolescent weight by an average of 3.5 kg (Al-Khudairy et al., 2017).

While engaging with the food industry has produced only limited success in high-income countries (Roberto et al., 2015), LMICs continue to struggle to effectively coordinate systems interventions along the entire food supply chain. For instance, one review of NCDs in LMICs found that 23 of 26 studies focused solely on agricultural interventions, even though manufactured, prepackaged foods accounted for the majority of unhealthy food consumption (Pullar et al., 2016). With the rapid penetration of multinational food companies into LMIC markets, research suggests that nutrition labeling and incentives for reformulating foods for greater nutrient value will be critical to obesity prevention in these countries (Lobstein et al., 2015).

Nutrition-Sensitive Programs

Given the critical window of opportunity to influence child growth, undernutrition, and cognitive development, nutrition-sensitive approaches have indirect causal associations with reductions in malnutrition. These agriculture and food systems; water, sanitation, and hygiene (WASH); social protection; and early childhood development (ECD) programs have the potential to be brought to scale.

Agriculture and Food Systems

Several key reviews have examined the evidence to date on how agriculture can improve nutrition. While more rigorous, well-designed research is still needed, some lessons are emerging on which areas of agriculture can be constructively targeted to improve diets and nutrition (Girard, Self, McAullife, & Olude, 2012; Masset, Haddad, Cornelius, & Isaza-Castro, 2011). *Nutrition-sensitive agriculture* is a food-based approach to agricultural development that prioritizes nutrient-rich foods, dietary diversity, and food fortification at the center of the fight against malnutrition and micronutrient deficiencies (FAO, 2014). **FIGURE 7-16** illustrates the seven primary pathways that connect nutrition-sensitive agriculture interventions to nutrition outcomes. Two pathways, based on service expenditures and women's empowerment, are discussed in this section in terms of their

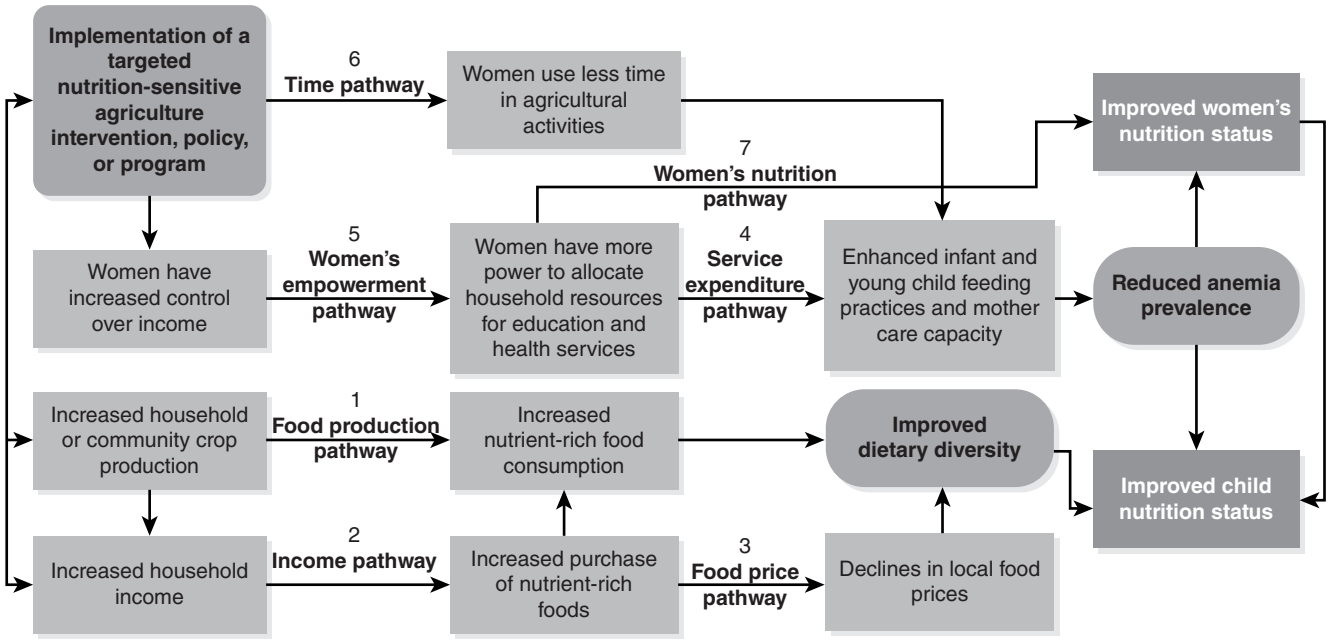

FIGURE 7-16 The pathways connecting nutrition-sensitive agricultural interventions and improvements in malnutrition.

Modified from Gillespie, S., Harris, J., & Kadiyala, S. (2012). *The agriculture-nutrition disconnect in India: What do we know?* Washington, DC: International Food Policy Research Institute.

opportunities to improve nutrition among women and adolescent girls.

Positive results from scaled-up programs have illustrated improvements in dietary patterns and intakes of specific micronutrients, including vitamin A (Girard et al., 2012; Reinhardt & Fanzo, 2014), but further research is needed to determine the direct causal linkages, if any, to childhood nutritional status (Ruel, Alderman, & Maternal and Child Nutrition Study Group, 2013). Bringing nutrition-sensitive agriculture projects to scale requires identifying context-specific enabling environments in relation to food systems, climate change and the physical environment, and coordination of investments and work with other development sectors (Hodge et al., 2015; van den Bold et al., 2015).

Agriculture is a critical component of food systems in which food supply chains and food environments can shape diets and nutrition outcomes (HLPE, 2017). The *food supply chain* encompasses all of the activities and actors that move food through production to consumption, concluding with waste disposal (Hawkes & Ruel, 2012). The supply chain is often referred to as the "farm to fork" transformation (Matopoulos, Vlachopoulou, Manthou, & Manos, 2007). Changes in decision making along this pathway can impact both food security and food's nutritional value, either positively (i.e., reductions of trans fats and sodium or increased micronutrient and macronutrient availability) or negatively (i.e., food loss and contamination). **FIGURE 7-17** illustrates the ways the food supply chain can enhance or inhibit a food's nutrient value.

The last arrow in Figure 7-18, consumption and food utilization, refers to food environments and consumer behavior. The *food environment* refers to the physical, economic, political, and sociocultural contexts that shape individual dietary preferences, food choices, and nutritional status (Global Panel on Agriculture and Food Systems for Nutrition [GLOPAN], 2017; Swinburn, Dominick, & Vandevijvere, 2014). Three elements of the food environment influence diets (HLPE, 2017):

- *Proximity and affordability*: Physical and economic access to food.
- *Food promotion, advertising, and information*: Broadcast, print, and digital advertising; packaging, labeling, and point-of-sale promotions; branding and sponsorships; merchandising and the use of licensed brand-based characters.
- *Food quality and safety*: Regulatory mechanisms to ensure quality control or safety standards; availability of cold storage; extent to which nutrient information and ingredients are readily available to consumers (Caspi, Sorensen, Subramanian, & Kawachi, 2012; Hawkes et al., 2015; Swinburn et al., 2014).

Food environments are considered "healthy" when they enable consumers to make nutritious dietary choices that may improve nutrition. Unfortunately,

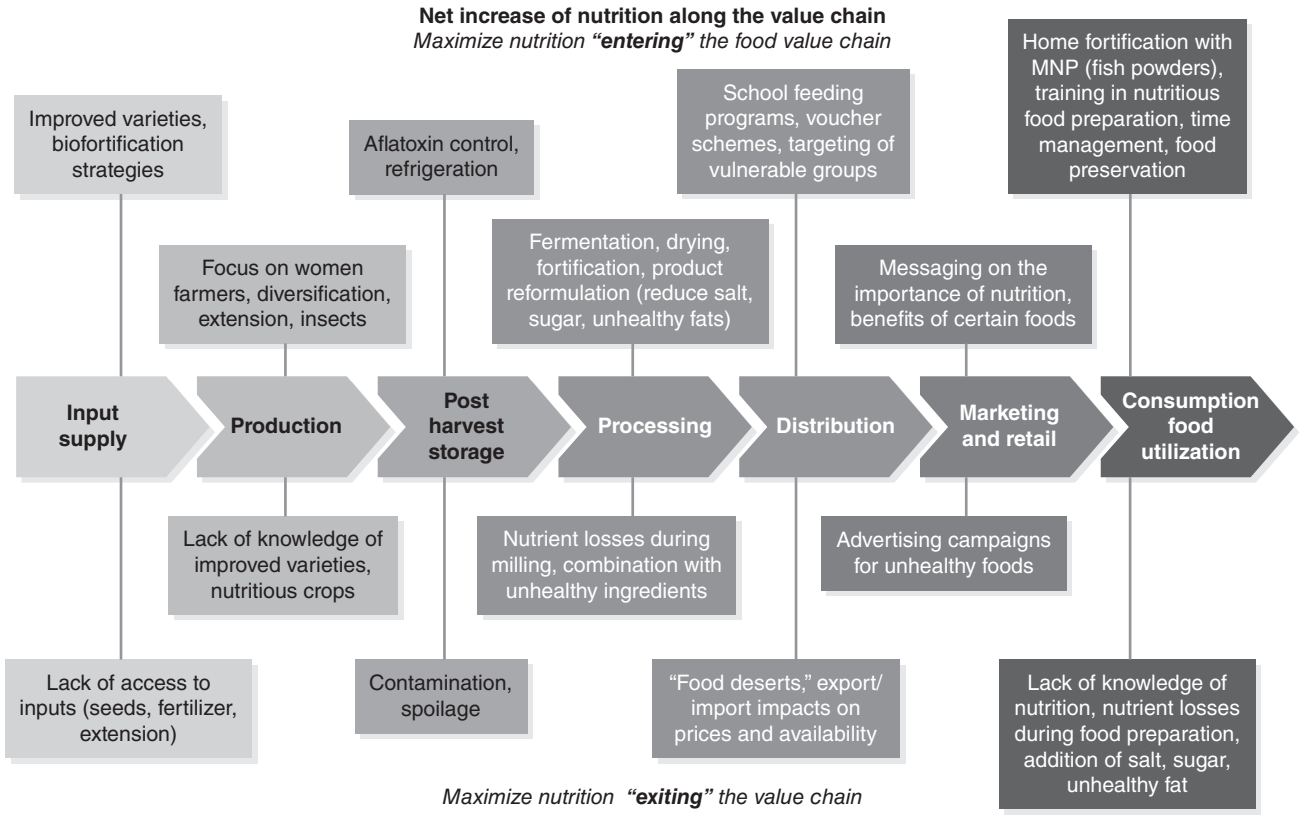

FIGURE 7-17 Maximizing and minimizing nutrition along the food value chain.

many food environments are deemed "unhealthy" because they promote nutrient-poor dietary choices through misleading marketing (i.e., product placements and advertising), pricing policies, and deceptive labels on packaging (Baker & Friel, 2014; Malik, Willett, & Hu, 2013; Monteiro & Cannon, 2012; Moodie et al., 2013; PAHO, 2015).

Water, Sanitation, and Hygiene

Unsafe drinking water sources, inadequate sanitation, and poor hygienic practices are commonly found in LMICs, where they may contribute to malnutrition either as risk factors for diarrhea or through subclinical intestinal infections resulting in environmental enteric dysfunction (Figure 7-12). WASH interventions aim to reduce the exposure to infectious agents transmitted by the fecal–oral route (e.g., diarrhea pathogens) or through the skin (e.g., intestinal worms).

The most relevant recent systematic review examined the effects of a variety of WASH interventions on the nutritional status of children (Dangour et al., 2013). This review of 14 studies found an intervention benefit on height-for-age of small magnitude and borderline statistical significance, but no effect on weight-for-age or weight-for-height. It has been thought that limited effects of WASH interventions may reflect that previous efforts had low uptake or did not include sufficient attention to sanitation, or because comprehensive WASH interventions are needed.

Reducing open defecation may be of critical importance (Spears, Ghosh, & Cumming, 2013). One randomized trial of community-led total sanitation in Mali found a 14% reduction in the prevalence of stunting following implementation of this intervention (Pickering, Djebbari, Lopez, Coulibaly, & Alzua, 2015). However, another total sanitation trial in India did not find any effects on anthropometric measures in children younger than 5 years (Patil et al., 2014); the same was true in another trial of rural sanitation in India (Clasen et al., 2014). Furthermore, trials in Kenya, Bangladesh, and Zimbabwe that included comprehensive WASH interventions, including those related to water quality, sanitation, and hand washing, were unable to demonstrate a benefit in terms of the

nutritional status of children (Humphrey, Prendergast, Ntonzini, & Gladstone, 2017; Luby et al., 2018; Null et al., 2018).

Early Childhood Development

Poor nutrition during the first 1,000 days of life (from birth to age 2) can have lifelong consequences, including in areas such as a child's cognitive, nutritional, and physical development (Black, Gove, & Merseth, 2017). In addition, infectious diseases, maternal mental health, and environmental conditions can affect the young child's mental development.

Early child development (ECD) programs have been conceptualized as providing "nurturing care" for infants and young children (Black, Gove, & Merseth, 2017). This care includes nutrition, health, early learning, responsive caregiving, and safety, and is based on caregiver–child interactions that enable children to reach their developmental potential (Black, Gove, & Merseth, 2017). Evidence for positive benefits from such interventions on mental development have largely come from programs that supported psychosocial stimulation to infants and young children through a variety of approaches, including home visits, group sessions, health center appointments, links with conditional cash transfer programs, or a combination of these (Aboud & Yousefzai, 2016). Successful programs have used active learning to enable caregivers and paraprofessionals to adopt stimulation practices. Stimulation has also been integrated with programs to promote nutrition—a relationship that makes sense given the role of undernutrition as a determinant of poor development—but the expected synergistic effects have not been demonstrated (Aboud & Yousefzai, 2016).

While many ECD programs have focused on the first 1,000 days, the need for supporting a child's development continues after the first 2 years of life. The platforms that are used to reach children after this age include childcare settings, preprimary schools, and primary schools (Black et al., 2017). All of these are also settings where nutritional interventions can be implemented. In approaches targeting stunting, the emphasis has rightly been on the first 1,000 days of life, but there can be additional nutritional benefits from these programs, especially with the childcare and preprimary age groups. While school feeding programs have not been recommended for their nutritional benefits, they may enhance school attendance and learning (Bhutta et al., 2013).

Women's Empowerment

Inclusive of social status, mental health, and nutritional outcomes, women's empowerment influences when women first have children and their associated nutritional status at birth, as well as resources at their disposal and the care they can provide. Empowered and educated women are more likely to maintain healthy infant and young child feeding (IYCF) practices (Malapit & Quisumbing, 2015).

The socioeconomic and political status of women impact child and maternal health through three primary pathways: autonomy and control of household resources (i.e., education and healthcare expenditures), workload and time availability (i.e., IYCF practices), and social support networks (i.e., gender-equitable education attainment and food distribution) (Cunningham, Ruel, Ferguson, & Uauy, 2015). A substantial literature indicates that improvements in women's socioeconomic status have long-term benefits for child nutritional status (Kamiya, 2012), household functioning (Quisumbing & Maluccio, 2003), and education equity (Yoong, Rabinovich, & Diepeveen, 2012). Nutrition-sensitive interventions targeted toward improving women's empowerment must be culturally salient and sensitive to local contexts, using holistic measurements to assess changes women's socioeconomic status (Ghuman, Lee, & Smith, 2006; Yount, VanderEnde, Dodell, & Cheong, 2016). Women's empowerment programming often incorporates social protection programs (discussed later in this section) and family planning.

Maternal Health and Family Planning

Exemplifying the vicious cycle of undernutrition, women's nutritional status has direct effects on their children's nutrition at birth, and potentially throughout their lives. Three significant determinants of maternal and child nutrition are child marriage, the age of first pregnancy, and spacing of pregnancies (Fraser, Brockert, & Ward, 1995; Goli, Rammohan, & Singh, 2015). Recent evidence suggests children born to adolescent girls who were married before age 18 have a 25% higher risk for stunting than children born to women who married as adults (Efevbera, Farmer, Bhabha, & Fink, 2017). Further, these children are at an increased risk of low birth weight and have a 50% higher risk of perinatal death as compared to newborns of older mothers (Santhya, 2011; Viner et al., 2011). Lastly, pregnancy complications are the primary cause of death (complications of preterm delivery) for children younger than age 5 and the second

leading cause of mortality in adolescent girls worldwide (UNICEF, 2015; WHO, 2011c).

Effective interventions to reduce child marriage rates in LMICs include social protection programs conditional on school attendance and reproductive health education and services (Kalamar, Lee-Rife, & Hindin, 2016). Provision of low-cost or free contraception is cost-effective, ameliorating the high unmet demand for pregnancy prevention methods. Nevertheless, one analysis found that only 75% of women in 76 countries were able to access contraception, demonstrating a remaining gap in coverage (UN, 2015b). Family planning counseling can help women space out pregnancies to reduce child mortality (Ganatra & Faundes, 2016; Zakiyah, van Asselt, Roijmans, & Postma, 2016).

Health

An expansive body of literature has demonstrated that the public health sector is key for delivering high-impact and cost-effective nutrition-specific and nutrition-sensitive interventions (Bhutta et al., 2013), including interventions directed toward both underweight and overweight/obesity. To address malnutrition among children, targeted health interventions generally aim to manage and prevent nutrition-related diseases or provide counseling on nutrition through the healthcare system. Among underweight populations, immunization packages, antibiotics, and BCC messaging about both non-communicable and communicable diseases, such as pneumonia and diarrhea, intestinal worms, malaria, and tuberculosis, are often delivered through the health system (Boschi-Pinto, Dillip, & Costello, 2016; Buse & Tanaka, 2011). Among overweight children, interventions aim to teach healthy eating patterns, prevent and/or treat diabetes, and encourage weight loss and physical activity, but have not shown much success (Foster, Farragher, Parker, & Sosa, 2015). Recent innovations in delivery strategies, including mobile-health technologies and community-led platforms, represent avenues through which nutrition-sensitive interventions can be brought to scale (Kahn, Yang, & Kahn, 2010; WHO, 2010a).

Education

Children of mothers who no formal education are the most at risk of poor nutrition, regardless of socioeconomic status and rural or urban residence (Alderman & Headey, 2014; Hasan, Soares Magalhaes, Williams, & Mamun, 2016; Subramanyam, Kawachi, Berkman, & Subramanian, 2011). In turn, the strongest predictor of childhood nutrition status is maternal education (Alderman & Headey, 2014; Wamani, Tylleskär, Åstrøm, Tumwine, & Peterson, 2004). The pathways through which maternal education influences child nutrition include improved health-seeking IYCF, WASH behaviors, and promotion of diverse food consumption (Burchi, 2010; Casanovas et al., 2013; Saleem, Mahmud, Baig-Ansari, & Zaidi, 2014).

Nutrition-sensitive education interventions include both primary or secondary schooling and nutrition education. In more than 100 LMICs, public investment in primary and secondary education have been shown both to improve women's health outcomes and to reduce stunting among children (Headey, 2013). Recent evidence suggests the threshold for significant stunting reductions is 10 years of schooling (senior secondary level and above), but completion of primary school can significantly reduce wasting and underweight (Makoka & Masibo, 2015).

Nutrition education must be culturally sensitive and adapted to local contexts. Educated women who have greater access to appropriate nutrition information have more opportunities for employment, higher earning power, and healthier children (Semba et al., 2008).

Social Protection

Social protection programs aim to intervene at key leverage points during the lifespan, reducing vulnerability and investing in human capital among low-resource populations (HLPE, 2012; Tirivayi, Knowles, & Davis, 2016). The most cost-effective social protection programs linked to improvements in nutrition outcomes include school feeding programs and subsidies or vouchers for child education and health services (Akresh, de Walque, & Kazianga, 2013; Bundy & Alderman, 2012; Lagarde, Haines, & Palmer, 2007). Other effective social protection programs include conditional or unconditional cash transfers (CCT and UCT, respectively). Both types of programs provide supplementary income in an effort to stabilize household income and provide resilience against economic shocks, when families would otherwise skip meals or buy inexpensive, nutrient-poor foods (Fenton et al., 2016; FAO, 2015). Evidence suggests poverty alleviation programs have direct effects on individual nutrition outcomes, particularly child anthropometry (Headey, 2013; Leroy, Ruel, & Verhofstadt, 2009). Programs are most successful when accessible foods are both nutritious and diverse, intra-household allocation is equitable, and implementation is coordinated among multiple sectors (FAO, 2012; Ruel et al., 2013).

The Future of Nutrition-Sensitive Approaches

Despite the success of nutrition-sensitive interventions for a variety of nutritional, dietary, and development outcomes, many programs have yet to be adequately funded or brought to scale. Policy makers in LMICs face significant obstacles in implementing multisectoral programs. Inequities in public services provision, limited program reach, funding gaps, and substantial understaffing are all challenges that must be overcome in program implementation. Project responsibilities may overlap between the Ministries of Health, Education, and Agriculture, as well as the dispersed activities of nongovernmental organizations (NGO)s and civil society groups. To date, the limited indicators and metrics used to track success and monitoring mechanisms have failed to demonstrate their ability to effect improvements in health and nutrition outcomes (Gill & Stewart, 2011; van den Bold, Quisumbing, & Gillespie, 2013).

Enabling Environments for Improved Nutrition

Good governance is defined as the use of public authority, agencies, and funding to provide effective and transparent public services that can withstand changing political or socioeconomic contexts over time (Acosta Mejia & Fanzo, 2012; Solon, 2006). *Nutrition governance* is therefore the prioritization and funding of nutrition programming in national policy agendas (WHO, 2010b). Characteristics to assess the quality of nutrition governance in any given country include the adoption of a national nutrition policy or dietary guidelines, regular nutrition monitoring and surveillance, and the existence of a funding line for nutrition in annual budgets (FAO, 2015).

Enabling environments, which are embedded within the theory of good nutrition governance and the political economy of nutrition, are deliberate actions incorporated into political and policy processes that build and sustain momentum for effective program implementation and enforcement (Gillespie, Haddad, Mannar, Menon, & Nisbett, 2013; Gillespie, Menon, & Kennedy, 2015; Haddad, 2013). Five primary components are often used to gauge the enabling environment for nutrition (Acosta Mejia & Fanzo, 2012; Haddad, 2013):

- Policy makers must politically commit to nutrition, by ensuring that the issues of undernutrition as well as overweight and obesity are visible and prominent on the national development agenda.
- There must be substantive allocation of funding for both nutrition-sensitive and nutrition-specific interventions.
- Government agencies or ministries must effectively coordinate—both vertically from national to local levels and horizontally—the various stakeholders working in the country on evidence-based nutrition programs.
- Governments must invest in the systemic, institutional, and human capacity needed to implement and deliver nutrition programs and interventions.
- Good policy requires transparency, accountability, efficiency, and cost-effectiveness—all of which require solid monitoring and evaluation mechanisms with robust national data information systems (Arora, Chauhan, John, & Mukhopadhyay, 2011).

With enhanced cooperation between governments, NGOs, and the global nutrition community since the start of the twenty-first century, the enabling environment for nutrition has improved. Though undernutrition has yet to be fully eradicated, the timeline in **FIGURE 7-18** illustrates the increased visibility, funding, coordination, and accountability mechanisms over the last two decades.

How has nutrition governance been measured? One such measure is the Hunger and Nutrition Commitment Index (HANCI), developed in the early 2010s to rank 45 governments on their political prioritization of reducing hunger and malnutrition through legal frameworks, policies, and public expenditures (te Lintelo & Lakshman, 2015). Because most political commitments are voluntary, other, more expansive accountability mechanisms include the Global Nutrition Report and the Scaling Up Nutrition Movement.

Transparency and accountability have proved to be the most challenging components of nutrition governance in the twenty-first century. Five of the six primary challenges identified by (Balarajan & Reich, 2016) that impede progress in the political economy of nutrition also incorporate accountability and themes from the study of political economy, as illustrated in **FIGURE 7-19**.

First, while some nutrition outcomes may be immediate, many multisectoral interventions often require years to demonstrate their impact. Data are the most readily available means to hold nutrition actors accountable to their commitments, but results

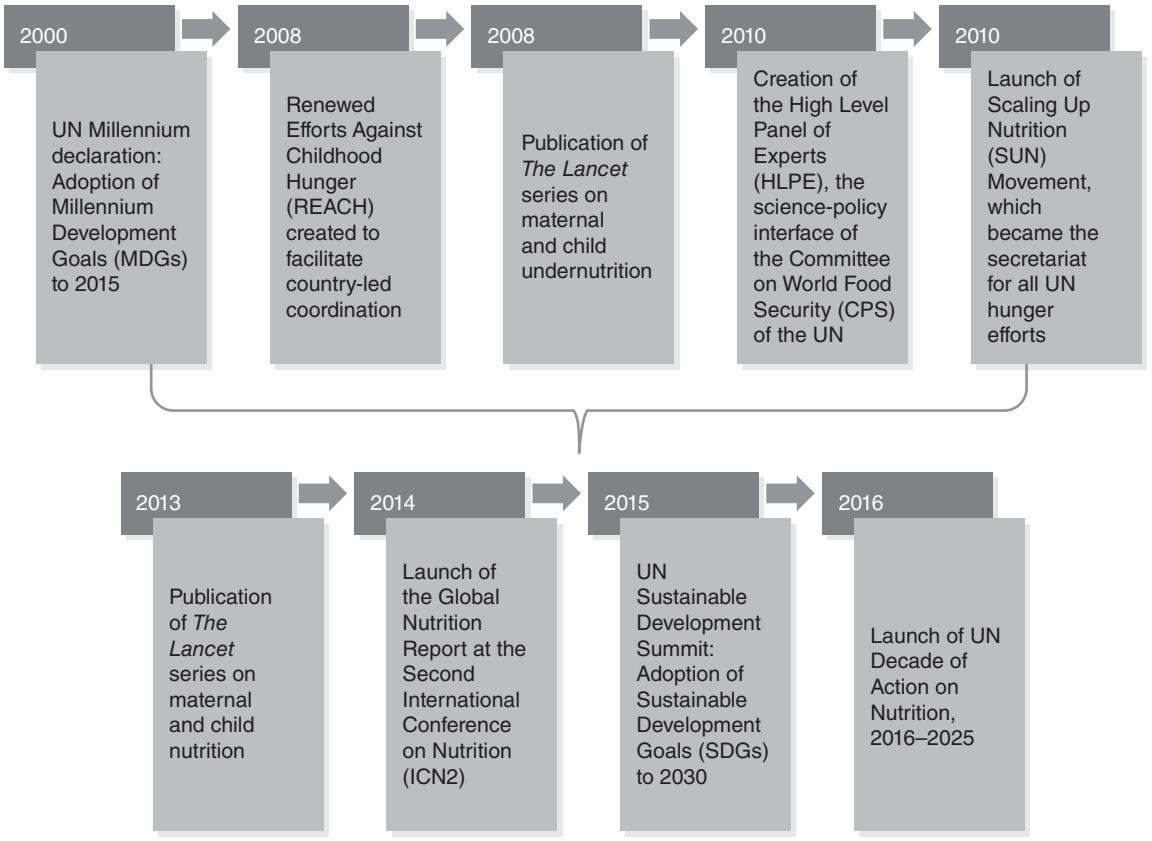

FIGURE 7-18 Timeline of global commitments, policies, and research priorities in the fight against undernutrition.

Modified from Gillepsie & Harris, 2015; Nisbett, Gillespie, Haddad, & Harris, 2014.

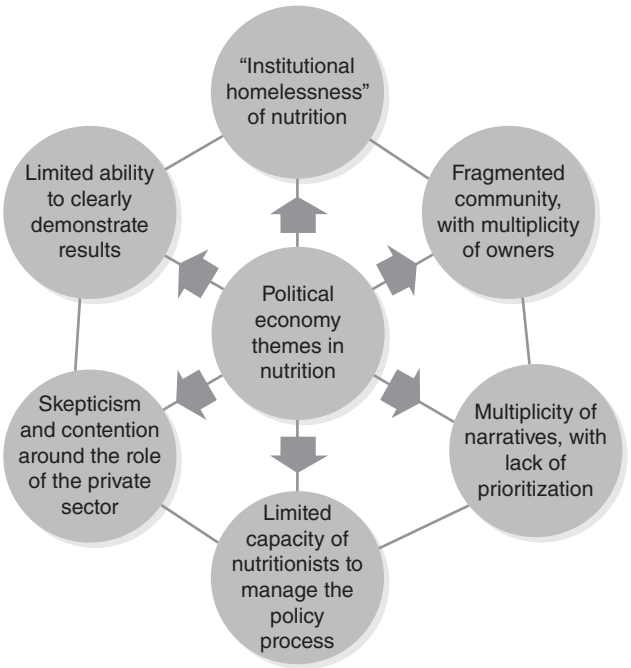

FIGURE 7-19 The six political economy factors of nutrition policy.

may not always be linear or easily quantifiable. Further, the variety and quantity of interventions make it difficult to compare results (Swinburn et al., 2015).

Second, "institutional homelessness" refers to the multisectoral nature of nutrition-sensitive interventions (Pinstrup-Anderson, 1993). Countries approach the design and responsibility for nutrition policy in a variety of ways; for example, nutrition responsibilities can be housed in the health or agriculture ministry, or may even be addressed by a stand-alone agency.

Third, and relatedly, fragmentation of ownership reflects nutrition policy's malleability (Morris, Cogill, & Uauy, 2008). Effective nutrition-sensitive interventions must be gender sensitive and culturally salient, targeted to a precise population (Ruel et al., 2013). In turn, opinions on the most relevant solution may differ widely among researchers, nutritionists, policy makers, community or religious leaders, and the population itself—and this discord impedes transparency and slows the policy process.

Fourth, nutritionists have low capacity, primarily working at the local level. Policy makers are generally not nutritionists, complicating the

EXHIBIT 7-4 Obstacles for Nutrition Governance in the Fight Against Obesity

In the last two decades, worldwide efforts to reduce obesity have been marked by poor progress. WHO's (2013) Global Action Plan for the Prevention and Control of NCDs set voluntary, international objectives through 2020 for improvements in health outcomes. The primary target for obesity—that is, to *halt* the rise in diabetes and obesity—recognizes the institutional, physical, psychosocial, and political complexities inherent in the political economy of obesity.

Researchers suggest obesity rates have plateaued or increased in most LMICs due to two conflicting core narratives over who is responsible for taking action to reduce those rates: The individual (consumers should make nutritious choices) or society (government should provide leadership through intervention) (Swinburn et al., 2015). Worldwide, most policies and programs have assumed the former, making it difficult to collect data, identify enabling environments, or hold powerful nutrition actors accountable.

The food industry, which devotes millions of dollars to lobbying for processed foods, has successfully opposed government efforts to create food-based obesity policies (Moodie et al., 2013; Popkin, 2013). Suggestions for enhancing accountability and transparency include managing private-sector conflicts of interest (i.e., food marketing to children, industry-sponsored nutrition studies), government monitoring, and improved engagement with civil society. The creation of data-sharing networks, such as the International Network for Food and Obesity/NCDs Research, Monitoring, and Action Support (INFORMAS), is effectively increasing collaboration between governments and NGOs in Europe and parts of Asia (Swinburn et al., 2013), but must be expanded to LMICs in the coming years to accelerate progress toward worldwide obesity-reduction targets.

Research has also contributed to the rise of awareness and advocacy to reduce the prevalence of obesity. Similar to the foundational *The Lancet* series on maternal undernutrition, two *The Lancet* series on obesity were published in 2011 and 2015. The first series focused on identifying the drivers of the obesity pandemic, economic and health burdens, and weight physiology. The second *The Lancet* series explored developments in effective policies, systems, and programs to reduce "obesogenic" food and built environments—the physical spaces, cultural traditions, and taste preferences that inhibit individuals from making nutritious diet choices and, therefore, contribute to overweight and obesity. Nutrition-sensitive interventions in obesogenic environments are ongoing, with proponents attempting to identify context-specific and culturally salient mechanisms with which to encourage nutritious food choices and initiate substantial reductions in obesity prevalence.

operationalization, accountability, and scaling-up of effective interventions from the local level to the national level.

Last, and relatedly, policy makers often scrutinize the private sector, unsure of their role in the fight against malnutrition. Despite this skepticism, NGOs and civil society organizations often work in tandem with public agencies to research and implement nutrition interventions, particularly in LMICs.

EXHIBIT 7-4 provides an overview of recent research that suggests strengthened accountability and transparency of systems is one of the key components in the continuing fight to eliminate overweight, obesity, and diet-related NCDs (Swinburn et al., 2015).

Discussion Questions

1. The same population may be affected by multiple micronutrient deficiencies, although people at different life stages and certain socioeconomic or geographic groups may be more vulnerable to individual nutrient deficiencies. Discuss ways in which single-micronutrient deficiency prevention strategies might be combined, integrated, or coordinated to achieve cost-effective control.
2. A lower-middle-income country may be afflicted with both high rates of childhood undernutrition and a rising epidemic of obesity among its lower socioeconomic groups while undergoing a nutrition transition. Discuss the challenges that this situation poses for the country's government in developing food and nutrition policies as well as national dietary guidelines for healthy eating.
3. The Ministry of Health of a lower-income country has decided to institute a national nutrition surveillance system to monitor the country's most pressing child and maternal nutrition problems. Discuss the kinds of nutritional problems, target groups, approaches to assessment, options for routine contact in the community, and types of agencies to organize into a surveillance system to guide the ministry.

CHAPTER 8

Chronic Diseases and Risks

Gillian P. Christie, Sandeep P. Kishore, David J. Heller, and Derek Yach

DISCLOSURE STATEMENT

Statements made and opinions expressed in this chapter are those of the authors and should not be construed as representing an official position of the organizations where the authors are employed.

Introduction

In the 1920s, Yale University's Charles-Edward Amory Winslow taught that the goal of each generation was to redefine the unacceptable. With chronic diseases now arguably "the social justice issue of our generation," this chapter intends to redefine the unacceptable by building a renewed case on the imperative to invest in and advocate for chronic disease prevention (Horton, 2015). It calls for young professionals and continuing students to engage in sustained and coordinated actions to combat the growing burden of chronic disease on global populations.

This chapter covers three objectives: (1) define and outline the global prevalence of chronic diseases, their health and economic impact, and their four key risk factors; (2) describe stakeholder efforts to date in chronic disease prevention; and (3) propose stakeholder actions—both policies and systems of care—that can further control the rising prevalence of chronic diseases.

The Burden of Chronic Disease: Causes and Impacts

Defining Chronic Diseases

At its founding in 1946, the World Health Organization (WHO) defined health as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity." At that time, most human death and disease was due to acute, infectious diseases from which people either recovered or died. Today, chronic conditions—those that cause illness gradually over the course of many months or years—have become the leading cause of human disability and death. Chronic diseases are among the greatest threats to the state of global human health that WHO was founded to protect.

Chronic diseases often emerge in middle age, after a long exposure to adverse social, environmental, genetic, behavioral, and lifestyle factors. Such diseases can affect the young and healthy—including children—and can emerge quickly and without warning. For example, an adolescent newly diagnosed

with type 1 diabetes and a seemingly healthy young woman who suffers an acute stroke due to undiagnosed high blood pressure both suffer from chronic disease. In affluent countries as well as in low- and middle-income countries (LMICs), chronic diseases often disproportionately affect lower-income persons and communities. Although most chronic conditions are not "infectious" in the typical sense, emerging evidence suggests that chronic conditions such as diabetes and atherosclerotic cardiovascular disease tend to cluster in families and communities with common lifestyle and environmental risk factors. These risk factors can *transmit* disease from one person to another in a social unit through shifts in behavior.

Despite their many forms, most chronic diseases have common underlying characteristics. These include a few common risk factors that act independently and synergistically; a long latency between cumulative exposure to risk and disease outcomes; a high degree of preventability; a low cure rate, necessitating decades of treatment and care coordination; considerable comorbidity; and strong linkages to poverty and socioeconomic development. Chronic diseases are predominantly caused by noninfectious risk factors, but can be caused or exacerbated by infection as well. The leading chronic diseases include cardiovascular disease, stroke, chronic respiratory diseases, cancer, diabetes, human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), mental illness, and traumatic injury. Fortunately, all of these conditions—and the morbidity and mortality they cause—are preventable and treatable through policies and programs that treat a few common risk factors, such as unhealthy diet, tobacco use, physical inactivity, and alcohol and other substance misuse.

Epidemiology of Chronic Diseases: Rising Risk

In the past 100 years, chronic and largely noncommunicable diseases have silently overtaken infectious diseases as the leading cause of death and disability worldwide (Stuckler, 2011). Initially proposed by Abdel Omran in 1971, this "epidemiologic transition" to chronic, noncommunicable diseases began in the early twentieth century in high-income countries such as the United States. Pneumonia, tuberculosis, and gastrointestinal infections were the leading killers in 1900, and by the early twenty-first century had spread to lower-income countries. This transition, which is largely due to improvements in sanitation, vaccination, and antibiotics that significantly curbed disease and death from infection, increased global life expectancy from 61.7 years in 1980 to 71.8 years in 2015. Nevertheless, achieving further advances in longevity will require a different approach, as human life expectancy now chiefly depends on the growing toll of chronic diseases (Global Burden of Disease [GBD] Collaborators, 2016). Each year, chronic diseases kill an estimated 39 million people, with cardiovascular diseases the leading cause of death (17.9 million people), followed by cancers (8.8 million people) and respiratory diseases (3.8 million people) (GBD Collaborators, 2016). Most of these deaths (approximately 28 million) occur in LMICs (WHO, 2017b). **TABLE 8-1** identifies the 10 leading causes of death globally based on income, while **TABLE 8-2** indicates changes in deaths from chronic diseases over time.

Individual Risk Factors for Chronic Disease. A few common, modifiable behavioral risk factors accumulate over the lifespan and drive the majority of all

TABLE 8-1 The Ten Leading Causes of Deaths in the World, and in Low-, Middle-, and High-Income Countries, 2015

Disease or Injury	Deaths (per 100,000)	Percentage Change (1990–2015)	Disease or Injury	Deaths (per 100,000)	Percentage Change (1990–2015)
World			*Low-Income Countries*		
1. Cardiovascular diseases	243.1	2.4	1. Lower respiratory infections	80.4	–52.5
2. Neoplasms	118.9	11.0	2. Malaria	64.5	–64.1
3. Diarrhea/lower respiratory infections/other	67.3	–55.4	3. Diarrheal diseases	59.0	–66.1
4. Chronic respiratory	51.5	–22.4	4. Ischemic heart disease	47.9	–4.6

Disease or Injury	Deaths (per 100,000)	Percentage Change (1990–2015)	Disease or Injury	Deaths (per 100,000)	Percentage Change (1990–2015)
5. Diabetes/urogenital/ blood/endocrine diseases	46.3	44.1	5. HIV/AIDS	44.5	76.4
6. HIV/AIDS and tuberculosis	31.3	–7.5	6. Tuberculosis	33.6	–43.9
7. Neurologic disorders	30.7	46.8	7. Hemorrhagic stroke	29.2	–18.0
8. Neonatal disorders	29.4	–55.7	8. Neonatal preterm birth complications	23.4	–51.2
9. Unintentional injuries	25.0	–31.5	9. Neonatal encephalopathy due to birth asphyxia and trauma	21.9	–43.2
10. Transport injuries	19.9	–12.7	10. Protein-energy malnutrition	21.6	–66.5
Middle-Income Countries			*High-Income Countries*		
1. Cardiovascular diseases	237.0	25.3	1. Ischemic heart disease	193.1	–16.0
2. Neoplasms	100.0	24.6	2. Alzheimer's disease	71.2	66.3
3. Chronic respiratory	61.3	–26.0	3. Ischemic stroke	65.5	–15.8
4. Diabetes/urogenital/ blood/endocrine diseases	46.4	59.0	4. Lung cancer	51.4	12.2
5. Diarrhea/lower respiratory infections/other	42.2	–64.9	5. Lower respiratory infections	39.7	30.2
6. HIV/AIDS and tuberculosis	24.4	–29.1	6. Chronic obstructive pulmonary disease	37.4	12.1
7. Transport injuries	23.8	–2.0	7. Hemorrhagic stroke	35.4	–15.8
8. Unintentional injuries	22.5	–42.8	8. Colorectal cancer	28.8	15.6
9. Neonatal disorders	19.2	–69.2	9. Diabetes	18.9	17.6
10. Cirrhosis	18.7	3.1	10. Self-harm	18.2	1.1

Data from Institute of Health Metrics and Evaluation (IHME) at the University of Washington, 2015.

TABLE 8-2 Changes in Deaths from Selected Chronic Diseases, 2005–2015

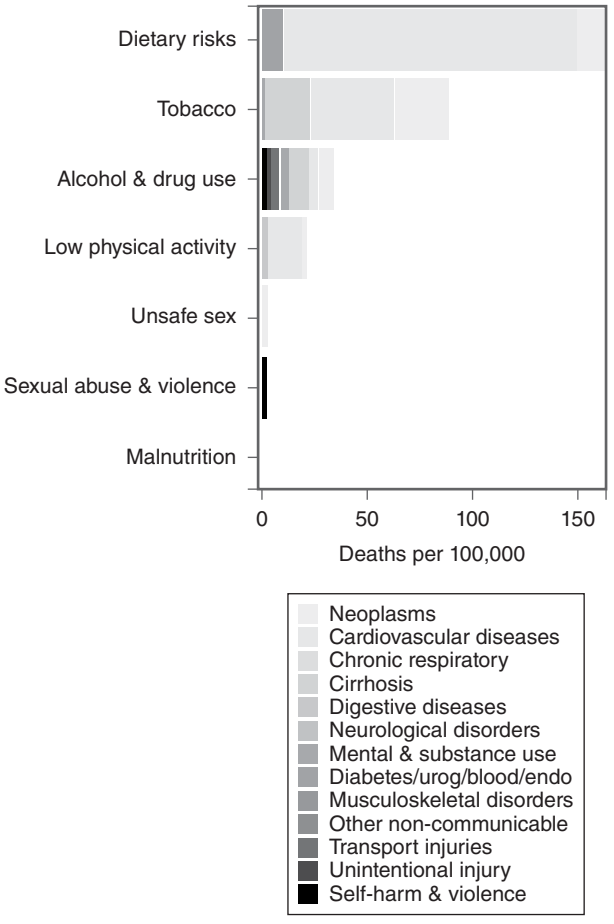
Chronic Disease	Deaths, 2005 (thousands)	Deaths, 2015 (thousands)	Percent Change (%)
Overall	34,835.6	39,804.2	14.3
Neoplasms	7,492.8	8,764.6	17.0
Cardiovascular diseases	15,933.7	17,921.0	12.5
Chronic respiratory diseases	3,709.1	3,795.5	2.3
Neurologic disorders	1,671.0	2,258.9	35.2
Mental and substance use disorders	305.9	324.9	6.2
Drug use disorders	128.8	169.9	31.8
Diabetes, urogenital, blood, and endocrine diseases	2,635.3	3,409.3	29.4
Musculoskeletal disorders	76.2	90.1	18.2

Note: Between 2005 and 2015, global deaths from chronic diseases increased by 14.3%. The greatest changes were in neurologic disorders; drug use disorders; and diabetes, urogenital, blood, and endocrine diseases.

chronic disease, from diabetes to cancer to cardiovascular conditions (**FIGURE 8-1** and **FIGURE 8-2**). These include unhealthy diet, tobacco use, abuse of alcohol and other substances, and low physical activity (**TABLE 8-3**). Chronic disease is also preventable through adherence to prescription medications and promotion of mental well-being, among other factors. Collectively, these risk factors drive a substantial portion (up to 60%) of the global burden of disease, both directly and by causing other risk factors for chronic disease such as elevated cholesterol, glucose, and blood pressure levels.

To explain the shift in chronic diseases from affluent countries, and predict its onset in LMICs, Omran conceptualized three stages of disease epidemiology: pestilence and famine, receding epidemics, and degenerative and human-made chronic diseases. Three major sets of determinants drive the transition toward the third "chronic disease" stage in each country: ecobiologic changes; socioeconomic, political, and cultural changes; and medical and public health interventions. Omran correctly predicted that chronic diseases would eventually impose a greater burden in all countries in the coming decades. In practice, however, chronic diseases have not displaced acute infectious diseases in LMICs. Rather, these countries suffer from a polarized and protracted double, triple, or quadruple burden of disease (Frenk, Bobadilla, Sepúlveda & Cervantes, 1989; Mayosi et al., 2009).

The four major chronic disease risk factors presented in Figure 8-1 are leading causes of the changes Omran described, especially with respect to



Note: *Four modifiable risk factors – dietary risks, tobacco, alcohol and drug use, and low physical activity – contribute to a significant majority of chronic diseases globally. Figure represents both sexes, all ages, 2015.*

socioeconomic, political, and cultural determinants of health. For example, rates of cigarette smoking and other tobacco use have declined in many high-income countries due in part to increased awareness of the chronic disease risks associated with this factor. Nonetheless, tobacco use has risen steadily in many lower-income countries—countries where tobacco was previously either unaffordable or unavailable, or fell outside local cultural norms. As a result, WHO (2017c) estimates that 80% of the world's 1 billion smokers now live in LMICs. Similar transitions have been reported in consumption of energy-dense, low-nutrition foods, as well as use of alcohol and other recreational substances. Although the causes of these shifts are complex, increasing disposable income, increasing contact with high-income countries and

their cultural norms, and aggressive marketing from food, beverage, alcohol, and tobacco industries all play a role in their emergence.

Macro Determinants of Chronic Disease. Chronic diseases are caused by multiple individual-level risk factors, and are also driven by health determinants at the level of entire economies and societies. These factors often correlate with levels of economic development, but society does not need to wait for rapid economic growth to take action against chronic diseases (see Exhibit 8-6, "Eight Myths of Chronic Disease Burden and Control," later in this chapter).

Global Population Aging

Populations around the world are living longer due to two demographic changes: (1) increases in life expectancy among older adults and (2) declines in fertility rates among younger adults. In 2015, the average life expectancy at birth was 71.4 years of age. Babies born in the year 1900 would not normally live beyond age 50 (National Institute on Ageing, 2011). Since then, scientific and behavioral advances, such as reductions in maternal mortality in childbirth, childhood undernutrition, and poor access to safe drinking water and sanitation, have driven the increases in life expectancy and led to a better understanding of the epidemiology underlying modifiable prevention risk factors. Discoveries such as advances in antibiotics and vaccines, as well as screening tools, have yielded more recent health gains.

It is expected that the global population age 60 and older will increase from 900 million in 2015 to 2 billion in 2050, increasing this group's share from 12% to 22% of the global population. The size of this population will also surpass the number of children younger than age 5 by 2020 (WHO, 2015a). Japan is the first country where the proportion of older adults exceeds 30%, but most of North America, Europe, China, and Russia will follow suit by 2050 (WHO, 2015b).

Despite people living longer, they are living longer in poorer health. James Fries's Compression of Morbidity Hypothesis proposes that with public health intervention, "the age of onset of chronic illness may be postponed more than the age at death, squeezing most of the morbidity in life into a shorter period with less lifetime disability." In other words, a larger proportion of life can be healthy. Many countries, however, have failed to follow this trend (Fries, Bruce, & Chakravarty, 2011). In the United States, life expectancy increased from 75.2 years to 78.2 years (3 years) between 1990 and 2010, though healthy life expectancy increased by only 2.3 years, from 65.8 years to 68.1 years (Salomon et al., 2013). Thus, longer life does not necessarily mean more freedom from chronic disease.

Globalization and Trade

Following World War II, nations signed the General Agreement on Tariffs and Trade (GATT) to coordinate international trade agreements. Between 1948 and the early 1990s, tariffs on trading products declined from 40% to 4%. GATT was eventually replaced with the World Trade Organization (WTO) in 1995.

Global trade agreements impact the cost of goods sold in a given country. Based on price differentials (and cultural preferences), the type and quantity of products and services vary among countries, and their trade can impact chronic disease risks. Production of palm oil, for example, takes place largely in Southeast Asia (led by Indonesia and Malaysia) and requires large-scale tropical rainforest deforestation. Palm oil contributes to many chronic diseases, including heart diseases and type 2 diabetes. Despite the health and environmental concerns, palm oil is produced inexpensively and sold on the international market, where it appears in packaged foods as well as toothpaste and detergent. The World Wildlife Fund estimates that 50% of packaged goods sold in supermarkets contain palm oil. Unregulated global trade agreements permit continued production and consumption of palm oil, despite the product's clear contributions to poor health and environmental damage (Yach et al., 2010).

Agricultural Subsidies

Governments provide agricultural subsidies to farmers to their boost incomes and influence the cost and supply of selected commodities. In many countries, agricultural policies are not aligned with health goals. The United States, for example, offers the majority of its agricultural subsidies to producers of grains, livestock, and dairy products. This leads to a surplus of these commodities and shortages of other foods such as fruits and vegetables. Farmers are penalized for growing "specialty crops," including fruits and vegetables, if they have received subsidies for planting other crops.

Despite evidence that fruits and vegetables prevent chronic disease, there is an estimated 22% supply shortage in the amount of fruits and vegetables needed for the world's population to meet their daily recommended servings, due in part to policies that penalize their cultivation (Siegel, Ali, Srinivasiah, Nugent, & Narayan, 2014). Meanwhile, subsidized unhealthy commodities such as grains, meats, and dairy, which are often found in low-nutrition, high-calorie "junk" foods, are over-produced.

Categories of Chronic Disease

This section details leading types of chronic disease that emerge from preventable risk factors. Each major category of chronic disease is described in terms of the trends in its prevalence and severity. These categories include neoplasms; cardiovascular diseases; chronic respiratory diseases; diabetes, urogenital, blood, and endocrine diseases; neurologic, mental, and substance use disorders; and musculoskeletal disorders.

Quantifying Chronic Disease: Deaths and Years of Life Lost

Measurement of health in across high-, middle-, and low-income countries has centered on deaths, years of life lost (YLLs), and disability-adjusted life years (DALYs) (**EXHIBIT 8-1**).

Neoplasms

Neoplasms include all benign and malignant cancers, which are caused by uncontrolled growth of cells that invade and spread to distant sites of the body (WHO, 2016a). The global prevalence of neoplasms increased by 17% between 2005 and 2015 (**TABLE 8-4**). This trend is largely due to preventable changes in lifestyle (e.g., sedentary behavior, tobacco, and alcohol use) associated with cancer as well as exposure to environmental pollutants and toxins that cause cancer. In men, the leading neoplasms causing death are lung, prostate, colorectal, stomach, and liver cancers. For women, they include breast, colorectal, lung, uterine, cervix, and stomach cancers (WHO, 2016a).

Recent data estimate that 30% of cancer deaths could be prevented by modifying underlying risk factors. Beyond behavioral risks, regular preventive screenings can assist with early detection by

EXHIBIT 8-1 Mortality Versus YLLs Versus DALYs

- **Mortality:** Measure of the number of deaths within a given population.
- **Years of life lost (YLLs):** Measure that estimates the average number of years a person would have lived if he or she had not died prematurely. Incorporates the age at which death occurs by weighing more heavily deaths at a younger age.
- **Disability-adjusted life years (DALYs):** Measure of the time lived with disability combined with the time lost due to premature mortality.

TABLE 8-4 Changes in Global Deaths from Selected Neoplasms, 2005–2015

Neoplasm	All-Age Deaths, 2005 (thousands)	All-Age Deaths, 2015 (thousands)	Percentage Change, 2005–2015 (%)
Overall	7,492.8	8,764.6	17.0
Esophageal cancer	459.3	439.0	–4.4
Stomach cancer	824.5	818.9	–0.7
Colon and rectum cancer	675.5	832.0	23.2
Liver cancer	726.7	810.5	11.5
Tracheal, bronchus, and lung cancer	1,434.5	1,722.5	20.1
Nonmalignant skin cancer	36.3	51.9	42.9
Breast cancer	439.8	533.6	21.3
Ovarian cancer	133.8	161.1	20.4
Prostate cancer	277.4	365.9	31.9
Brain and nervous system cancer	190.4	228.8	20.1

Data from Global Burden of Disease (GBD) Collaborators. (2016). Global, regional, and national life expectancy, all-cause mortality, and cause-specific mortality for 249 causes of death, 1980–2015: A systematic analysis for the Global Burden of Disease Study 2015. *The Lancet, 388* (10053), 1459–1544.

identifying abnormal cells that may develop into cancer, improving the effectiveness of treatment on survival (Vitality Institute, 2016).

Cardiovascular Diseases

Cardiovascular diseases are the leading cause of death globally. These include diseases of the heart vessels and valves, such as ischemic heart disease and rheumatic heart disease, as well as diseases involving other blood vessels, such as cerebrovascular disease, hypertensive heart disease, and peripheral arterial disease (WHO, 2016b). Between 2005 and 2015, global deaths from cardiovascular diseases increased by 12.5%, with the greatest percent increases due to hypertensive and ischemic heart diseases (**TABLE 8-5**).

Cardiovascular diseases are largely preventable through interventions that target behavioral risk factors. Many of these risk factors are similar to those for neoplasms and cancer, including sedentary behavior, diets poor in fruits and vegetables, and tobacco use. These behavioral risks, in addition to nonmodifiable risk factors such as male gender and advanced age, contribute to development of silent chronic conditions that culminate in overt cardiovascular disease—for example, high blood pressure, elevated cholesterol levels, and elevated fasting glucose levels. Approximately 75% of all cases of cardiovascular diseases occur in LMICs.

Chronic Respiratory Diseases

Chronic respiratory diseases are diseases in the airways and other structures of the lung. The most common are chronic obstructive pulmonary disease (COPD), pneumoconiosis, and asthma. Tobacco use is the leading risk factor underlying chronic respiratory diseases, although air pollution, occupational chemicals and dusts, and lower respiratory infections during childhood all increase the risk of developing chronic respiratory diseases (WHO, 2016c). Chronic respiratory diseases are largely incurable, but can be managed through treatments that improve shortness of breath and dilate air passages.

Deaths from chronic respiratory diseases increased by 2.3% between 2005 and 2015 (**TABLE 8-6**). The relatively small increase in mortality from chronic respiratory diseases is largely a result of the effective tobacco control programs that have been implemented in recent decades.

Diabetes, Urogenital, and Endocrine Diseases

Deaths associated with diabetes, urogenital, blood, and endocrine diseases increased 29.4% between 2005 and 2015 (**TABLE 8-7**). The majority of these deaths are attributable to type 1 and 2 diabetes mellitus (**EXHIBIT 8-2** explains the difference between the types). Persons with type 1 diabetes are entirely dependent on insulin injections to survive, but persons with type 2 diabetes can also take oral medication to help the body use its existing insulin. Type 2 diabetes is both preventable and treatable with behavioral modifications, including changes to diet, physical activity, medications, and regular blood glucose screenings. The Diabetes Prevention Program is one approach to addressing diabetes (**EXHIBIT 8-3**).

Neurologic Disorders

Neurologic disorders are diseases of the central and peripheral nervous systems, which include the

TABLE 8-5 Changes in Global Deaths from Selected Cardiovascular Diseases, 2005–2015

Cardiovascular Disease	All-Age Deaths, 2005 (thousands)	All-Age Deaths, 2015 (thousands)	Percentage Change, 2005–2015 (%)

EXHIBIT 8-2 Diabetes: What's the Difference?

- **Diabetes mellitus (diabetes):** Disease caused by an increased concentration of glucose in the blood, due to dysregulation of insulin, the hormone that removes glucose from the bloodstream. This condition arises either from the pancreas not producing enough insulin (type 1 diabetes) or from the body not effectively being able to use the insulin it produces (type 2 diabetes). Type 2 diabetes is far more common (95%), and is caused by hormonal changes arising from excess body weight, excess intake of sugars and carbohydrates, and physical inactivity.
- **Urogenital diseases:** Diseases affecting the urinary tracts, including the kidneys, ureters, bladder, or urethra, or the reproductive organs (Nature, 2016).
- **Endocrine diseases:** Diseases affecting hormonal glands such as the thyroid, ovaries, testes, pancreas, and pituitary gland.

Data from World Health Organization (WHO). (2016d). Retrieved from: http://www.who.int/topics/diabetes_mellitus/en.

brain, spinal cord, and cranial and peripheral nerves. Deaths from neurologic disorders increased by 35.2% between 2005 and 2015, due largely to an increase in age-related conditions such as Alzheimer's disease and Parkinson's disease as global life expectancy and median age have increased (**TABLE 8-8**).

Alzheimer's disease, the most common form of dementia, is characterized by memory loss and deterioration of cognitive abilities that interfere with daily activities. Symptoms of Parkinson's disease include tremors, slowed movement, and rigid muscles. Both diseases are incurable, but treatments exist to alleviate their symptoms to some extent. It is estimated that the number of people affected by dementia will double every 20 years (WHO, 2006a). Both Alzheimer's and Parkinson's diseases,

EXHIBIT 8-3 Diabetes Prevention Program

The Diabetes Prevention Program (DPP) was an evidence-based program to demonstrate that lifestyle changes (modest weight loss through dietary changes and increases in physical activity) or pharmacologic therapy (through the oral drug metformin) can prevent or delay the onset of type 2 diabetes. The program was administered to 3,234 participants at 27 centers across the United States. Participants, who were 45% racial and ethnic minorities, were initially classified as having prediabetes, meaning they had abnormally high blood glucose levels but had not yet developed diabetes. The study found that the lifestyle intervention resulted in a 58% reduction in the risk of developing diabetes (U.S. Department of Health and Human Services [DHHS], National Institutes of Health, & National Institute of Diabetes and Digestive and Kidney Diseases, 2008). The pharmacologic therapy group taking metformin reduced their risk by 31%. With the effectiveness of the DPP, organizations such as Omada Health (2016) have emerged to translate the program to an online platform. Following rigorous testing, the U.S. Centers for Medicare and Medicaid Services announced that Omada Health's program would be reimbursed for at-risk seniors in 2016.

like other neurologic disorders, are associated with social stigma in many countries, which may cause persons suffering from these conditions to delay evaluation and treatment.

Mental and Substance Use Disorders

WHO (2014) defines mental health as "a state of well-being in which every individual realizes his or her own potential, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to her or his community." Although the slogan "no health without mental health" aims to integrate physical and mental health, on a practical level the two often occupy separate worlds of treatment and prevention (Horton, 2016). Between 2005 and 2015, all-age deaths from mental and substance use disorders increased by 6.2% (**TABLE 8-9**) (GBD Collaborators, 2015).

The global productivity loss attributable to poor mental health is approximately $1 trillion each year, or 10 billion days of lost work (Mnookin, 2016). This global cost of mental disorders is predicted to reach $6 trillion by 2030, an increase of 240% from 2010. With that said, mental and substance disorders are treatable with cost-effective interventions such as cognitive-behavioral therapy and oral medication (see the *Global Mental Health* chapter for more details on mental health). Access to mental health care can increase participation in the workforce, improve functioning at work, and reduce rates of absenteeism.

As with neurologic disorders, the stigma associated with poor mental health often inhibits effective treatment. This stigma can contribute to social

Data from Global Burden of Disease (GBD) Collaborators. (2016). Global, regional, and national life expectancy, all-cause mortality, and cause-specific mortality for 249 causes of death, 1980–2015: A systematic analysis for the Global Burden of Disease Study 2015. *The Lancet, 388* (10053), 1459–1544.

isolation, low self-esteem, and fewer chances for succeeding in maintaining employment, undertaking education, and securing housing.

Substance Use Disorders

A substance in this context is "a psychoactive compound with the potential to cause health and social problems." The most severe manifestation of a substance or drug use disorder is addiction (DHHS, 2016). Deaths from drug use disorders rose by 31.8% between 2005 and 2015 (**TABLE 8-10**).

The rising global substance-related mortality is being driven by opioid, cocaine, and amphetamine use disorders. In the United States, recent studies suggest increases in substance-related mortality among middle-aged white men, but not in other ethnic groups such as blacks and Latinos (Case & Deaton, 2015). In 2016, the Office of the U.S. Surgeon General released its first report on addiction and substance abuse, which outlined several solutions with global applicability. These include new policies and programs, investment in expanding the scientific evidence base, and a cultural shift in how addiction is viewed and treated, as the stigma of substance dependence often impairs access to treatment.

Musculoskeletal Disorders

Musculoskeletal disorders relate to the body's movement system, including the joints, ligaments, muscles, nerves, and tendons. They are the most common cause of severe long-term pain and physical disability worldwide. Deaths from musculoskeletal disorders increased by 18.2% between 2005 and 2015, largely a result of aging global populations (**TABLE 8-11**). New technologies—particularly those focused on artificial intelligence and robotics—are emerging that have the potential to enable people to maintain their movement in older age.

Country-Level Analysis

With the burden of chronic diseases becoming more prevalent in LMICs through the epidemiologic transition, various countries are attempting to tackle the prevention and management of chronic diseases. **TABLE 8-12** identifies the levels of major chronic

TABLE 8-11 Changes in Global Deaths from Musculoskeletal Disorders, 2005–2015

Risk Factors (DALYs per 100,000)					
Tobacco	3,324.50	3,166.13	2,080.53	355.4	627.69
High body mass index (BMI)	3,295.25	1,576.46	1,261.52	510.75	492.64
Dietary risks	3,143.06	4,022.99	3,159.35	686.33	816.49
Alcohol and drug use	2,787.24	1,944.27	1,259.82	1,372.99	1,874.15
Low physical activity	425.12	334.74	336.10	71.5	62.45
Chronic Diseases (DALYs per 100,000)					
Cardiovascular diseases	4,591.46	5,713.55	4,987.41	1,382.93	1,904.42
Neoplasms	4,231.83	4,285.42	1,772.68	1,300.64	1,707.27
Chronic respiratory	1,449.04	1,303.01	2,251.40	475.59	750.63
Diabetes	2,227.00	1,485.19	1,987.82	1,516.62	1,097.35
Mental and substance use	3,724.87	2,200.73	1,983.87	1,705.66	1,839.89

Data from Global Burden of Disease (GBD) Collaborators. (2016). Global, regional, and national life expectancy, all-cause mortality, and cause-specific mortality for 249 causes of death, 1980–2015: A systematic analysis for the Global Burden of Disease Study 2015. *The Lancet, 388* (10053), 1459–1544.

diseases and their associated risk factors for a selection of upper-, middle-, and low-income countries.

Despite the growing prevalence of chronic diseases in many LMICs, governments have been slow to introduce effective interventions. For example, 80% of the world's tobacco smokers reside in LMICs, yet few of the governments in these countries have introduced excise taxes on tobacco. If a 33% price increase on tobacco cigarettes were implemented globally, 22 million to 65 million smoking-related deaths would be averted over the next 50 years—almost 90% of those deaths would occur in LMICs (Gaziano & Pagidipati, 2013). **TABLE 8-13** highlights the most cost-effective interventions for chronic diseases in

TABLE 8-13 Cost-Effective Interventions for Chronic Diseases in Resource-Constrained Environments

Risk Factor/Disease	Interventions
Tobacco use	■ Tax Increases ■ Smoke-free indoor workplaces and public places ■ Health information and warnings ■ Bans on tobacco advertising, promotion, and sponsorship
Harmful alcohol use	■ Tax increases ■ Restricted access to retailed alcohol ■ Bans on alcohol advertising ■ Reduced salt intake in food
Unhealthy diet and physical inactivity	■ Replacement of trans fat with polyunsaturated fat ■ Public awareness through mass media on diet and physical Inactivity
Cardiovascular disease (CVD) and diabetes	■ Counseling and multidrug therapy for people with a high risk of developing heart attacks and strokes (including those with established CVD) ■ Treatment of heart attacks with aspirin
Cancer	■ Hepatitis B immunization to prevent liver cancer (already scaled up) ■ Screening and treatment of precancerous lesions to prevent cervical cancer

Note: NCD = noncommunicahle disease.

resource-constrained environments. Country examples of effective chronic disease control strategies are detailed later in this chapter.

Clinical Features of Common Chronic Diseases

After a chronic disease has developed, it can often be treated, controlled, or even cured with early detection, a process known as *secondary prevention*. Although some chronic conditions can be diagnosed only with laboratory tests and other investigations, many individuals display signs and symptoms that can be detected with minimal medical training. This allows physicians and community health workers alike to refer high-risk persons for further specialized testing. **TABLE 8-14** summarizes common clinical signs of key chronic conditions.

Comorbid Conditions

Comorbidity refers to the simultaneous occurrence of two or more disorders in one person. A common chronic disease comorbidity is diabetes and cardiovascular disease. Heart attacks, for example, are significantly more common in people with diabetes, as are deaths following a first heart attack (International Diabetes Federation, 2003). Similarly, high cholesterol and hypertension are both causative of and concomitant with coronary heart disease and cerebrovascular disease, and both are growing more common with urban development (see **EXHIBIT 8-4**). In addition, persons with chronic conditions have a greater risk of developing mental disorders such as depression (WHO, 2003a). The proportion of patients with depression who also have other common chronic diseases, such as cardiovascular disease, diabetes, and cancer, ranges from 22% to 33% (WHO, 2003a).

There are also interactive effects between certain infectious and noninfectious diseases. Several infectious agents cause cancer: Hepatitis B virus causes liver cancer; human papillomavirus (HPV) causes cervical cancer; *Helicobacter pylori* causes stomach cancer; HIV causes several cancers, including Kaposi's sarcoma and non-Hodgkin's lymphoma; and *Schistosoma haematobium* causes bladder cancer (Stewart & Kleihaus, 2003). All of these cancers are common in LMICs, especially where resources for treatment are inadequate. Vaccines to prevent these infections and effective drugs to treat them could greatly reduce the cancer burden in these countries.

TABLE 8-14 Clinical Features of Common Chronic Conditions

Conditions	Typical Clinical Features	Diagnostic Requirements
Hypertension	No obvious symptoms	Measure blood pressure using standardized procedures
Hyperlipidemia	No obvious symptoms	Measure total cholesterol, high-density lipoprotein cholesterol, and triglyceride levels in fasting blood samples
Obesity	Fatigue, daytime somnolence, excessive snoring, and osteoarthritis	Measure height (meters) and weight (kilograms); calculate body mass index (BMI) = weight/height^2; measure waist circumference
Diabetes	Malaise, excessive thirst, excessive urination, hunger, blurred vision, and tendency to develop infections	Measure fasting or random blood glucose, perform glucose tolerance test, or check blood hemoglobin A1c (HbA1c) level
Asthma	Wheezing, difficulty with breathing, and coughing (bronchospasm) relieved by asthma medication	Peak flow measurements and other lung function tests, chest x-ray, and relief of symptoms with bronchodilators
Chronic bronchitis	Productive cough for 3 months per year in 2 consecutive years, shortness of breath, and frequent chest infections	Lung function tests, chest x-ray
Myocardial infarction (heart attack)	Sudden onset of severe crushing chest pain that could radiate down left arm, to the neck or jaw, with associated sweating, faintness, shortness of breath, and nausea	Clinical examination, electrocardiograph, blood tests for cardiac enzymes
Cerebrovascular disease (stroke)	Sudden weakness; loss of motor or sensory function, usually unilateral; inability to speak; vision disturbances; or unconsciousness	Neurologic and full clinical examination, head computed tomography (CT) scan if available, identify underlying causes
Angina	Central chest pain precipitated by exertion and relieved by resting	Electrocardiograph, pain relieved by angina medication
Transient ischemic attack	Same presentation as stroke—weakness, loss of motor or sensory function, inability to speak, or vision disturbance—but resolving within 24 hours	Neurologic and full clinical examination, head CT scan if available, identify underlying causes
Neoplasms and cancers	Unexplained loss of weight, malaise, and tiredness	Full clinical examination; biopsy, imaging, and/or special blood tests as appropriate

Finally, there are interactions between chronic disease risk factors and nonchronic infectious diseases. Tobacco increases the death rate from tuberculosis (TB)—a common disease of poverty—in those persons already infected with the TB bacterium. In India, smokers are 4.5 times more likely to die of TB than are nonsmokers (Gajalakshmi, Peto, Kanaka, & Jha, 2003). An estimated 80% of TB-infected patients smoke. As a result, tobacco is probably the major cause of death in treated TB patients (Yach & Raviglione, 2004).

The current burden of chronic diseases reflects cumulative risks over people's lifetimes. The accumulation of chronic disease risk begins in fetal life, and

EXHIBIT 8-4 Hypercholesterolemia and Hypertension in Africa

After many decades of scientific debate, data from large community-based trials in the 1970s and 1980s proved that high total blood cholesterol levels are an independent major risk factor for atherosclerotic chronic diseases such as coronary heart disease and cerebrovascular disease (strokes). Total blood cholesterol levels vary considerably between populations with different dietary patterns. For example, people in Africa who follow traditional diets may have lower blood cholesterol levels than people in Europe or the United States, including those who migrated from LMICs and adopted typical Western lifestyles.

These differences are present from a young age. In Johannesburg and Soweto, South Africa, Steyn and colleagues (2000) found that the mean total cholesterol level in ethnically African and multiracial 5-year-old children was 3.9 mmol/L, compared with 4.1 mmol/L for Indian children and 4.4 mmol/L for white children. Several studies in Africa have shown that total cholesterol levels usually differ between urban and rural settings independent of ethnicity, reflecting the effects of urbanization on increasing total cholesterol levels (Knuiman, Hermus, & Hautvast, 1980; Seftel et al., 1993; Swai et al., 1993).

It is estimated that between 10 million and 20 million people in sub-Saharan Africa alone have hypertension and, further, that adequate hypertension treatment could prevent approximately 250,000 deaths in this region (Cappuccio, Plange-Rhule, Phillips, & Eastwood, 2000). Unfortunately, hypertension is universally underdiagnosed and inadequately treated, such that extensive end-organ damage and premature death are often seen. Furthermore, hypertension frequently coexists with other chronic diseases such as diabetes.

Early surveys in sub-Saharan African countries showed that the lowest prevalence of hypertension occurred in the lowest-income countries; as affluence increased, however, prevalence increased. Researchers also found that hypertension is more common in urban than rural settings (Nissinen, Bothig, Granroth, & Lopez, 1988). The Kenyan Luo migration study conducted by Poulter and colleagues (1990) showed that people migrating from traditional rural villages on the northern shores of Lake Victoria to the urban settings of Nairobi had higher body weights, blood pressure, pulse rates, and urinary sodium–potassium ratios than those who remained in the rural areas. This result suggests a marked change in the diet of the new arrivals in Nairobi, including higher salt and calorie intakes, along with a reduced potassium intake due to consumption of fewer fruits and vegetables.

marches forward starting early in infancy and childhood (**FIGURE 8-3**). Thus, emerging evidence supports starting health promotion efforts during pregnancy and early childhood and continuing prevention efforts throughout the life course (Institute of Medicine, 2010).

Early-life and prenatal risk factors—such as suboptimal diet, early termination of breastfeeding, exposure to tobacco and alcohol, exposure to indoor air pollution from biomass fuels, and repeated respiratory infections—are important for the development of chronic diseases in adulthood. Recent research from birth cohort studies has documented how and when these life course influences happen (Aboderin et al., 2001; Batty & Leon, 2002). Some life-course influences are disease-specific, whereas others are cohort-specific, but nearly all depend on a few risk factors. For example, 80% to 90% of patients who develop clinically significant congenital heart disease and more than 95% of patients who have experienced a fatal congenital heart disease event have at least one of the major cardiac risk factors—smoking, diabetes, hypertension, or hypercholesterolemia (Canto & Iskandrian, 2003). Studies also indicate that early postnatal nutrition permanently affects the major components of the metabolic syndrome that determine the individual's propensity to cardiovascular disease (Singhal & Lucas, 2004) and that influences in fetal life and early childhood are related to systolic blood pressure (Levitt et al., 1999).

Chronic obstructive pulmonary disease and lung dysfunction in adults are also the result of cumulative exposures that start early in life. South African studies have shown that what were assumed to be genetic differences in lung size are probably due to early childhood respiratory infections occurring in crowded homes where biomass fuel is used, combined with tobacco use and adverse occupational exposures (Goldin, Louw, & Joubert, 1996). A recent population survey of chronic bronchitis in 5,671 men and 8,155 women in South Africa estimated that 25% of these cases were due to tobacco use, 14% to occupational exposure, and 10% to past TB. In women, these fractions were 14% for use of smoky domestic fuel, 10% for past TB, and 11% for tobacco use (Ehrlich et al., 2004). This study demonstrates how multiple assaults on the lung—including infectious agents, fuel use, exposure at work, and tobacco use—are important in chronic lung disease. All of these factors have been shown to be related to poverty as well.

Global Costs and Consequences of Chronic Diseases

Although chronic diseases will exact a grave financial toll if not addressed by global stakeholders, their potential impact on other aspects of human well-being, such as environmental welfare and socioeconomic inequity, is also severe. This section explores the global costs and consequences of chronic diseases.

Direct Economic Costs

By 2030, it is estimated that the cost of chronic diseases will amount to $30 trillion worldwide (Bloom et al., 2011). In the United States, for example, chronic diseases are the primary healthcare cost drivers, with diabetes ($101 billion), heart disease ($88 billion), and low back and neck pain ($86 billion) being the top three in terms of healthcare expenditures (Dieleman et al., 2016). Chronic diseases not only threaten the fiscal integrity of health budgets and shorten productive work careers, but also undermine the long-term sustainability of systems that deliver universal health coverage (Greenberg, Leeder, & Raymond, 2016). Unfortunately, chronic diseases remain greatly underfunded in LMICs (Clinton & Sridhar, 2017). None of the major health development funders, such as the Bill and Melinda Gates Foundation, WHO, World Bank, Global Fund to Fight HIV/AIDS, TB and Malaria, and Global Alliance of Vaccine Initiatives, is dedicated exclusively to chronic diseases.

Further Macroeconomic Impacts

Indirect productivity losses due to chronic diseases will affect the global economy because premature death and disability will dampen the engine of productivity and reduce economic growth in LMICs (Leeder, Raymond, Greenberg, Liu, & Esson, 2004). Some economists argue the potential returns for high-income-country investors from LMICs could be higher than from high-income countries over the long term (Clark & Hebb, 2002; Heller, 2003; Kimmis, Gottchalk, Armendariz, & Griffith-Jones, 2002). If chronic diseases do diminish productivity as predicted, the effects will, therefore, impact both wealthy countries and lower income countries alike. Both multinational corporations and pension funds face risks from this source, as demonstrated by the HIV/AIDS pandemic, which showed that chronic conditions can place heavy financial burdens on a company when treatment is expensive.

Impact on Health Inequalities

In 1952, Gunnar Myrdal asserted that people are sick because they are poor, and they become poorer because they are sick. This downward spiral certainly occurs with chronic diseases. Increased cumulative exposure to risk factors over the life course, combined with social and economic inequalities, leads to inequalities seen in later adult life.

Chronic diseases impose a significant burden on low-income populations. In high-income countries, the relationships among poverty and cardiovascular disease, cancer, diabetes, and their associated risk

factors are well described, and chronic diseases drive health inequalities by social class, ethnicity, and gender (Aboderin et al., 2001; Batty & Leon, 2002; Brands & Yach, 2001; Kogevinas, Pearce, Susser, & Boffetta, 1997; Mackenbach et al., 2000; Marmot, Adelstein, Robinson, & Rose, 1978; Wong, Shapiro, Boscardin, & Ettner, 2002).

In LMICs, the poorest populations already exhibit the highest risk of tobacco and alcohol use (Jha & Chaloupka, 2000), but the relationship with intermediate risk factors and diseases is complex and varies between countries:

- India: Currently, rates of hypertension, cholesterol, diabetes, and cardiovascular disease increase directly with socioeconomic status (Singh et al., 1999; Vikram et al., 2003). Yet, high rates of hypertension and elevated cholesterol levels are now being measured in urban slums (Misra et al., 2001), and tobacco consumption is higher among the most poorly educated. Death rates from TB—a disease associated with poverty— are four times higher among people who smoke relative to nonsmokers (Gajalakshmi et al., 2003). Poorer people also suffer from relatively higher rates of complications from diabetes, owing to their frequent exposure to multiple risk factors (Ramachandran, Snehalatha, Vijay, & King, 2002).
- Brazil: In urban Brazil, research in the 1980s demonstrated an inverse relationship between socioeconomic status and smoking and alcohol consumption in men and women (Duncan et al., 1993). Researchers also found inverse links between socioeconomic status and hypertension in men, and between sedentary lifestyle and obesity in women.
- Jamaica: Obesity increases with income level strongly in men and weakly in women (owing to high levels of obesity among the poorest women) (Mendez et al., 2004). The relationships among income, diabetes, and hypertension, however, are nonlinear. In women, plotting diabetes and hypertension prevalence against income forms a U-shaped curve, with the highest rates of diabetes found in the poorest women. Obesity and diabetes are strongly related, especially among poor women. The lack of a strong income gradient in hypertension or diabetes—despite a strong relationship between income and obesity—might be partly attributable to greater adverse effects of obesity among the poor.
- China: A U-shaped relationship exists between socioeconomic status and hypertension in women. This result in part reflects the fact that poorer women tend to have lower body mass indices and to smoke less but engage in less physical activity; the reverse is true for the wealthiest group (Bell, Adair, & Popkin, 2004).

Owing to long and often variable lag times between exposure to risk factors and disease onset, the relationships among poverty, exposure to chronic disease risks, and development of disease remain unclear in LMICs. Over time, accumulation of risk among low-income groups will likely increase as availability and marketing of products associated with a Western lifestyle (e.g., higher-fat, higher-calorie foods) increases in tandem with economic development. In the long term, this trend could worsen associations between chronic diseases and poverty.

Obesity data provide an example. Until the late 1980s, socioeconomic status and obesity tended to be inversely related in high-income populations and directly related in low- and middle-income populations (Sobal & Stunkard, 1989). In other words, in LMICs, obesity was associated with more affluent groups. More recently, however, work from Brazil has shown that over time female obesity shifts toward lower-income groups in economically more developed regions and urban areas (Monteiro, Conde, Lu, & Popkin, 2004). Although low socioeconomic status still confers protection from obesity in low-income nations, once the gross national product (GNP) reaches a value of approximately $2,500 per capita, obesity rates correlate directly with low socioeconomic status (Monteiro et al., 2004; Peña & Bacallao, 2000).

A recent study in the United States and China illustrates this point (Kim, Symons, & Popkin, 2004). Using a composite lifestyle index (LI) that included data on diet, smoking, alcohol, and physical activity, the authors found an inverse relationship exists between socioeconomic status and the LI in the United States, whereas a direct relationship exists in China. This result suggests that policy makers in LMICs should not wait for a social class gradient to appear in the occurrence of chronic disease (or risk factors) before implementing disease-preventive and health-promoting policies.

A growing challenge is the rise of health inequalities among the elderly. With the global population age 60 years and older forecast to more than triple in the next 45 years, the size of this gap will increase substantially (WHO, 2008a). In LMICs, where the proportion of older people is growing fastest, the lack of pension schemes and deteriorating traditional social security arrangements act together to worsen the burden of health inequalities (Commission on Social

Determinants of Health, 2008). Although health inequalities in the elderly tend to be smaller than in younger populations, they remain an important and poorly understood public health challenge (von dem Knesebeck, 2010). Older women, especially widows, are particularly affected because they tend to be poorer and more susceptible to chronic diseases (Women and Gender Equity Knowledge Network [WGEKN], 2007). The *Health and 'The Economy'* chapter provides more information on the relationship between health and the economy.

Impact on Sustainable Development and the Environment

Sustainable development, which in recent decades has linked economic and political development with environmental stewardship, has long impacted chronic disease control strategies and priorities, including the United Nations' recent Sustainable Development Goals. Global research and policy agreements now agree that chronic disease proliferation and environmental threats are inextricably linked.

Sustainable Development and Planetary Health

In 1987, the Bruntland Commission proposed what is now the commonly accepted definition of sustainable development: "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (World Commission on Environment and Development, 1987). Realizing the linkages between human health and the environment, the Commission aimed to place environmental issues on the agenda of the United Nations. It provided the foundation for the 1992 Earth Summit in Brazil, which culminated in Agenda 21 and the Rio Declaration on Environment and Development, and later for the Commission on Sustainable Development (**EXHIBIT 8-5**).

The outputs from UNCED established that human health was both an input and an output of sustainable development. In other words, sustainable development cannot be achieved if there is a high prevalence of chronic disease, whereas human health cannot be maintained without healthy environments (von Schirnding, 2002). Conversely, if left unchecked, drivers of chronic disease can and will impact sustainable environmental growth—for example, through global demand for energy-dense foodstuffs, such as refined grains and red meats, that consume more production resources than vegetables; or use of fossil fuels to power automobiles in lieu of more physically energetic transport choices such as walking or biking.

EXHIBIT 8-5 The United Nations' Summits on Sustainable Development

- **United Nations Conference on Environment and Development** (UNCED: 1992, Rio de Janeiro, Brazil): The primary output was Agenda 21, a nonbinding, voluntary action plan voted on by 178 governments to achieve sustainable development. The UN General Assembly established the Rio Declaration on Environment and Development to coordinate follow-up from the conference.
- **World Summit on Sustainable Development** (2002, Johannesburg, South Africa): The World Summit evaluated progress from the UNCED. The Johannesburg Declaration was the result of the summit, which espoused multilateralism to achieve the objectives of sustainable development.
- **United Nations Conference on Sustainable Development** (2012, Rio de Janeiro, Brazil): The output was an outcome document to facilitate action promoting a sustainable future for the planet for present and future generations. This conference began to establish the Sustainable Development Goals, to build on the Millennium Development Goals.

Chronic diseases have multiple causes and effects, at the level of both individuals and society. Studies of chronic diseases' impact—and the best ways to control it—have debunked several prior assumptions commonly held in global health and development circles (**EXHIBIT 8-6**).

Stakeholder Responses to the Growing Burden of Chronic Disease

The causes of chronic diseases are many and complex, and arise at both individual and population levels. Nevertheless, control of chronic disease is possible, though it requires creative thinking, avoidance of myths and false assumptions, and engagement of multiple stakeholders. A variety of stakeholders have begun to tackle this burden worldwide. This section explores their responses to the growing burden of chronic diseases.

EXHIBIT 8-6 Eight Myths of Chronic Disease Burden and Control

Myth 1: We can wait until infectious diseases are controlled.
Reality: As development progresses, chronic diseases do not smoothly displace acute diseases. Many countries have a double burden of disease; thus we must deal with both and develop the health system accordingly. Further, some infectious diseases are chronic in nature (e.g., HIV/AIDS).
Myth 2: Economic growth will improve all health conditions.
Reality: Economic development can improve health in LMICs, yet economic growth can also exacerbate chronic diseases.
Myth 3: Chronic diseases are diseases of affluence.
Reality: Chronic diseases are not solely diseases of affluence in high-income countries and in most LMICs. Low socioeconomic status leads to cumulative exposure to risk factors, greater comorbidity, and decreased access to quality health care.
Myth 4: Chronic diseases are diseases of the elderly.
Reality: Chronic diseases in LMICs are no longer just diseases of the elderly. Instead, chronic diseases in these countries affect a much higher proportion of people during their prime working years, compared to high-income countries.
Myth 5: Chronic diseases result from freely adopted risks.
Reality: Chronic diseases cannot be blamed solely on the failure of individual responsibility, because the cultural and environmental contexts in any society or community inevitably affect personal choices. Thus governments, industry, and others play a role in their incidence.
Myth 6: Benefits of chronic disease control accrue only to individuals.
Reality: Chronic disease control fosters positive social development and benefits societies economically, thereby benefiting the public as a whole. Like acute disease control, chronic disease control is an appropriate public investment.
Myth 7: Acute, infectious disease models are applicable to chronic diseases.
Reality: Interventions for acute diseases are relatively simple, whereas chronic diseases require a planned, proactive approach to health care, and the active participation of patients, families, and communities.
Myth 8: Treating individuals in the health sector is the only appropriate chronic disease strategy.
Reality: The medical community has focused on using traditional approaches to screen "high-risk" individuals—that is, those persons with a high probability of contracting chronic diseases. Yet, prevention requires a multisectoral commitment in addition to more comprehensive health service interventions for clinical prevention.

EXHIBIT 8-7 Government Levers to Influence Public Health

- **Taxes:** A tax is a financial charge imposed by a government to fund public expenditures. Governments often introduce taxes on products harmful to human health, such as tobacco and alcohol products, and more recently sweetened beverages. Differential taxes—that is, taxes proportionate to the health risk of a product—are particularly effective in deterring unhealthy behaviors and generating additional income for government (Pomeranz, 2016).
- **Access restrictions:** Governments frequently introduce restrictions on the availability of harmful products. For example, minimum age restrictions on the purchase of tobacco and alcohol products limit their use by children and adolescents. Restrictions on purchasing times and locations are also common.
- **Educational campaigns:** Educational campaigns inform a population on a specific health issue, such as physical activity or diet. This approach may also include compulsory labeling on nutrition content in foods.

Government

In many high-income countries, maintaining and improving public health is a government responsibility. Governments can introduce a variety of interventions to influence and motivate the public's health behaviors (**EXHIBIT 8-7**). These are sometimes predicated on paternalistic measures that entail modifying health behaviors at the population level.

One notable example is Finland's North Karelia Project, which represented a response to the high cardiovascular mortality in the country, and which used education, community outreach, and policy and care delivery changes to fight cardiovascular disease in this northern Finnish province. This pilot project began in 1972. Between 1969 and 2005, age-adjusted coronary heart disease mortality rate among the 35- to 64-year-old male population declined in North Karelia by 85% and in all of Finland by 80% (**FIGURE 8-4**, **EXHIBIT 8-8**) (Puska, 2016). The project formally ended after 25 years, though national prevention activities continue.

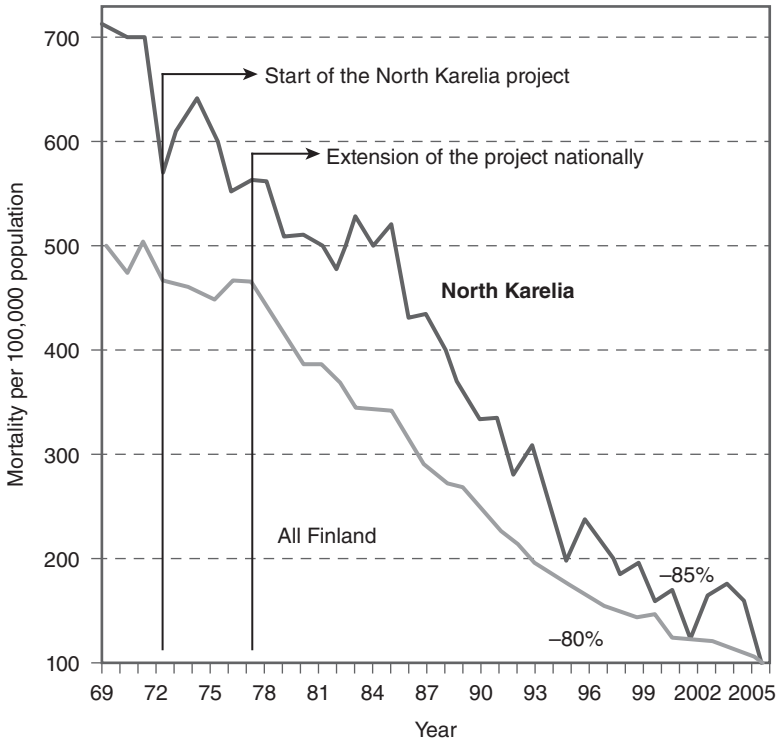

FIGURE 8-4 Age-adjusted mortality rates of coronary heart disease in North Karelia, 1969–2005.

Reproduced from Puska P, Vartiainen E, Laatikainen T, Jousilahti P & Paavola M. (2009). *The North Karelia Project: From North Karelia to national action.* National Institute for Health and Welfare & North Karelia Project Foundation. Retrieved from: https://www.julkari.fi/bitstream/handle/10024/80109/731beafd-b544-42b2-b853-baa87db6a046.pdf?sequence=1.

EXHIBIT 8-8 Why Was the North Karelia Project Successful?

- **Appropriate theory base:** Correct and appropriate public health understanding of the problem that identified major causal risk factors in the population and effective interventions.
- **Flexible intervention:** Ability for interventions to be modified based on practical situations and natural occurrences in the community.
- **Intensive intervention:** Interventions with the potential to mobilize and reach a large number of people.
- **Working with the people:** Collaborative approach with the community that established ownership by the people.
- **Community organization:** Engagement with organizations in the community to contribute to practical objectives.
- **Work with health services:** Health services must be supportive and form a backbone to the local initiatives.
- **Official authority:** Linkage to official administrative structures and health authorities.
- **Limited targets/outcome orientation:** Targeted interventions that were oriented to health outcomes.
- **Positive messages:** Positive framing of health messages to overcome a challenging problem.
- **Bottom-up, top-down:** A blended model that integrated approaches from the top and the bottom.
- **Working with the media:** Partnerships with the media to disseminate information about key activities and results.

Data from Puska, P. (2016). Why did North Karelia-Finland work?: Is it transferrable? *Global Heart, 11*(4), 387–391.

Another country making strides in curbing chronic diseases is Mexico. Diabetes is the leading cause of death and disability in Mexico, and its prevalence increased by 60% between 2000 and 2012. During the same period, hypertension increased by approximately 30%. Despite the large burden of chronic diseases in the country, access to services and effective interventions remains low. The national health system has responded by establishing a chronic disease department within the Ministry of Health, and implementing strategies to improve physical activity, minimize unhealthy diets, and reduce the harmful effects of tobacco and alcohol use.

Mexico also introduced a soda tax of 1 peso per liter on sugar-sweetened beverages in January 2014. Purchases of the taxed beverages decreased by 5.5% in

2014, and by 9.7% in 2015. Households at the lowest socioeconomic level had the largest declines in purchases of taxed beverages. While the tax is a starting point, greater advocacy and interventions are needed to shift the growing burden of chronic diseases in Mexico.

A third country addressing chronic diseases is Ghana, which is testing a community-based approach to cardiovascular disease (CVD) management and control through an international public–private partnership. The project aims to use task-shifting and new technology to improve the Ghana Health Service's response to hypertension (high blood pressure) and other cardiovascular diseases, and to help patients to better manage these conditions (Lamptey et al., 2017). It includes five components:

- Strengthening the health system to better manage hypertension services, including a referral system between the national health system and private drug outlets
- Shifting screening, monitoring, and management services to community health officers and private drug outlets
- Training patients to manage their own hypertension and control other risk factors
- Leveraging technology to improve communication, education, clinical management, adherence, and health information management
- Minimizing out-of-pocket costs by ensuring health coverage by the Ghana National Health Insurance Scheme (National Academies of Sciences, Engineering, and Medicine, 2017)

In 1986, WHO held the First International Conference on Health Promotion in Ottawa, Canada. This conference led to the Ottawa Charter for Health Promotion, which provided a blueprint to achieve "Health for All" by the year 2000 (WHO, 1986). The Ottawa Charter proposed to situate health within the ambit of the individual, in addition to the broader social and structural context that government provides. This framework foreshadowed the importance of behavioral economics by indicating that "the healthier choice [will become] the easier choice" for promoting health.

Behavioral economics has emerged as a complementary approach to government interventions in health (**TABLE 8-15**). Pioneered by Daniel Kahneman and Amos Tversky, behavioral economic theory acknowledges that human decision making can be irrational. For example, individuals give greater weight to payoffs that are closer in the present (termed "present bias") and are more likely to select a smaller reward delivered in the short term than a larger award in the longer term (termed "hyperbolic discounting"). Behavioral economic strategies, aiming to nudge and reward individuals to reject these behaviors, have emerged to correct these decision-making "irrationalities" (Kahneman, 2011). Though government-led, these approaches to behavioral economics to change behaviors are not paternalistic. The U.S. and U.K. governments have embraced behavioral economics by establishing behavioral insight teams that apply research from behavioral economics and psychology to policy making to encourage healthy and other desirable behaviors.

Business

Some companies are starting to invest in the environment and society, realizing that nonfinancial performance impacts their financial bottom line. Moving beyond strategic philanthropy (charitable donations) and corporate social responsibility (sustainability activities), many companies are striving to create shared value (Porter & Kramer, 2011)—that is, business models that generate economic benefit, while addressing societal issues. This approach rests on the premise that companies must generate societal benefit at profit. As explained in **EXHIBIT 8-9**, there are three

TABLE 8-15 Government and Behavioral Economics Approaches to Health Promotion

	Government	Behavioral Economics
Intervention approach	Paternalistic	Nonpaternalistic
Target	Population	Individual
Examples	Directing behaviors through taxes, age and purchasing restrictions, education campaigns	Nudging behaviors through financial or nonfinancial incentives, discounts, or rewards

EXHIBIT 8-9 Classification of Companies Creating Value Beyond the Financial Bottom Line

1. **Companies promoting health:** The company develops products and services that are aligned with promoting better health. Companies pursuing this strategy most often focus on expanding the reach of their portfolio of offerings. Health and life insurers, workplace health providers, and drug and vaccine developers are examples.
2. **Companies undergoing transformations to advance health:** The company offers a mix of products and services that both promote and harm health. Companies adopting this approach work to lower the risks of their unhealthy products and improve the healthiness of their other offerings. Examples include major food and beverage companies.
3. **Companies harmful to health:** The company solely develops products and services that are harmful to human health. There is no intent to transform to develop healthier alternatives. Tobacco and firearms companies are examples.

TABLE 8-16 Corporate Reporting Platforms

Reporting Platform	Description
Dow Jones Sustainability Indexes	Launched in 1999 as the first global sustainability benchmark. Tracks company stock performance based on economic, environmental, and social criteria.
FTSE4Good	Ethical investment stock market indices launched in 2001 by the FTSE Group.
Global Reporting Initiative	Independent organization that helps organizations understand and communicate the impact of business on sustainability issues, including climate change, human rights, and corruption.
International Integrated Reporting Council	Global coalition of regulators, investors, companies, standard setters, the accounting profession, and nongovernmental organizations (NGOs) that establishes integrated reporting practices.
King Report on Corporate Governance	Guidelines for the governance structures and operation of companies in South Africa. Four reports have been issued to date: 1994 (King I), 2002 (King II), 2009 (King III), and 2016 (King IV).
Sustainability Accounting Standards Board	Nonprofit organization incorporated in 2011 to develop and disseminate sustainability accounting standards.
United Nations Global Compact	Voluntary initiative based on CEO commitments to implement universal sustainability principles.

classifications of companies that operate within a shared value lens.

To encourage companies to embrace this concept of shared value, corporate reporting platforms now encourage voluntary disclosures on the extent to which companies address environmental, social, and governance (ESG) indicators (**TABLE 8-16**). This information is often presented in a sustainability or integrated report published by the company.

Realizing the central role that health plays within the workplace, marketplace, and community, companies are beginning to explore how to report on their business's impact on health. For example, companies are investigating ways to indicate the health status of their employees, the extent to which health is considered in their products and services, or how they improve health within the communities where they operate or are located.

In the workplace, many companies have introduced programs to improve the health of employees by targeting major chronic disease risk factors, and thereby minimize their healthcare costs. Recent studies suggest a correlation between a company's investment in workplace health and its financial performance,

due to reduced healthcare costs, increased productivity, and improved financial gains. In a portfolio of U.S. companies that had received a designated workplace health award, the rate of return outperformed the Standard & Poor (S&P) 500 average over a 13-year time frame (Goetzel et al., 2016). This analysis was later replicated in South Africa using Discovery Ltd.'s Healthy Company Index, where the portfolio of healthy companies consistently outperformed the market (Conradie, van der Merwe Smit, & Malan, 2016). This work has also led to partnerships between businesses and community organizations to promote health (Oziransky, Yach, Tsao, Luterek, & Stevens, 2015).

United Nations

In addition to national governments and multinational businesses, international agencies such as the United Nations are increasingly responding to chronic diseases. The United Nations hosted its first High-level Meeting on Non-communicable Diseases in 2011. UN member-states have agreed to convene a third High-level Meeting on chronic diseases in 2018 (Mendis, 2016). Additionally, the Sustainable Development Goals (SDGs), which emerged in 2015 from the Millennium Development Goals (MDGs), now incorporate multiple chronic disease goals and targets.

Sustainable Development Goals

Building on the eight MDGs proposed in 2000 and closed in 2015, the United Nations launched the SDGs. These 17 goals aim to end poverty, protect the planet, and ensure prosperity for all. Member-states agreed to the SDGs on September 25, 2015, and they came into force on January 1, 2016. Each goal has specific targets for 2030 (United Nations, 2016). The *Introduction* to this book lists all 17 goals.

Related to chronic diseases and sustainable development, SDG3 focuses on "good health and well-being." It incorporates targets against infectious and chronic diseases, with the aim of ensuring healthy lives and promoting well-being for all at all ages (GBD SDG Collaborators, 2015). This goal specifically aims to reduce by one-third premature mortality from noncommunicable diseases through prevention and treatment; promote mental health and well-being; provide access to affordable essential medicines and vaccines to all; and strengthen the implementation of the World Health Organization Framework Convention on Tobacco Control in all countries.

Several other SDGs also affect chronic diseases, including SDG11 (sustainable cities and communities), SDG12 (sustainable consumption and production), SDG8 (decent work and economic growth), SDG5 (gender equality), SDG10 (reduced inequalities), SDG4 (inclusive and quality education for all and lifelong learning), and SDG17 (multi-stakeholder partnerships for the goals).

The United Nations has also launched a Global Compact (UNGC) that engages 8,600 businesses and 4,000 nonbusiness organizations from more than 170 countries. These partners have pledged to work to advance responsible and sustainable business practices, and invest in solutions for tackling societal challenges. The UNGC has recently announced plans to advance the SDGs by convening and catalyzing action from within the UN system, and with global businesses in the workplace, marketplace, and community.

World Health Organization

WHO is the dedicated specialized UN agency for health. It engages in chronic disease control both directly and through partnerships with other actors, such as member-states' governments. For example, under the leadership of Gro Harlem Brundtland, the Framework Convention on Tobacco Control (FCTC) was adopted in 2003 as the first international treaty on tobacco control. Since 2003, 177 countries have worked to implement the provisions (WHO, 2003b). More recently, the WHO introduced a Framework for Engagement with Non-State Actors (FENSA), which includes engagement by actors, including the private sector, NGOs, philanthropic foundations, and academia (WHO, 2016e).

Beyond the FCTC, WHO has pioneered a variety of new resolutions related to chronic diseases. In May 2016, the World Health Assembly agreed to a resolution on healthy aging. This agreement entails the creation of a global strategy and action plan on healthy aging between 2016 and 2020, with the overarching aim of having every country commit to actions that support older adults. For example, countries are expected to foster age-friendly environments, provide equitable and sustainable long-term care systems, and implement improved monitoring and research (WHO, 2015b). Stakeholders are further mobilizing to propose a resolution on physical activity to the World Health Assembly.

Lastly, WHO has led commissions related to chronic diseases and their associated risk factors. For example, the Commission on Ending Childhood Obesity was established in 2014. Its mandate was to "review, build upon and address gaps in existing

mandates and strategies in order to prevent infants, children and adolescents from developing obesity."

Donor Agencies

Despite the prevalence of chronic diseases, donor agencies (both governmental and civil society) have to date provided scant funding to prevention and treatment of chronic diseases (Greenberg et al., 2016) for various reasons. Most notably, interventions for chronic disease control are complex and require sustained efforts over multiple years. Their targets are, therefore, not usually achievable within the confines of a grant agreement or electoral cycle, leading to underfunding even in affluent nations. Perhaps for this reason, less than 10% of the U.S. National Institutes of Health's (NIH) $30 billion budget is allocated to behavioral interventions that target major modifiable chronic disease risk factors (Calitz, Pollack, Millard, & Yach, 2015). Similarly, the U.S. Agency for International Development (USAID) has spent almost nothing supporting chronic disease control as a donor agency, for the reasons cited in **EXHIBIT 8-10** (Holmes, 2016). Beyond the NIH and USAID, the total budget from the U.S. government for chronic diseases was $0 in 2013 (Ralston, Reddy, Fuster, & Narula, 2016).

EXHIBIT 8-10 USAID's Reasons for Neglecting Chronic Diseases

- **Our current job is not done.** Current health priorities are challenging enough.
- **Chronic diseases occur only in higher-income countries and populations.** This pervasive myth is still espoused within USAID.
- **Chronic diseases are not an urgent problem.** Chronic diseases are not an issue today, but rather a future health priority.
- **The current focus works well and is well funded.** There is no need to adapt or evolve, as existing health priorities demand a reliable funding stream.
- **Congress says no.** There is a perception that the U.S. Congress does not want USAID to explore new topics.
- **There is no funding.** Funding is in short supply in an era of financial austerity.
- **There are no good solutions and chronic diseases are not USAID's strong point.** Chronic diseases are complex and require a multisectoral approach.
- **USAID is contributing in some way.** USAID's efforts may spill over to chronic diseases.
- **The chronic disease community is easy to ignore.** The chronic disease community is too quiet, pedestrian, and polite to demand more action on this front.

Data from Holmes, P. (2016). USAID: Standing by on NCD. *Global Heart, 11*(4), 425–427.

Foundations and Nongovernmental Organizations

The largest source of global chronic disease funding is foundations and NGOs, which collectively provided 46% of total external support in 2015 (Nugent, 2016). Nonetheless, many remain skeptical about the extent to which these stakeholders can facilitate improvements in health. Much of their work has focused on educational and awareness materials, which are often ineffective in modifying behaviors. Additionally, some argue that behavioral change, and the desire to change, resides at the individual—and not at the institutional—level.

Among foundations, the Robert Wood Johnson Foundation (RWJF) is the largest philanthropic organization in the United States dedicated solely to better health. With an endowment of $9.2 billion, RWJF is working to build a culture of health by placing well-being at the center of every aspect of life. Bloomberg Philanthropies, founded by Michael Bloomberg, focuses on ensuring better and longer lives for the greatest number of people. Together with WHO, Bloomberg Philanthropies has established the Partnership for Healthy Cities, a global network of cities with $5 million in funding to develop and deliver interventions to save lives through the prevention of chronic diseases.

NCD Alliance is a network of 2,000 NGOs focused on chronic diseases. They have emerged as a recognized global leader on chronic disease policy, a convener of civil society movements, and a partner to governments and UN agencies (NCD Alliance, 2016). The Young Professionals Chronic Disease Network (YP-CDN) is another leading example of an organization founded (in 2009) to advocate for chronic diseases. Since its inception, YP-CDN has expanded to more than 7,000 people, and focuses largely on facilitating access to essential medicines in LMICs. Its petitions on essential medicines have led to the addition of 2% of all medicines to the WHO Essential Medicines List (Young Professionals Chronic Disease Network, 2016).

Academic Institutions

In 1913, the Rockefeller Commission's Welch–Rose Report advocated for the development of schools of public health to fight population-level causes of disease. Shortly thereafter in 1916, the Rockefeller

TABLE 8-17 Supporters and Opponents of Selected Policy Issues

Major Risk Factor	Policy Issue	Supporters	Opponents
Tobacco	Excise tax	Finance, World Bank	Tobacco industry
	Advertising bans	N/A	Advertisers, media, libertarians
	Smoke-free areas	Restaurants	Hospitality and restaurant sector
	Agricultural subsidies	Enlightened countries	Farmers, rural voters
	Advertising to children	N/A	Advertisers, multinational food companies, media
Diet, nutrition	Commodity changes, sugar	Fruit, vegetable farmers	Sugar farmers, producers, lobbyists
	Promotion to children	Sports, gyms	Sports, toys, fast-food industries

N/A = not applicable.

Foundation provided a grant to found the first school of public health, at Johns Hopkins University. To date, public health schools have largely focused on infectious diseases. In the United States, chronic diseases remain absent from the curriculum in schools of public health as well as medicine. Many other countries and regions, including Europe (especially the United Kingdom) and Canada, have made more progress in targeting chronic diseases in academia relative to the United States.

Partnerships for Chronic Disease Control: Challenges and Conflicts

Progress in infectious disease control is achievable with additional funding for surveillance, effective treatment, and new drugs and vaccines. It also requires general improvements in housing and related infrastructure (water, sanitation, and energy). None of these investments are considered politically contentious. In contrast, chronic disease prevention and control requires public health partners to urge individuals to stop smoking; eat less fat, sugar, and salt; engage in more physical activity; and eat more fruits, vegetables, nuts, and grains. These messages, and the policies that promote them, often prove controversial or even unacceptable to other stakeholders, such as private industry and its advocacy groups.

TABLE 8-17 summarizes policy issues prone to such conflict, which often requires resolution at a level of government outside of the health department. The table lists traditional opponents to healthy public policies, along with possible supporters of change. As noted earlier, tobacco use, unhealthy diet, and physical inactivity are major contributors to the burden of disease in both high-income countries and LMICs.

For example, the call to stop smoking has unified a variety of opposition groups—the tobacco industry itself, the hospitality and entertainment industries, farmers, advertising companies, and even some media outlets—frequently around false or misleading messages related to the economic impacts of smoking. Opponents of tobacco control have perpetuated myths including the following:

- *Restaurants and pubs will go bankrupt if smoke-free policies are introduced.* The opposite is the truth.
- *Finance departments will lose revenue from smuggling and reduced tax receipts if excise taxes increase.* Although smuggling may have a small impact on revenue, it can be lessened through customs and excise controls.
- *Tobacco farmers in countries such as Zimbabwe and Malawi will be unemployed in a few years as tobacco consumption declines.* Unfortunately from a public health perspective, tobacco consumption rarely drops faster than 2% per year, even in the face of

vigorous tobacco control campaigns. At those rates, and in the face of continued population growth, the demand for leaf tobacco will remain high for many decades. The immediate threat to African tobacco farmers comes more from the introduction of mechanization locally and subsidies in high-income countries, rather than from less smoking.

Similar conflicts have emerged around sugar control policies. During the development of the WHO Global Strategy on Diet, Physical Activity and Health, simple messages regarding moderate sugar consumption faced fierce opposition (A. Waxman, 2004; H. Waxman, 2004). Soda manufacturers have led the global efforts to deny that sugar causes obesity or dental caries, or that specific levels of sugars are desirable. Sugarcane farmers in LMICs are concerned that if new WHO/Food and Agriculture Organization (FAO) guidelines on sugar consumption were applied globally, they would lose their jobs. The economic stakes are greater for sugar than tobacco: The lobbying community is far larger and the evidence base on the economics of sugar use is not as well described.

For several years, proponents of antismoking campaigns prepared for critiques of any efforts to control tobacco use. These included engaging with the FAO, World Bank, International Monetary Fund (IMF), United Nations Children's Fund (UNICEF), and other UN partners, and jointly agreeing that the key tobacco policy goal was demand reduction. This harmony was later reflected in subsequent policy agreements. Similar work has yet to emerge with respect to many food policy issues, which are inherently more complex and involve a wider array of stakeholders. But as with tobacco (and opposite to what some lobbyists maintain), there will be only very modest impacts on the demand for sugar over the next few decades even if the WHO recommendations are fully implemented (LMC International, 2004).

New Initiatives

Access Accelerated. Twenty biopharmaceutical companies have partnered with the World Bank and the Union for International Cancer Control to address gaps in essential medicine access through a new initiative dubbed "Access Accelerated," which addresses key barriers among low-income populations. The initiative combines public, private, and philanthropic endeavors, and is evaluated by Boston University's Global Health department.

Resolve. In 2017, the former director of the U.S. Centers for Disease Control and Prevention (CDC) announced a $225 million initiative to address cardiovascular disease and epidemics through an initiative hosted at Vital Strategies, known as "Resolve." The initiative aims to save up to 100 million lives by scaling up proven interventions, including improved treatment of high blood pressure, elimination of artificial trans fats, and reduction in sodium consumption.

Other Collaborative Networks

Advocates for health promotion and chronic disease prevention have yet to coalesce around common messages or key themes. Different stakeholders support different interests within health. Until recently, public health would not collaborate with business, while policy makers often focused on curative care at the expense of chronic disease prevention.

Businesses are increasingly forming precompetitive partnerships to collectively advocate for better health. One example is Bupa's Chief Medical Officer (CMO) Network. This group convenes world-class clinicians to address the world's largest problems through workplace health initiatives. It has decided to focus on behavior change within the workplace as the first major target area. Other examples include the World Economic Forum's Council on Human-centric Health and the American Heart Association's CEO Roundtable, which productively engages for-profit and nonprofit partners to fight chronic disease.

Future Drivers for Prevention and Management of Chronic Diseases

Although existing chronic disease control work has been limited to date, and remains fraught by complex political and economic conflicts, multiple initiatives have demonstrated effective chronic disease control strategies. These tend to involve several common health system strategies, centered on the judicious use of scarce resources and on the structuring of care around prevention in addition to cure.

Management of Chronic Diseases by Healthcare Systems

Country governments, NGOs, businesses, and other international stakeholders have multiple tools to target the *population-level* determinants of chronic diseases (such as rising consumption of tobacco and sugar-sweetened beverages) using *population-level* interventions such as taxes and public education

campaigns. Nonetheless, local and national health systems must also respond to chronic diseases—through both prevention and treatment—at the level of *individual patients* and their communities. In lower- and higher-income countries, these interventions are still evolving. Most take aim at preventing or treating the core lifestyle risk factors for chronic disease (poor diet, tobacco use, sedentary activity), treating and preventing diseases that emerge from these conditions (hypertension, obesity), and treating and preventing the chronic conditions that emerge in turn from those disorders (congestive heart failure, stroke). Successful programs have taken many forms, but display several common features:

- The use of non-physician healthcare workers (NPHWs), including community health workers (CHWs)
- Leveraging or expanding existing programs for other diseases, such as HIV, to adapt to new conditions such as cardiovascular disease
- Using models of care that address multiple chronic disease simultaneously, such as hypertension and diabetes

These approaches use scarce resources effectively in LMICs, but are increasingly being applied to chronic disease care in high-income countries as well. Further research is needed on the most efficient way to design and evaluate these interventions.

In LMICs, there is a profound shortage of physicians, nurses, and other qualified health providers for patients with both chronic and acute conditions (Kar, Thakur, Jain, & Kumar, 2008; WHO, 2006b). In high-income countries, these providers are more abundant, but are often disproportionately involved in specialist care rather than the primary care activities most germane to prevention of chronic disease risk factors, and tend to concentrate in urban areas (Bodenheimer & Smith, 2013; Goodyear-Smith & Janes, 2008). As a result, local health systems have used staff with less formal training to complete tasks normally shouldered by these providers, a process called task-shifting (Callaghan, Ford, & Schneider, 2010; Federspiel et al., 2015; Joshi et al., 2014).

Task-shifting is not a new concept: Nonphysicians functioned as health officers in nineteenth century France, and so-called barefoot doctors provided widespread medical care to rural China in the mid-twentieth century. This work inspired the universal primary care movement of the late 1970s (Heller, 1978; Sidel, 1972) and many of the programs that grew out of it (Black et al., 2017; Mann, Eble, Frost, Premkumar, & Boone, 2010). However, the concept rose to prominence in the mid-2000s as a vehicle for the control of HIV/AIDS in lower-income countries, when the uncontrolled epidemic vastly outstripped the human resources available for its containment ("The 3 by 5 Initiative," n.d.; WHO, 2008b). By 2010, a systematic review of task-shifting approaches to the control of HIV in Africa found 51 separate studies with measurable outcomes (Callaghan et al., 2010). These largely demonstrated that NPHWs can increase access to medication and other treatment, at comparable cost-effectiveness to physician care models and with no change in quality of care.

Based on these data, delivery programs have increasingly used NPHWs for the screening and control of chronic diseases, with similar results. For example, studies in India and Pakistan have demonstrated that nonphysician health workers can screen for persons at high risk of cardiovascular disease with good accuracy, agreeing with physicians in 89% of cases (Abegunde et al., 2007; Joshi et al., 2012). Further work has corroborated this result in South Africa, Guatemala, Mexico, and Bangladesh (Gaziano et al., 2015; Gaziano et al., 2013), and shown its feasibility for other chronic conditions such as depression (Adams, Almond, Ringo, Shangali, & Sikkema, 2012) and oral and cervical cancer (Gajalakshmi, Krishnamurthi, Ananth, & Shanta, 1996; Swai et al., 2005; Warnakulasuriya et al., 1984). For some conditions, such as cardiovascular disease, simplified screening algorithms have facilitated this process, both by avoiding blood tests and other often-unavailable investigations, and by approximating complex decision matrices with a few key criteria that NPHWs can apply even with incomplete knowledge of medical physiology (Fernandez-Alvira et al., 2017; Gaziano, Young, Fitzmaurice, Atwood, & Gaziano, 2008; WHO, 2017a).

NPHWs can also provide treatment for chronic conditions using related algorithms. These include prescribing medications for conditions including hypertension (Kengne, Awah, Fezeu, Sobngwi, & Mbanya, 2009; Ogedegbe et al., 2014; Vedanthan et al., 2017), diabetes (Kengne et al., 2009; Labhardt, Balo, Ndam, Grimm, & Manga, 2010), and asthma (Kengne et al., 2008), as well as counseling for conditions such as depression (Chibanda et al., 2011; Patel et al., 2010) and tobacco cessation (Siddiqi et al., 2013). Increasingly, WHO and other international organizations have developed algorithms that leverage task-shifting (as well as task-sharing, in which doctors aid NPHWs in providing care) for cost-effective integrated management of chronic diseases (WHO, 2004, 2017a). In part as a result of these successes, models using CHWs and other NPHWs to help patients control chronic conditions are now increasingly common in

high-income countries as well. One example is City Health Works (2017) in New York City.

The optimal role of NPHWs in chronic disease care is incompletely understood, and likely depends on the context of the local health system. Systematic reviews have demonstrated these workers' efficacy (Joshi et al., 2014; Mutamba, van Ginneken, Paintain, Wandiembe, & Schellenberg, 2013; Khetan et al., 2017), but also document such barriers as skepticism toward permitting NPHWs to prescribe medications, lack of sufficient supplies at the NPHW clinic level, limited formal NPHW training, and difficulty tracking patient records (Joshi et al., 2014). Conversely, health systems that provide short, practical NPHW trainings; that permit these workers to have sufficient autonomy; and that ensure they have reliable supplies for practice have reported more success (Joshi et al., 2014). NPHWs are an essential tool for chronic disease care, but their role must be properly clarified and adapted to the context of the local care delivery system, in both high-income countries and lower-income countries.

Leveraging or Expanding Programs for Other Conditions

Task-shifting and NPHW-led care rose to recent prominence during the mid-2000s when the HIV/AIDS pandemic in LMICs was at its height and medications and human resources were severely inadequate to cope with the disease burden imposed by that pandemic. In part due to improved clinical outcomes in persons living with HIV and AIDS (PLWHA), chronic conditions have become more prevalent in this population as they age (Kwarisiima et al., 2016; Rabkin, Kruk, & El-Sadr, 2012). Moreover, HIV infection and treatment are associated with many chronic conditions, such as cardiovascular disease, stroke, and multiple types of cancer (Narayan et al., 2014). Additionally, the mechanics of modern HIV/AIDS care—which now usually involves universal screening, lifestyle counseling, and medical treatment for all persons with a positive test—closely resemble validated approaches to the control of chronic conditions such as hypertension and diabetes (Chamie et al., 2012).

As a result, HIV/AIDS programs in LMICs are increasingly leveraging their resources to concurrently screen for chronic conditions in both HIV-positive and HIV-negative persons using physicians and NPHWs. The Sustainable East Africa Research in Community Health (SEARCH) study, for example, is a massive randomized trial of 300,000 persons in Uganda and Kenya aimed at establishing whether screening entire communities for HIV/AIDS—and ensuring adequate treatment of all PLWHA—can arrest the spread of HIV (SEARCH, n.d.). SEARCH has also succeeded in screening tens of thousands of people for hypertension and diabetes in the communities, and consistently linked those persons with a positive test to follow-up care (Chamie et al., 2012; Kotwani et al., 2014). Other studies have also shown the efficacy of this model in other contexts (Janssens et al., 2007) and for other conditions such as depression (Adams et al., 2012). AMPATH's model, for example, has focused on HIV and chronic diseases such as Burkitt's lymphoma since its inception in the 1990s, and now provides NPHW-led hypertension care (Vedanthan et al., 2014). Although there are limited examples, recent meta-analyses have demonstrated that these programs are largely effective (Haldane et al., 2018). Predictors of success included the use of multidisciplinary teams such as pharmacists and other NPHWs as well as engagement with community leaders and members (Haldane et al., 2018).

Programs for chronic conditions can also be integrated into other existing care structures such as programs related to maternal and child health. As an example, a study is under way in northern Ghana that will leverage the Community-Based Health Planning and Services (CHPS) program, which has used community health nurses to decrease maternal and under-5 child mortality through education and referral, for the screening and treatment of risk factors for cardiovascular disease (Phillips, 2016–2018).

Integrating Multiple Chronic Conditions

Achieving control of chronic conditions in resource-poor settings requires careful parsimony—for example, using nonphysicians when doctors are unavailable, or using existing health programs rather than building new ones. Further efficiency is achievable by focusing on more than one chronic condition using the same cadre of staff and resources. Cardiovascular epidemiologic data demonstrate that it is less effective to treat persons with each major cardiovascular disease risk factor separately (such as high blood pressure and smoking) than to calculate the overall risk of an individual based on these factors and provide integrated care for all such persons (WHO, 2007). WHO's (2017a) HEARTS initiative is aimed at providing such care, although controversy remains over whether it has addressed all elements of heart disease care (Kishore, Heller & Vasan, 2018). A predecessor of the HEARTS protocol was implemented successfully in China and Nigeria (Mendis et al., 2010), and studies are under way in Jordan and Uganda, among other sites, to implement this approach (Collins et al., 2017; Sandy Gove, personal communication, 2017).

Although models like HEARTS for the integrated care of diabetes, hypertension, and other cardiovascular disease risk factors have become more common (Chamie et al., 2012; Coleman, Gill, & Wilkinson, 1998; Labhardt et al., 2010), programs that integrate cardiovascular disease care with care of other chronic conditions such as asthma or epilepsy remain rare (Kengne et al., 2008; Labhardt et al., 2010). In high-income countries, where chronic diseases already constitute nearly the entire disease burden, persons who suffer from multiple concurrent chronic conditions often experience poor health outcomes and struggle to access consistent preventive care. In addition to CHW-led models, new research aims to build primary care systems focused on more effective management.

Characteristics of Effective Systems of Care for Chronic Diseases

Health care for patients with chronic conditions requires a fundamental change in perspective from the familiar acute care model. The magnitude of this challenge is eased somewhat by the fact that chronic conditions share many common features. Whereas biomedical management changes depending on the unique features of the specific disease, the general components of care organization and delivery for patients with chronic conditions are essentially the same. These components include a well-defined care plan, patient self-management, scheduled follow-up appointments, monitoring of outcome and adherence, and stepwise treatment protocols. Collectively, these approaches represent a significant shift in healthcare practices. The differences between typical current and desired future approaches are described in the following subsections.

Patient-Centered Care

Patient-centered care recognizes the patient as a person; fully informs patients about the risks and benefits of treatment options; tailors decision making in response to individual patients' values, needs, and expressed preferences; shares power and responsibility among patients and providers; and develops patients' abilities to participate in their care. Across its multiple meanings, research shows that patient-centered care is crucial for obtaining good outcomes for chronic conditions.

Several experiences within LMICs have demonstrated the utility of patient-centered care across diverse cultures and resource contexts. WHO's Integrated Management of Adult Illness (IMAI) general principles of chronic care, for example, focus on equipping first-level healthcare workers to provide patient-centered health care. Specifically, the guidelines and related training materials prepare such workers to solicit patients' concerns and preferences, work in collaboration with patients to decide specific goals and treatment plans, and support patients in their daily efforts regarding prevention, medication adherence, and self-management.

Early results indicate that this approach is understandable and usable by first-level health workers. To date, physicians, nurses, and lay providers have been trained in this approach in Burkina Faso, Burundi, Ethiopia, Sudan, and Uganda. In Shanghai, China, a community-based chronic disease self-management program was shown to improve health status and reduce hospitalizations among patients with hypertension, heart disease, chronic lung disease, arthritis, stroke, and diabetes. Participants learned to take responsibility for the day-to-day management of their disease and the physical and emotional problems caused by their disease. The program was led by lay people with chronic conditions, who followed a detailed leader's manual throughout the program (Fu et al., 2003).

Emphasis on Primary Health Care

In LMICs, patients with chronic conditions present and need to be managed mainly at the primary healthcare level. This represents a departure from the approach used in healthcare systems that are driven by tertiary-care, specialty settings. Oman has successfully made the shift to a decentralized primary healthcare system, with health programs and activities in this country now being coordinated with the regional health services via referrals and linkages (WHO, 2002a). Similarly, the health policy of the Islamic Republic of Iran is based on primary health care, with particular emphasis on the expansion of health networks and programs in rural areas.

Population-Based Care

Health care for chronic conditions is most effective when policies, plans, and practices prioritize the health of a defined population rather than the single unit of a patient seeking care. A population focus implies that healthcare systems assess and monitor the health of communities, emphasize prevention and promote healthy behavior, assure universal access to appropriate and cost-effective services, and contribute

to the evidence base for effective treatments and systems of care.

Cuba's family doctor program is a notable application of population-based care. Each family doctor is responsible for the general health of the entire population in a small, defined area. Physicians are expected to provide preventive, maternal, and curative services to children and adults, and to monitor all patients with chronic conditions. They live in the communities that they serve, often residing in the same apartment block as their patients. In addition to engaging in medical consultations, Cuba's family doctors play an active role in promoting health among the communities they serve. They provide informal advice and counseling to community members, and they run regular prevention and self-management groups concerning a range of issues. They are also expected to set a positive example for their patients in the conduct of their day-to-day lives (Warman, 2001).

Proactive Care

Proactive care anticipates patients' needs rather than relying on a patient-initiated, often acute care–focused interaction. In rural South Africa, a proactive noncommunicable disease management program for hypertension, diabetes, asthma, and epilepsy was established within primary health care. This program emphasized planned care: Clinic-held treatment cards and registries were introduced, and diagnostic and management protocols were followed, which included regular, planned follow-up with a clinic nurse. Using this proactive care approach, nurses were able to achieve good disease control among most of the patient population—68% of patients with hypertension, 82% of those with diabetes, and 84% of those with asthma (Coleman et al., 1998).

A Model of Care: Innovative Care for Chronic Conditions

The WHO has developed a model based on these approaches. The Innovative Care for Chronic Conditions (ICCC) framework provides a roadmap for decision makers who want to improve their health system's capacity to manage chronic conditions (WHO, 2002b) (**FIGURE 8-5**). This framework is composed of fundamental components within the levels of patient interactions, organization of health care, community, and

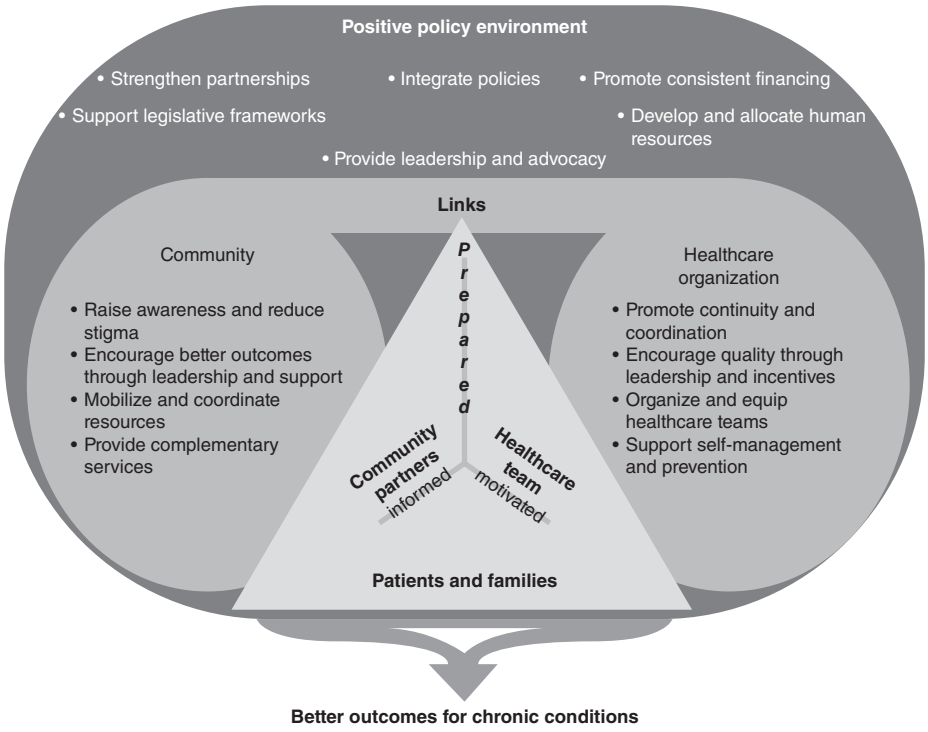

FIGURE 8-5 The World Health Organization's Innovative Care for Chronic Conditions framework.

policy. These components are described as building blocks that can be used to help decision makers progressively create or redesign a healthcare system to expand its capacity to manage long-term health problems. Although the framework does not prescribe specific changes that must be tailored to unique needs and resources, it highlights the need for comprehensive system design or change in the requirements for effective care.

Barr et al. (2003) have also proposed an expanded chronic care model (**FIGURE 8-6**) that emphasizes the inclusion of elements of the population health promotion field so that broad-based prevention efforts, recognition of the social determinants of health, and enhanced community participation can all be part of the work of health system teams as they address the prevention and control of chronic diseases. **TABLE 8-18** compares the components of the expanded chronic care model with those of the chronic care model developed by Wagner and colleagues (1996).

Comprehensive Care Applied to Clinical Prevention

The preponderance of evidence suggests that effective healthcare strategies for reducing risk do exist, but tend to be weakly implemented (Coffield et al., 2001). Many professional competencies for delivering effective clinical prevention are outside the scope and culture of clinical medicine, so healthcare professionals frequently have little or no training in the skills required to improve care (Glasgow, Orleans, & Wagner, 2001).

Many opportunities for better integration of the treatment of chronic diseases and the prevention of risk factor behaviors remain largely untapped. For example, stronger support for smoking cessation among patients with TB would save lives in the long term, and smoking cessation among patients with congenital heart disease is the single most effective intervention for reducing mortality in these patients who smoke. As demonstrated by the 36% reduction in the relative risk of mortality among patients with congenital heart disease who quit tobacco use, smoking is at least as important as other secondary prevention measures such as use of statins (a 29% reduction), aspirin (15%), beta blockers (23%), or angiotensin-converting enzyme (ACE) inhibitors (23%) (Critchley & Capewell, 2003). Smoking cessation is also a priority for people with mental disorders. In one of the major studies on comorbidity between tobacco use and depression, researchers found that people with mental disorders are almost twice as likely to smoke as individuals without such disorders. Further, they found that people with a mental disorder had consumed 44.3% of all cigarettes smoked by a nationally representative sample in the previous days (Lasser et al., 2000).

Another challenge is that effective clinical prevention services must extend beyond the mere provision of information to patients. The era of exhortation by healthcare professionals to "eat better" or "drop some weight" is long past: Modern, evidence-based interventions emphasize shared decision making and collaborative goal setting among providers and patients (Serdula, Khan, & Dietz, 2003). The clearer and more personalized

TABLE 8-18 Comparison of the Chronic Care Model with the Expanded Chronic Care Model

Components of the Chronic Care Model		Components of the Expanded Chronic Care Model		Examples
Health system—organization of health care	Program planning that includes measurable goals for better care of chronic illness			
Self-management support	Emphasis on the importance of the central role that patients have in managing their own care	Self-management/develop personal skills	Enhancing skills and capacities for personal health and wellness	■ Smoking prevention and cessation programs ■ Seniors' walking programs
Decision support	Integration of evidence-based guidelines into daily clinical practice	Decision support	Integration of strategies for facilitating the community's abilities to stay healthy	■ Development of health promotion and prevention "best practice" guidelines
Delivery system design	Focus on teamwork and an expanded scope of practice to support chronic care	Delivery system design/reorient health services	Expansion of mandate to support individuals and communities in a more holistic way	■ Advocacy on behalf of (and with) vulnerable populations
Clinical information systems	Developing information systems based on patient populations to provide relevant client data	Information system	Creation of broadly based information systems to include community data beyond the healthcare system	■ Emphasis in quality improvement on health and quality of life outcomes, not just clinical outcomes ■ Use of broad community needs assessments that take into account: • Poverty rates • Availability of public transportation • Violent crime rate
Community resources and policies	Developing partnerships with community organizations that support and meet patients' needs	Build healthy public policy Create supportive environments Strengthen community action	Development and implementation of policies designed to improve population health Generating living and employing conditions that are safe, stimulating, satisfying, and enjoyable Working with community groups to set priorities and achieve goals that enhance the health of the community	■ Advocating for/developing: • Smoking bylaws • Walking trails • Reductions in the price of whole-wheat flour • Maintaining older people in their homes for as long as possible • Work toward the development of well-lit streets and bicycle paths • Supporting the community in addressing the need for safe affordable housing

Reproduced with permission from Barr, V. J., Robinson, S., Marin-Link, B., Underhill, L., Dotts, A., Ravensdale, D. et al. (2003). The expanded Chronic Care Model: An integration of concepts and strategies from population health promotion and the Chronic Care Model. *Hospital Quarterly, 7*, 73–82.

the goal, the better (Estabrooks, Glasgow, & Dzewaltowski, 2003). Skill building to overcome barriers, self-monitoring, personalized feedback, and systematic links to community resources such as peer support groups are other important elements for success (Steptoe et al., 2003). Many healthcare settings deliver these kinds of interventions in group formats, which enhances the efficiency of healthcare professionals and provides the added element of social support (Noel & Pugh, 2002).

Comprehensive Care Applied to Adherence

The ICCC framework recognizes the importance of treatment adherence as a primary determinant of the effectiveness of treatment. Good adherence confers both health and economic benefits. Adherence has been associated with improved blood pressure control (Luscher, Vetter, Sigenthaler, & Vetter, 1985) and lessened complications of hypertension (Morisky et al., 1983; Psaty, Koepsell, Wagner, Lo Gerfo, & Inui, 1990). Despite the clear importance of treatment adherence, a number of rigorous reviews have found that in high-income countries, adherence among patients with chronic diseases averages only 50%; it is even lower in LMICs. In Gambia, China, and the United States, for example, only 27%, 43%, and 51%, respectively, of patients adhere to their medication regimen for high blood pressure. Similar patterns have been reported for other conditions, such as depression (range of 40% to 70%), asthma (43% for acute treatments and 28% for maintenance), and HIV/AIDS (range of 37% to 83%) (WHO, 2003a).

Adherence is a complex behavioral process that is influenced by five interacting dimensions: social and economic factors, healthcare system factors, condition-related factors, therapy-related factors, and patient-related factors. Because each dimension plays an important role in determining adherence rates (WHO, 2003a), all of them should be considered when designing interventions to improve outcomes. The most effective interventions have been shown to be multilevel, targeting more than one factor with more than one intervention (Dickinson, Wilkie, & Harris, 1999).

Contemporary perspectives have pointed out the importance of conceptualizing adherence as the active, voluntary involvement of the patient in the management of his or her disease, including a mutually agreed-upon course of treatment and sharing of responsibility between the patient and healthcare providers (Flood & Chiang, 2001). According to these perspectives, adherence is an active, responsible, and flexible process of self-management, in which the person strives to achieve good health by working in close collaboration with healthcare staff instead of simply following rigidly prescribed rules.

Summary of Effective Health Care

Reviews of interventions to improve health care for chronic conditions have demonstrated the importance of using multifaceted approaches as opposed to "magic bullet" or "single lever" interventions (**TABLE 8-19**) (Grimshaw et al., 2001; Renders et al., 2002; Wagner et al., 2001). Models of integrated, coordinated care, such as the ICCC framework, capture this complexity in an organized way.

Several key concepts have emerged from research within this area. First, it is necessary to work across multiple levels in a coordinated fashion to effect meaningful change in health care for chronic diseases. Second, organized systems of care—not just individual healthcare workers—are essential in producing positive outcomes for chronic disease. Third, it is crucial to work across the disease continuum in a comprehensive way. Comprehensive care for chronic conditions must span the full range of phases from clinical prevention, to treatment, to rehabilitation, to palliation (see **EXHIBIT 8-11**).

Healthcare Access and Quality

WHO has introduced a range of tools to support the management of chronic diseases that aim to impact healthcare access and quality. These have included the Package of Essential Medicines and Technologies for Non-Communicable Disease Interventions (PEN) and the HEARTS protocol, whose initial emphasis is on cardiovascular health. The HEARTS protocol includes the following elements:

H: healthy lifestyle

E: evidence-based treatment protocols

A: access to essential medicines and technologies

R: risk-based management

T: task-shifting and team-based care

S: systems for monitoring (WHO & CDC, 2017)

These guidelines, toolkits, and roadmaps are being co-developed for use at four levels: community, facility, district, and national, and are meant to guide decision making in the face of a paucity of domestic financing.

A growing body of work on implementation science in the public and private sectors has emerged to

TABLE 8-19 Stepwise Policy and Program Targets for National Prevention and Control of Chronic Diseases

Resource Level	Population Approaches		Individual High-Risk Approaches
	National Level	Community Level	
Step 1: Core	The WHO Framework Convention on Tobacco Control (FCTC) is ratified in every country. Tobacco control legislation consistent with the elements of the FCTC is enacted and enforced. A national nutrition and physical activity policy consistent with the global strategy is developed and endorsed at the cabinet level, including laws. Health impact assessment of public policy is carried out; priority areas include transport, urban planning, taxation, trade, and agriculture.	Local infrastructure plans include the provisions for and maintenance of accessible and safe sites for physical activity (e.g., parks and pedestrian-only areas). Health-promoting community projects include participatory actions to cope with the environmental factors that increase individuals' risk of chronic diseases—inactivity, unhealthy diet, and tobacco and alcohol use. Active health promotion programs focusing on chronic diseases are implemented in different settings (e.g., villages, schools, workplaces) and explicitly aim to reach poor communities.	Context-specific guidelines for chronic disease prevention and control have been adopted and are used at all healthcare levels. A sustainable, accessible, and affordable supply of appropriate medication is assured for priority chronic diseases. A system exists for the consistent, high-quality application of clinical guidelines and for the clinical audit of services offered. A proactive follow-up system for patients with diabetes and hypertension is in operation.
Step 2: Expanded	Tobacco legislation provides for incremental increases in taxes on tobacco, and a proportion of the revenue is earmarked for health promotion. Food standards legislation is enacted and enforced; it includes nutrition labeling. Sustained, well-designed, national programs (counter advertising) are in place to promote nonsmoking lifestyles, consumption of fruits and vegetables, and physical activity. Country standards are established that regulate marketing of unhealthy food to children.	Sustained, well-designed programs are in place to promote tobacco-free lifestyles (e.g., smoke-free public places, smoke-free sports). Healthy diets (e.g., low-cost, low-fat foods; fresh fruit and vegetables). Physical activity (e.g., "movement") in different domains (occupational and leisure).	Systems are in place for selective and targeted prevention aimed at high-risk populations, based on absolute levels of risk. Publicly financed "quit-line" for smokers; weight control line.
Step 3: Optimal	Policies shown to work for chronic disease prevention and control are implemented. There is policy coherence between agricultural systems and chronic diseases. Country standards are established that regulate marketing of unhealthy food to children.	Recreational and fitness centers are available for community use.	Opportunistic screening, case-finding, and management programs are implemented. Self-management groups are fostered for tobacco cessation and overweight reduction. Appropriate diagnostic and therapeutic interventions are implemented.

EXHIBIT 8-11 Case Study: Hypertension

Two of us (DJH and SPK) have argued that an approach to medication access used for HIV/AIDS mobilization should be leveraged for hypertension, the leading risk for cardiovascular disease (Heller & Kishore, 2017). Leveraging lessons learned from HIV/AIDS and infectious disease programs, we believe it is crucial to focus on the gap—and outline steps to close it.

> Antihypertensive medicines, called thiazides, can close the treatment gap for less than $20 per person per year. Over a decade, they could save almost 5 million lives worldwide, at a cost under $9 billion per year: significantly less than the estimates that galvanized the global HIV community 15 years ago. Thiazides are the initial medication of choice for blood pressure control in nearly all settings. Although developed in 1958, they remain a drug of first resort, according to the International Society for Hypertension (ISH), European Society for Cardiology, and others (James et al., 2014; Mancia et al., 2013; WHO, 2007). They are also generic, costing a dollar or less per year in developing countries (Partners in Health, Bukhman, & Kidder, 2011). Although they require annual blood tests and doctor visits to screen for (rare) changes in kidney function, groups such as Partners in Health (2011) have treated patients with hydrochlorothiazide for $4–13 per year in settings like Rwanda.
>
> As in the early days of HIV control, conventional wisdom holds that universal hypertension treatment is prohibitively expensive. In 2007, WHO and ISH published guidelines arguing that only high-risk persons should receive antihypertensive medications, because "treatment of [hypertensive] patients with very low cardiovascular disease risk may be cost-effective only if inexpensive antihypertensive drugs are used" (WHO, 2007). Subsequent studies concurred (Gaziano, 2008; Ilesanmi, Ige, & Adebiyi, 2012), with one case finding many patients spent 10% or more of their annual income on antihypertensive medications (Ilesanmi et al., 2012) Yet recent data suggest universal treatment is now cost-effective and a better value than HIV/AIDS treatment at the dawn of the Global Fund and PEPFAR. Partners in Health (2011) pays $0.3 cents per thiazide tablet in Rwanda or $1.03 per patient-year of treatment. Patients requiring further treatment receive amlodipine, whose annual cost is $4.69. Each patient also receives one to two clinic visits per year at $3 each, as well as laboratory tests costing $0.17 per check. Conservatively, assuming that all patients require two medications, clinic visits, and laboratory tests per year, these results correspond to a per-patient annual cost of $12.90. Mills et al. (2016) report that about 32% of all adults in LMICs have hypertension—approximately 1.039 billion people. Some 11.6% have chronic kidney disease, according to a recent systematic analysis (Mills et al., 2015), or other severe hypertension (9.1% in Partners in Health's cohort) requiring treatment beyond thiazides and amlodipine (Partners in Health, 2011). Of the remaining 830 million, 29% are currently treated (Mills et al., 2016), leaving 589 million persons in need of treatment worldwide.

Reproduced from Heller D. J., Kishore S. P. (2017). Closing the blood pressure gap: An affordable proposal to save lives worldwide. *BMJ Global Health 2*:e000429, with permission from BMJ Publishing Group Ltd.

champion appropriate models. For example, *The Lancet*'s Commission on NCDs and Injuries provides tools for national ministries to execute better care on chronic diseases (*The Lancet* NCDI Poverty Commission, 2017). Moreover, while antiretroviral drugs (ARVs) for HIV/AIDS can cost $3,500 or more annually, access to low-cost, first-line treatments for hypertension such as thiazides could be achieved for less than $20 per person (Partners in Health, Bukhman, & Kidder, 2013).

A Model of Care: Innovative Care for Chronic Conditions

New models exist on how to best tackle chronic conditions in resource-poor communities. As an example, AMPATH in Eldoret, Kenya, has pioneered an innovative model for caring for patients with chronic illnesses (**FIGURE 8-7**). This model is based on the HIV model that is shifting toward population health, to include income, food security, clinical care delivery for chronic diseases, as well as community partnerships and social networks that are durable and long-lasting.

This shift toward population health is being mirrored by other academic initiatives such as global health partnerships amplified by the research outputs of the Fogarty Institute for Innovation and other global health institutes across the globe. A key emphasis of this model is team-based care and task-shifting to ensure that nurse- and community health worker-driven models are scaled appropriately, including in rural settings. Adherence and linkage to care are hallmarks of the approach. These models are patient centered, population based, data driven, and proactive (rather than reactive).

Cost-Effectiveness

Chronic disease interventions, including medications, often have low costs and no patent protection. Many of these interventions are also listed on WHO's Essential Medicines List, which guides national purchasing,

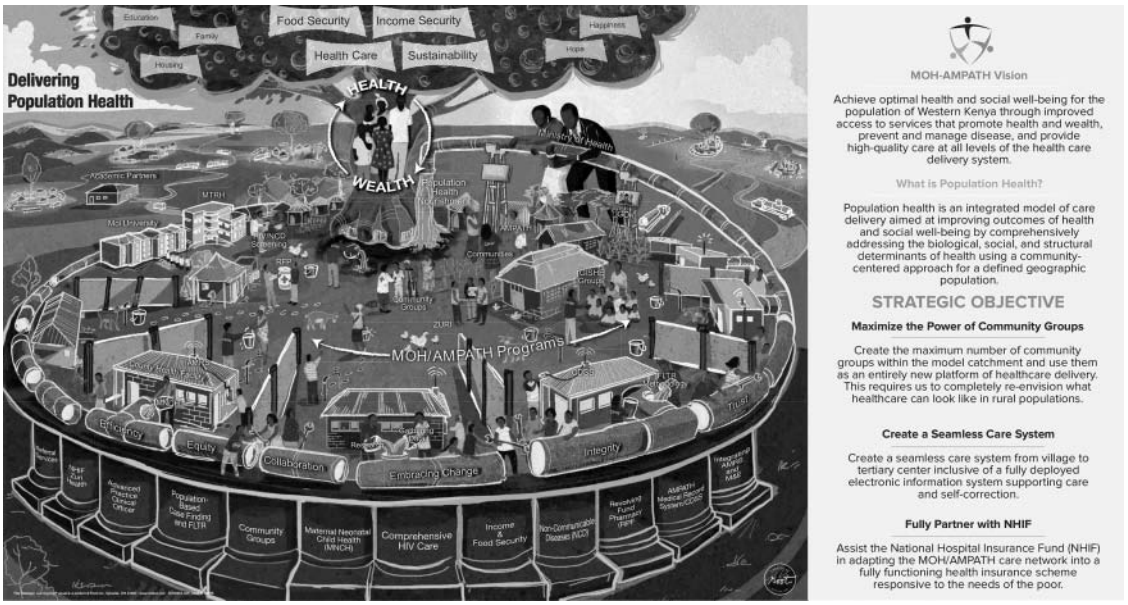

FIGURE 8-7 AMPATH's framework for population health.

The Root Learning Map® visual was created by Root Inc and provided courtesy of AMPATH.

procurement, and distribution at districts and facilities. With the exception of oncologic products (e.g., trastazumab for *HER2*-positive breast cancers), these tools are cost-effective per established WHO standard (cost ÷ DALY is less than 3 times the gross national income per capita).

One fast-growing movement is coalescing around the use of a multidrug regimen in a single fixed-dose combination—known as the polypill—for use for cardiovascular disease. This tool could be rapidly deployed for primary and secondary prevention to promote adherence and deliver clinical results across meaningful population sizes at low cost.

Reorientation of Health Services to Address Chronic Disease

Many lives continue to be lost prematurely because of inadequate treatment and long-term management of chronic diseases, even though simple and inexpensive approaches to address these diseases exist. Even in high-income countries, the full potential of these interventions is not realized. The situation in both poorer countries and poor communities within rich countries is even less satisfactory. In most countries, effective means of preventing, treating, and providing palliative care for cancer exist, but are not broadly implemented. There are many opportunities for coordinated risk reduction, care, and long-term management of chronic disease. For example, smoking cessation is a priority for all patients who smoke; dietary and physical activity information and skill building should be provided to most patients in virtually all healthcare settings. Unfortunately, few efforts have been made to explicitly target poor communities with such interventions.

Considerable progress has been made in improving access to, and reducing the prices of, antiretroviral agents for HIV/AIDS, drugs to treat TB, and several vaccines. Similar progress has yet to be made for essential drugs that are required to improve survival for treatable cancers, diabetes, and cardiovascular disease. A patient with heart disease in a poor nation has the same right to effective drug treatment as a patient with malaria, tuberculosis, or HIV/AIDS. NGOs have yet to advocate as effectively for better access to chronic disease treatment as they have for selected infectious diseases, despite the huge savings in lives and suffering that would result from broader access to such health care.

Continued strengthening of certain aspects of infectious disease control, particularly those related to chronic infectious diseases such as TB and HIV/AIDS, will in turn benefit the control of cardiovascular disease, diabetes, and cancer. The same transformation of healthcare systems is required to address prevention and long-term disease management for both infectious and noninfectious chronic diseases. In sub-Saharan African countries, an opportunity exists to ensure that the new platforms for health services delivery that are being built to expand access to treatment for HIV/AIDS also address noninfectious chronic diseases. The marginal increased investments required to provide this more comprehensive infrastructure would, in all likelihood, yield substantial gains for public health among poor communities whose members already suffer from cardiovascular disease, diabetes, and cancer.

Summary

It is often stated that "An ounce of prevention is worth a pound of cure." Yet too often, treatment is valued over prevention. This emphasis is maintained despite evidence suggesting the cost-effectiveness of prevention interventions compared to treatments for chronic diseases. One major driving factor underlying this phenomenon is the time value of prevention versus treatment. Prevention saves statistical figures in the future, yet treatment saves real people today. In too many instances, this factor leads to treatment being prioritized over prevention.

This chapter has presented the urgent case for acting on chronic diseases today and not tomorrow. It defined and outlined the global prevalence of chronic diseases, their health and economic impact, and their four key risk factors; described stakeholder efforts to date in chronic disease prevention; and proposed stakeholder actions that can further control the rising prevalence of chronic diseases. To fully realize these objectives and to place these actions and activities in context, **FIGURE 8-8** presents a graphic of major milestones in chronic disease prevention. It includes future predictions related to chronic diseases through the year 2030, when the United Nations measures progress against the SDGs.

To assist students planning careers related to chronic diseases, we have also developed a roadmap on potential future developments in health. This roadmap (**EXHIBIT 8-12**) lists multiple often-uncharted paths for action and advocacy against chronic conditions in the context of the SDGs.

Discussion Questions

1. What are the leading risk factors that contribute to death and disability globally? How do these risk factors compare between LMICs versus high-income countries?
2. Given current trends in risk factors, what are likely to be the major causes of death and disability in LMICs versus high-income countries over the next decade?
3. Which policies and actions taken at national and international levels could influence trends in chronic disease and their associated risk factors? Which indicators might facilitate their implementation?
4. Describe how globalization could be positively harnessed for chronic disease prevention. In doing so, consider how public–private partnerships involving major multinational corporations could play a more effective role in promoting health.

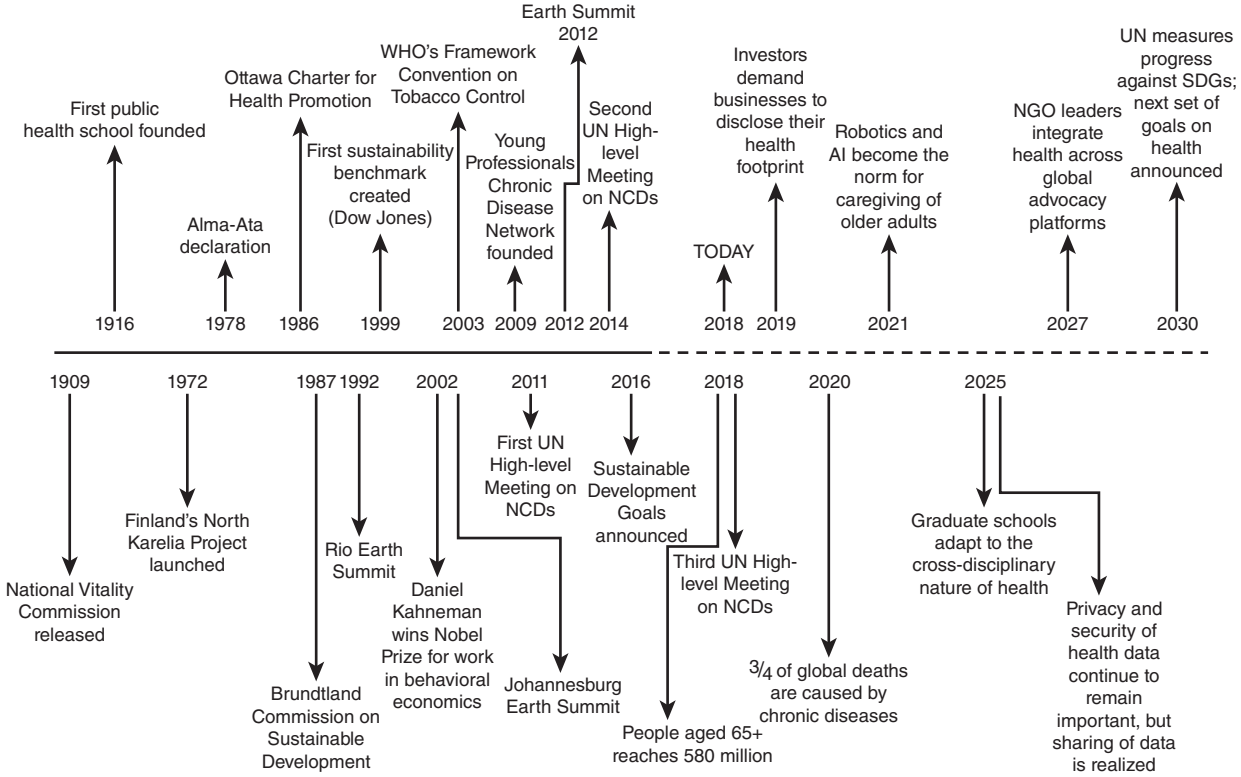

FIGURE 8-8 Milestones in chronic disease prevention, 1900–2030.

EXHIBIT 8-12 Future Roadmap for Health

To encourage interest in chronic diseases and to offer ideas on emerging trends, this list summarizes predictions about global trends related to health and well-being. It serves to inform actions to advance the Sustainable Development Goals (SDGs) and advocate for chronic disease prevention in coming decades.

- **Demographic changes:** Life expectancy now exceeds 70 years in many countries; rural workers are moving to cities to search for economic opportunities; and climate and political instability drives migration toward safer lands. These are intensifying pressures to develop healthy and vibrant communities.
- **Epidemiology structures:** Declines in undernutrition and maternal deaths have been complemented by rises in overweight/obesity and poor mental health. Infectious disease agents—most recently Ebola and Zika—will continue to threaten the resiliency of global populations. Strategies that encourage positive, individual behavioral change, and that prevent infectious disease outbreaks, will be critical to creating healthy populations and ensuring the sustainability of healthcare systems.
- **Health inequalities:** Health inequalities and inequities between different social groups are widening in many countries. Individuals' risk of poor health increases with declines in their socioeconomic position. Obesity rates, for example, are expected to rise in coming decades, especially among more disadvantaged groups.
- **Affordable health services:** Government austerity and rising healthcare costs threaten the sustainability of health systems. This has led to increased demand for affordable health services. Provisions for universal health coverage, investments into personalized treatments, and workplace health programs can reduce healthcare costs by governments and employers.
- **Digital technologies:** Rapid advances in technology are enabling individuals to quantify their health status, and can improve the well-being of disparate populations. These technologies empower individuals to better prevent, control, and treat disease, though associated privacy and security concerns must be proactively addressed to ensure their uptake among all populations.
- **Media and their consumers:** Media, including social media, serve to spark action and investment by documenting events with relevance to health, making consumers increasingly more vocal in their demands for creating healthier societies.

CHAPTER 9

Unintentional Injuries and Violence

Margaret Peden, Berit Kieselbach, Alexander Butchart, and Adnan A. Hyder

Introduction

Injuries are no "accident" and violence does not "just happen." Recognition that a scientific approach to the prevention and control of injuries and violence can be effective has significantly raised these conditions' profile on the public health agenda. Twenty-plus years ago, injuries and violence hardly merited mention in the curricula of most schools of public health, whereas today their prevention and control is an integral part of a well-balanced training program in public health in most high-income countries and in increasing numbers of low- and middle-income countries (LMICs).

Injuries have traditionally been defined as physical damage to a person caused by an acute transfer of energy (mechanical, thermal, electrical, chemical, or radiation energy) or by the sudden absence of heat or oxygen. It is now recognized, however, that this definition is too narrow, but rather should be broadened to include impacts that result in psychological harm, maldevelopment, or deprivation (Krug, Dahlberg, Mercy, Zwi, & Lozano, 2002).

Injuries can be grouped in various ways, but most commonly are categorized with reference to the presumed underlying intent—that is, as injuries of unintentional, intentional, and undetermined intent. Unintentional injuries are those where there is no evidence of predetermined intent—sometimes referred to as "accidents"—which erroneously gives the impression they are not amenable to prevention. They include injuries sustained as a result of road traffic crashes, poisonings, falls, burns, and drowning, as well as occupational and sports injuries.

Intentional injuries result from violence, defined as "the intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either results in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment or deprivation" (Krug et al., 2002). In addition to intentional injuries, victims of violence are at increased risk of a wide range of psychological and behavioral problems, including depression, alcohol abuse, smoking, anxiety, and suicidal behavior, as well as reproductive health problems such as unwanted pregnancy, sexually transmitted diseases, and sexual dysfunction (Krug et al., 2002). Violence can be categorized as self-directed violence (violence that a person inflicts upon himself or herself), interpersonal violence (violence inflicted by another individual or a small group of individuals), or collective violence (violence inflicted by larger groups such as states, organized political groups, religious groups, militia groups,

and terrorist organizations). *Self-directed* violence includes completed suicides, attempted suicides, suicidal ideation, suicidal behaviors, and self-harm. *Interpersonal* violence includes child maltreatment, intimate-partner violence, and elder abuse—all forms that occur largely between family members—as well as youth violence and sexual violence, which occur largely in the community between people who are unrelated and may or may not be acquainted. *Collective* violence can be subdivided into social, political, and economic violence.

It is not always clear whether an injury has occurred from violence or an unintended cause. In such cases, the injury is classified as being of *undetermined* intent, although for legal or social reasons, it may well be classified as an unintentional injury.

This chapter considers unintentional injuries and violence, including issues related to a number of cause-specific injuries. The latter include those injuries that are routinely analyzed and for which statistics are published by the World Health Organization (WHO); individually, these injuries account for the greatest injury burden in terms of mortality and disability-adjusted life-years (DALYs). They include road traffic injuries, poisonings, falls, burns, and drowning, as well as self-directed violence, interpersonal violence (including child maltreatment, youth violence, intimate-partner violence, sexual violence, and elder abuse), and collective violence, including war.

The first section provides an overview of the global burden of injuries and violence. It includes discussion of data sources and the challenges of obtaining accurate data on these types of events, especially in LMICs. The next section outlines known and potential risk factors for unintentional injuries and violence. Included here is information on the extent to which knowledge about risk factors in one setting can be applied to other settings, and especially the extent to which knowledge about risk factors can be transferred from high-income settings to low- and middle-income settings.

Current evidence about effective interventions to prevent and control injuries and violence is then summarized. Again, the extent to which evidence of effectiveness from high-income countries can be extrapolated to LMICs is considered.

The last section considers the opportunities and challenges that exist in advancing the injury and violence prevention agenda. Issues addressed include the ongoing need for advocacy for prevention, the essential role of research, the significance of a workforce trained to deal with these issues, and the role of national and international organizations in promoting the injury and violence prevention agenda, including international societies.

The Global Burden of Unintentional Injuries and Violence

Data Sources

Data on unintentional injuries and violence may be obtained from sources both within and outside the health sector. Health sector data sources include the usual data sources for other health conditions, such as health information systems, vital registration systems, and hospital discharge data, in addition to sources that are more specific to injuries and violence, such as ambulance data and trauma registries. Sources outside the health sector cover a wide spectrum of resources, depending on the type and nature of the injuries or violence. Commonly used non-health-sector data sources include police data, transport-sector data, legal records, and insurance company claims. Innovative data sources for injuries have also been used, such as newspapers and consumer reports. For both unintentional injuries and violence, population-based surveys are an essential complement to service-based sources of information, especially in settings where access to services such as health care and the police is limited, and where victims may be reluctant or unable to seek help, such as in cases of child maltreatment, intimate-partner violence, and elder abuse. This diversity of data sources makes the field of injuries and violence both unique and challenging—unique, in terms of the intersectoral nature of the information, and challenging, because the biases and nature of data from each source need to be understood.

Comprehensive global data on unintentional injuries and violence are available from the WHO as part of that organization's Global Health Estimates (GHE).[1] Attempts to obtain consistent and internationally comparable data have been made by WHO since 1990. WHO data do have some limitations: Notably, the information relies on death certificate data submitted to WHO from governments around the world. Also, in specific instances, it may not cover the entire country or might be incomplete;

[1] http://www.who.int/gho/mortality_burden_disease/causes_death/en/

for example, some countries do not classify all subcategories of unintentional injuries and violence. In addition, data on burns include only fire burns (and not scalds), while data on drownings do not include drownings due to floods. Nevertheless, its aggregation of all unintentional injuries and violence into one unified system of information makes the WHO database most useful for public health purposes, as it is also publicly available.

The Global Burden of Disease (GBD) database from the Institute for Health Metrics and Evaluation is another valuable source of data. These data are collected by a consortium of researchers from more than 130 countries on premature death and disability from more than 300 diseases and injuries. The data are updated regularly, and each update revises all previous estimates for all years (GBD 2015 DALYs and HALE Collaborators, 2016).

For specific types of injury, alternative data sources are available, and they frequently provide estimates that differ from those provided by WHO. The most comprehensive global road safety database is regularly compiled by WHO into a series of global status reports on road safety with its associated database published in the Global Health Observatory.[2] Examples of regional databases include the International Road and Traffic Accident Database, which collates data from 32 Organisation for Economic Co-operation and Development (OECD) member countries, and OISEVI, which collates data from 20 Latin American countries.[3] The road traffic death estimates from various databases may vary depending on the source of data—for example, vital registration (death certificates) versus police report forms, or whether these data are reported, adjusted, or estimated

WHO regularly compiles data on homicide, prevalence of child maltreatment, and intimate-partner and sexual violence in the Global Health Observatory (GHO),[4] which is a gateway to health-related statistics providing data and analyses on a set of global health priorities.

Comprehensive data on national efforts to address interpersonal violence, including the existence of national surveys, policies, laws, prevention programs, and services for victims of violence, are regularly published in WHO's Global Status Reports (Butchart & Mikton, 2014).[5]

The United Nations' Organization on Drugs and Crime publishes the Global Study on Homicide every other year; this report includes homicide rates, trends, mechanisms of homicide, and information about who is most at risk obtained from either criminal justice or public health systems.[6]

The quantity and quality of data for different health outcomes from unintentional injuries and violence vary. Generally, more and better-quality data are available for deaths than for morbidity and disability. Data on the types and severity of nonfatal health outcomes are important, yet challenging to obtain, especially from LMICs. Data on nonfatal health outcomes have primarily been derived from high-income countries, although in the past decade significant information on injuries and violence has emerged from several LMICs. In general, however, the state of routine health information in LMICs has been fragile, especially in regions such as sub-Saharan Africa and South Asia. Thus, it is not surprising that these regions have little tradition of developing specific information sources for unintentional injuries and violence. Notably, population-based studies from these regions frequently suggest that the unintentional injury and violence burden is higher than that reported in national official statistics, indicating that these conditions are significantly underreported in official estimates.

Estimates of Unintentional Injuries and Violence Mortality and Disability

In the following section, data from WHO's Global Health Estimates as well as the most recent global status reports on road safety[7] and violence prevention[5] are presented to demonstrate the global burden of injuries and violence. Additionally, specific studies or sources have been quoted, to highlight recent or unique information from LMICs.

Almost 5 million deaths occurred from all unintentional injuries and violence worldwide in 2015, of which nearly 90% were in LMICs. Approximately 27% of these deaths were caused by road traffic injuries, with suicide and homicide accounting for 16% and 9.5% of deaths, respectively (**TABLE 9-1**). Notably, 14% of deaths were classified as "other" types of unintentional injury deaths, which include injuries such as animal bites, insect bites, and unspecified

TABLE 9-1 Distribution of Global Deaths from Injury, 2015

Cause of Injury	Number of Deaths	Proportion of All Injury Deaths (%)
Unintentional Injuries		
Road traffic injuries	1,342,265	27.2
Poisoning	107,705	2.2
Falls	646,271	13.1
Fire, heat, and hot substance burns	180,051	3.6
Drowning	359,717	7.3
Exposure to mechanical forces	201,581	4.1
Natural disasters	14,088	0.3
Other unintentional injuries	674,907	13.7
Intentional Injuries		
Self-harm	788,089	16.0
Interpersonal violence	467,619	9.5
Collective violence and legal intervention	156,271	3.2

Reproduced from World Health Organization (WHO). (2016). *Global health estimates 2015: Deaths by cause, age, sex, by country and by region, 2000–2015*. Geneva, Switzerland: World Health Organization. Retrieved from http://www.who.int/healthinfo/global_burden_disease/estimates/en/index1.html

injuries. Not surprisingly, injury-related death rates were highest for road traffic injuries, followed by suicide, "other" unintentional injuries, falls, and homicide (**TABLE 9-2**). Somewhat similar patterns were observed for burden of disease rates, which include nonfatal health outcomes (using DALYs); however, falls had higher rates of nonfatal health outcomes due to the high morbidity from such injuries (**TABLE 9-3**). Importantly, the rates were highest for all "other" unintentional injuries, which likely reflects the challenges inherent in coding the specific causes of nonfatal unintentional injuries.

Unintentional Injuries

In 2015, more than 3.5 million unintentional injury deaths occurred, which were collectively responsible for 6.3% of the global mortality burden. The vast majority (90%) of unintentional injury deaths occurred in individuals in LMICs. The worldwide crude death rate for unintentional injuries was 48 deaths per 100,000 population; the highest rate was found in the African region (73.4 per 100,000 population) and the lowest rate in the Americas (36.1 per 100,000 population). Unintentional injuries were also responsible for more than 212 million DALYs in 2015, with 91% occurring in LMICs and the rates being highest in those regions that include large numbers of LMICs.

Road traffic injuries killed more than 1.3 million people in 2015, making these types of injuries the tenth leading cause of death worldwide. Road traffic injuries accounted for 2.4% of global mortality and resulted in a heavy death toll among people in all age categories. According to the Global Health

TABLE 9-2 Global Injury Death Rates per 100,000 Population, 2015

Type of Injury	Number of Deaths (000s)	Proportion of Total Deaths (%)	Crude Death Rate (per 100,000 population)	Age-Adjusted Death Rate (per 100,000 population)
Unintentional Injuries	3,527	6.3	48.0	47.2
Road traffic injuries	1,342	2.4	18.3	18.2
Poisoning	108	0.2	1.5	1.4
Falls	646	1.2	8.8	8.5
Fire, heat, and hot substances burns	180	0.3	2.5	2.4
Drowning	360	0.6	4.9	4.9
Exposure to mechanical forces	202	0.4	2.7	2.7
Natural disasters	14	0.0	0.2	0.2
Other unintentional injuries	675	1.2	9.2	9.0
Intentional Injuries	1,412	2.5	19.2	19.2
Self-harm	788	1.4	10.7	10.7
Interpersonal violence	468	0.8	6.4	6.4
Collective violence and legal intervention	156	0.3	2.1	2.1

Reproduced from World Health Organization (WHO). (2016). *Global health estimates 2015: Deaths by cause, age, sex, by country and by region, 2000–2015*. Geneva, Switzerland: World Health Organization. Retrieved from http://www.who.int/healthinfo/global_burden_disease/estimates/en/index1.htm

Estimates, deaths from road traffic injuries are projected to increase in the future, becoming the seventh leading cause by 2030.[8] Globally, more than 1 million of those persons killed from road traffic injuries during 2013 were from LMICs, corresponding to 24 deaths per 100,000 population in low-income countries and 18.4 per 100,000 in middle-income countries (WHO, 2015a). The absolute number of fatalities and the mortality rate resulting from road traffic injuries vary considerably across countries and regions, ranging from 84,143 fatalities (9.3 per 100,000 population) from this cause in the European region to 323,296 deaths in the Western Pacific region (17.3 per 100,000 population) (**FIGURE 9-1**). Although all age groups are affected by fatalities resulting from road traffic injuries, young adults—particularly males, who account for 75% of deaths—are at greatest risk of loss of life. Because this age group corresponds to the most economically productive segment of the population, road traffic injuries have serious implications for national economies (**FIGURE 9-2**).

Road traffic injuries are frequently defined in terms of the types of road users involved. Typically, data specify whether the users were the occupants of four-wheeled motorized vehicles or pedestrians, cyclists, or riders of motorized two-wheeled vehicles, with the latter being described as the *vulnerable road*

[8] http://www.who.int/healthinfo/global_burden_disease/projections/en/

TABLE 9-3 Global Injury DALYs by Sex, 2015

Type of Injury	All	Males	Females
Unintentional Injuries	212,206,821	141,651,044	70,555,777

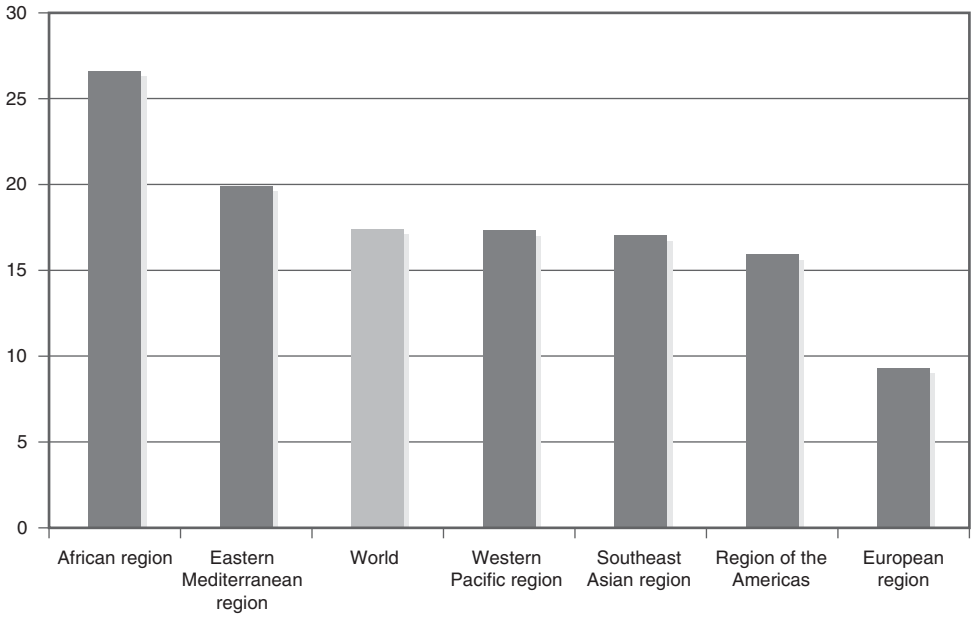

FIGURE 9-1 Road traffic fatality rates per 100,000 population, by WHO region, 2013.

Reprinted from World Health Organization (WHO). (2015). *Global status report on road safety, 2015*. Geneva, Switzerland: World Health Organization.

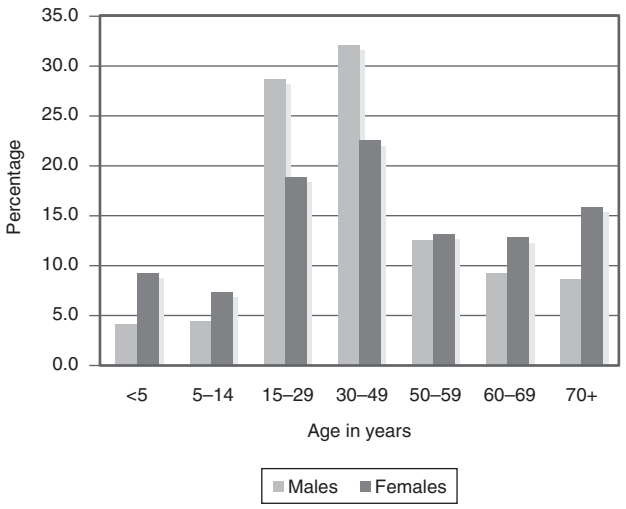

FIGURE 9-2 Global road traffic deaths by age, 2015.

Reproduced from World Health Organization (WHO). (2016). *Global health estimates 2015: Deaths by cause, age, sex, by country and by region, 2000–2015*. Geneva, Switzerland: World Health Organization. Retrieved from http://www.who.int/healthinfo/global_burden_disease/estimates/en/index1.htm

users. A recent survey undertaken by WHO (2015a) indicated that vulnerable road users account for almost half of all global deaths and contribute disproportionately to deaths in LMICs (**TABLE 9-4**).

According to WHO estimates, 107,705 *poisoning* deaths occurred in 2015. More than 90% of these deaths occurred in LMICs.

Falls caused more than 646,000 deaths worldwide in 2015, with the majority (83%) of these fatalities occurring in LMICs, and the male-to-female ratio being quite similar but with a distinctive skewing toward older age ranges (**FIGURE 9-3**). These numbers translate to an age-adjusted mortality rate of 8.5 deaths per 100,000 population globally and a loss of approximately 31 million DALYs. Clearly, falls make an important contribution to morbidity and disability on a global basis.

WHO registers data only for *burns* that result from fire, heat, and hot substances; it does not tally data for scalds (water burns)—an important limitation of this data source. More than 180,000 deaths were caused by fires in 2015, resulting in more than 12 million DALYs lost. Unlike other types of injuries, more females than males died from fire-related burns (male-to-female ratio of 0.8:1.00).

Drowning is the process of experiencing respiratory impairment from submersion or immersion in liquid leading to death or morbidity (Bierens, 2006). In 2015, an estimated 360,000 people drowned. More than half of all drownings occurred in the Southeast Asia and Western Pacific regions, and drowning rates in LMICs are more than three times higher than those in high-income countries (WHO, 2014a). Furthermore, more than half of all drowning deaths are among those younger than 25 years, with this type of event being ranked in the top 10 causes of death in most regions (**FIGURE 9-4**). It is important to note that these data include only "accidental drowning and submersion"; they exclude drowning due to floods (cataclysms), boating, and water transport.

TABLE 9-4 Road Traffic Deaths by Type of Road User, by WHO Region, 2013

Region/Area	Cyclists (%)	Pedestrians (%)	Motorized Two- or Three-Wheelers (%)	Car Occupants (%)	Other (%)

Intentional Injuries

In 2015, almost 1.5 million deaths occurred due to violence, which equals 2.5% of the global mortality burden. Most of these deaths occur in LMICs (86%). Regions where the most violent deaths occurred in 2015 included the Eastern Mediterranean region (30.6 per 100,000), the Americas (28.3 per 100,000), and the African region (20.7 per 100,000). The high rate in the Eastern Mediterranean region was mainly driven by the large number of deaths related to the conflict in Syria. Suicide kills more than 788,089 people annually, which makes it the 17th leading cause of death worldwide. Interpersonal violence accounts for more than 467,619 deaths annually, affecting young men in particular (**TABLE 9-5**). Such violence is highly concentrated in terms of geographic area, and in some countries it is the leading cause of death in young people. Collective violence is responsible for 156,271 deaths annually, with approximately one-third of these deaths being due to interpersonal violence. Beyond deaths, violence causes significant impacts on disability and quality of life.

Self-directed violence caused the deaths of more than 788,000 people globally in 2015 and was associated with more than 37 million DALYs lost. These injuries include suicides, attempted suicides, self-destructive behaviors, and self-mutilation. Although data on self-directed injuries are challenging to obtain, case studies from several parts of the world indicate that they are being increasingly documented globally (**EXHIBIT 9-1**). *Preventing Suicide: A Global Imperative* (WHO, 2014b), the first global report on suicide of this kind, calls for more investments in data collection

TABLE 9-5 Intentional Injuries by Sex, 2015

	Both Sexes	Males	Females
Intentional injuries	1,411,979	997,018	414,961
Self-harm	788,089	504,216	283,873
Interpersonal violence	467,619	380,347	87,272
Collective violence and legal intervention	156,271	112,455	43,816

EXHIBIT 9-1 Suicides in South Asia: Case Study from Pakistan

No official data on suicides are collected in Pakistan, a conservative South Asian Islamic country with traditionally low suicide rates. As a result, national rates of suicide are neither known nor reported to WHO. Nevertheless, an accumulating body of anecdotal evidence suggests that suicide rates have been gradually increasing in Pakistan over the past few years. To date, both suicide and attempted suicide have been under-studied and under-researched subjects in this country. A general lack of trained mental health researchers in the country is partly to blame for this situation. Furthermore, a lack of interest by available researchers may be related to the generally held belief that suicide and attempted suicide are rare events in Muslim countries and, therefore, unworthy of scientific study. Other reasons behind the paucity of data may be the difficulty in gaining access to such data, as there are many legal, social, and cultural issues related to suicide and attempted suicide. Both suicide and attempted suicide are illegal acts, socially and religiously condemned, making research in this area difficult.

Police data from Sindh—one of the four provinces of Pakistan—provide a unique historical picture of trends of suicide over a 15-year span (1985–1999). During this period, there were 2,568 reported suicides (71% men, 39% women; ratio 1.8:1.00). The lowest number was 90 in 1987, and the highest number was 360 in 1999. Poisoning by organophosphates was the most common method of suicide, followed by hanging.

A more recent review of 23 studies found young age, male gender, marriage, and low socioeconomic status to be reported risk factors for suicides. These data, although limited in scope, provide evidence of an important public health issue of suicides in Pakistan. Firearms, hanging, and organophosphorus poisoning were the most common methods of suicide. There is urgent need for further research on suicide in countries like Pakistan, so that interventions for suicide prevention can then be planned.

on self-harm, while at the same time scaling up interventions to prevent suicide.

Interpersonal violence disproportionately affected LMICs, where more than 90% of all interpersonal violence-related deaths were estimated to have occurred. The estimated rate of violent death in LMICs was 7.1 per 100,000 population in 2015, compared to 2.6 per 100,000 population in high-income countries.

The extent of *child maltreatment* is difficult to gauge because most of this abuse goes unreported. Nevertheless, child maltreatment is a global problem with serious lifelong consequences for many of its victims. In studies of self-reported child maltreatment (Stoltenborgh, van Ijzendoorn, Euser, & Bakermans-Kranenburg, 2011; Euser et al., 2015), the data reveal that 76/1,000 boys and 180/1,000 girls experienced sexual abuse, 226/1,000 children reported physical abuse, and 363/1,000 children reported emotional abuse; 163/1,000 children reported physical neglect, and 184/1,000 children endured emotional neglect. In 2015, almost 31,000 children younger than 15 years died from homicide, although this number probably underestimates the true extent of the problem. A significant proportion of deaths due to child maltreatment are missed because the maltreatment is not apparent to medical practitioners—that is, these deaths appear to be a result of unintentional injuries such as falls or burning. In conflict and refugee

settings, girls and boys may be at particular risk of sexual violence, exploitation, and abuse by combatants, security forces, members of their communities, aid workers, and others.

Youth violence is defined as violence committed by or against individuals between the ages of 10 and 29 years. In 2012, an estimated 205,303 youth homicides took place globally—equivalent to 562 children and young people age 10 to 29 years being killed every day. Youth homicide rates vary dramatically between countries. In some countries of Latin America, the Caribbean, and sub-Saharan Africa, youth homicide rates are 100 or more times higher than the rates in Western Europe and the Western Pacific (WHO, 2015b). In all countries, young males are both the main perpetrators and the main victims of homicide, and female rates of youth homicide are almost everywhere much lower than male rates. For every young person killed by violence, an estimated 20 to 40 more sustain injuries that require hospital treatment (Mercy, Butchart, Farrington, & Cerda, 2002).

Physical fighting and bullying are also common among young people. A global analysis of data from the Global School-Based Student Health Survey found that depending on the region, between 31.4% and 46.7% of adolescents age 13 to 15 have been involved in physical fighting in the past year. Between 2.1% and 5.1% of adolescents report they engaged in frequent physical fighting (more than 12 times) in the past year (WHO, 2015b).

A study of bullying in school-age children in 40 countries (mainly in Europe) found that exposure to bullying varies across countries, with estimated exposure rates ranging from 8.6% to 45.2% among boys, and from 4.8% to 35.8% among girls. Adolescents in Baltic countries reported higher rates of bullying and victimization, whereas their peers in northern European countries reported the lowest prevalence. Boys reported higher rates of bullying in all countries. Rates of victimization were higher for girls in 29 of 40 countries (Craig et al., 2009).

Intimate-partner violence is defined as "any behavior within an intimate relationship that causes physical, psychological or sexual harm to those in the relationship." Such behaviors include "acts of physical aggression—such as slapping, hitting, kicking, and beating; psychological abuse—such as intimidation, constant belittlement, and humiliation; forced intercourse and other forms of sexual coercion; and various controlling behaviors—such as isolating a person from their family and friends, monitoring their movements, and restricting their access to information or assistance" (Heise & García-Moreno, 2002; García-Moreno, Jansen, Ellsberg, Heise, & Watts, 2005). Globally, according to population-based self-report surveys, 30% of ever-partnered women have experienced intimate-partner violence at least once in their life (García-Moreno et al., 2013), and women often become victims of intimate-partner violence repeatedly. The highest prevalence of such violence appears to occur in the WHO African, Eastern Mediterranean, and Southeast Asian regions, where approximately 37% of women have reported they were exposed to intimate-partner violence at some point in their lives.

Sexual violence includes rape (by either an intimate partner or a stranger), attempted rape, gang rape, and other forms of forced sexual acts in any setting (e.g., home, work). Globally, 30% of women have been exposed to intimate-partner violence including sexual violence at least once in their lifetime. Physical and sexual violence by intimate partners overlap to a large extent, and surveys often do not distinguish between physical intimate-partner violence and sexual intimate-partner violence. Global prevalence estimates indicate that 7.2% of women have experienced sexual violence by someone other than their intimate partner (García-Moreno et al., 2013).

Abuse of the elderly includes physical, sexual, emotional, and psychological acts or neglect directed toward older people. It is an important type of violence, especially given the prediction that the global population of persons older than 65 years of age will reach more than 1 billion in the first half of the 21st century (Wolf, Daichman, & Bennett, 2002). More than 80% of these older people will reside in LMICs, where they will represent more than 12% of the population. Abuse of the elderly occurs in both home and institutional settings and is difficult to measure; thus, there is a persistent lack of global statistics on this issue. Globally, 15.7% of older people have experienced abuse: 11.6% of older people reported they experienced psychological abuse, 6.8% reported financial abuse, 4.2% reported they had been a victim of neglect, 2.6% had experienced physical abuse, and 0.9% of older people experienced sexual abuse (Yon, Mikton, Gassoumis, & Wilber, 2017).

Collective violence—including armed conflict with and between states—was estimated by WHO to cause more than 156,271 deaths worldwide in 2015. Men are more than two and a half times more likely to die from collective violence as compared to women. This estimate includes only deaths caused directly by war; it does not include deaths caused indirectly by war, such as those that result from disruption of the health system or those that occur after the end of war.

Estimates of the Economic and Social Costs of Injury and Violence

Loss of life and health is just one dimension in explaining why injuries and violence are an important public health problem. Other important dimensions include these conditions' social and economic toll on individuals, families, and societies. Death of loved ones, lifelong disabilities resulting in unemployment, and the staggering costs of medical care for victims are some of the other effects of injuries and violence that need to be described. In addition, factors such as lost productivity, insurance claims, income-replacement activities, and family consequences are important. Unfortunately, such information is not readily available and is rarely collected in large parts of the world; as a consequence, our knowledge of the economic and social impacts of injuries and violence remains limited. This section, while not presenting a comprehensive review of the economic and social costs of all injuries and violence, provides examples of the breadth and—importantly—the limitations of what has been documented for a few specific injuries.

Costs associated with *unintentional injuries* have been studied in some high-income countries. In one study of unintentional injuries that occurred in home settings in the United States, the total societal cost was estimated at $217 billion; falls accounted for the largest proportion (42%) of this cost (Zaloshnja, Miller, Lawrence, & Romano, 2005). In another study, focusing on childhood unintentional injuries, the total cost, which included loss of future work and quality of life, was $347 billion per year, or $17,000 per child injured (Danseco, Miller, & Spicer, 2000).

A few cost-focused studies have addressed unintentional child injuries in LMICs. For example, analysis of more than 6,000 children younger than 15 years of age who were hospitalized for unintentional injuries in China showed a mean institutional cost of $166 and a mean length of stay exceeding 17 days per injury case (Jiang et al., 2010). Further, the cost associated with poisoning averaged $53 per case; for scald burns, this cost was $198 per case. A community-level analysis in Vietnam showed that the total annual cost of unintentional child injuries was more than $235,000—equivalent to the income of nearly 1,800 people in the country (Thanh, Hang, Chuc, & Lindholm, 2003) (**EXHIBIT 9-2**).

Despite the global significance of *road traffic injuries* in terms of mortality and disability, the economic and social consequences of such injuries have been documented only in the past decade, and most countries in the world report not having undertaken costing exercises (WHO, 2009). Work performed by Transport Research Laboratory (TRL), based on road crash costs from 21 high-income and LMICs, found that the average annual cost of road crashes was approximately 1% of the gross national product (GNP) in LMICs, 1.5% of GNP in countries in economic transition, and 2% in highly motorized countries. Based on these data, the researchers suggested that the annual burden of the economic costs of road traffic injuries globally

EXHIBIT 9-2 Impact of Helmet Laws in Vietnam

On December 15, 2007, a new law mandating the use of helmets among motorcycle riders and passengers took effect in Vietnam. Strong enforcement and severe financial penalties, accompanied by public education through media campaigns including print, radio, and television, were established to support the law. As a result of these efforts, the helmet-wearing rate increased from 30% to 93% (Nguyen et al., 2013) and remained greater than 90% for both riders and passengers even one year after passage of the law (Pervin et al., 2009).

The increased helmet usage resulted in an 18% reduction in the risk of death and a 16% reduction in the risk of head injury among motorcyclists in the country (Passmore et al., 2010). It also saved individuals approximately $18 million in direct acute care costs and averted $29 million in individual income losses in the year following the introduction of the law. The combination of benefits suggests that similar policy changes could be beneficial in countries with high motorized two-wheeler usage but where helmet-wearing rates are low (Olson et al., 2016).

amounted to $518 billion in 2000, with the annual costs of road traffic injury in LMICs being approximately $65 billion, exceeding the total annual amount received by these countries in development assistance at that time (Jacobs, Aeron-Thomas, & Astrop, 2000). These data have more recently been reviewed by the World Bank and the global estimate lost to road traffic deaths and injuries is now estimated to be approximately 3% of gross domestic product (GDP) (Dahdah & McMahon, 2008).

Further work has attempted to document and compare the impact of road traffic injuries on low-income households in Bangladesh and India (Aeron-Thomas, Jacobs, Sexton, Gururaj, & Rahmann, 2004; Prinja, Jagnoor, Chauhan, Aggarwal, & Ivers, 2015). In both of these countries, males who provided the majority of the household income were the most common victims of road traffic fatalities; their deaths reduced household income and food consumption for the victim's family. The poor were also found to spend a much greater proportion of their income on funeral and/or medical costs compared to the nonpoor; as a consequence, road traffic injury was a contributor in tipping households into poverty.

Interpersonal violence is expensive. Estimates of the cost of violence in the United States put this figure at 3.3% of GDP. In England and Wales, the total costs from violence—including homicide, wounding, and sexual assault—amount to an estimated $40.2 billion annually. Although interpersonal violence disproportionately affects LMICs, studies addressing the economic effects of this violence in LMICs remain scarce (Waters, Hyder, Rajkotia, et al., 2004). Estimates from LMICs indicate that the overall costs of violence are substantial (**EXHIBIT 9-3**).

Comparisons with high-income countries are complicated by the fact that economic losses related to productivity tend to be undervalued in lower-income countries because these losses are typically based on foregone wages and income. For example, a single *homicide* is calculated to cost, on average, $15,319 in South Africa, $602,000 in Australia, $829,000 in New Zealand, and more than $2 million in the United States (all monetary values have been converted to 2001 U.S. dollars to enable comparisons and to adjust for inflation and varying exchange rates).

Many of the studies detailing the costs of specific types of violence have been conducted in the United States. The economic burden due to newly identified cases of child maltreatment in one year was estimated at $124 billion (Fang et al., 2012). If other types of violence were included, this number would rise further. A costing study from East Asia and the Pacific estimated the associated treatment costs to mitigate negative health consequences of child maltreatment at 1.4% to 2.5% of the GDP of this region (Fang et al., 2015).

Evidence abounds that the public sector—and thus society in general—picks up much of the tab for interpersonal violence. Several studies in the United States have shown that 56% to 80% of the costs of caring for victims of gunshot and stabbing injuries are either directly paid by public financing or not paid at all; in the latter case, the costs are absorbed by government and society in the form of uncompensated care financing and overall higher payment rates. In LMICs, it is also probable that society absorbs much of the costs of violence, through direct public expenditures and negative effects on investment and economic growth.

EXHIBIT 9-3 Estimating the Economic Costs of Violence

In 2008, WHO, the U.S. Centers for Disease Control and Prevention, and the Small Arms Survey developed economic costing guidelines to assess the direct and indirect economic burden of interpersonal and self-directed violence (Butchart et al., 2008). These guidelines were subsequently tested to assess the costs of fatal and nonfatal interpersonal and self-directed violence in Brazil, Jamaica, and Thailand. In Brazil during 2004, the direct medical cost of injuries due to violence (R$519 million or ~$152 million) amounted to 0.4% of the total health budget, while loss of productivity due to violence-related injuries (R$15.5 billion or ~$4.54 billion) accounted for approximately 12% of all health expenditures, or 1.2% of GDP. In Jamaica, the direct medical costs of interpersonal violence in 2006 totaled J$2.1 billion (~$16.9 million)—the vast majority of which was concentrated among young males. Indirect medical costs were 10 times higher, exceeding J$27.5 billion (~$222 million). Direct medical costs accounted for approximately 160% of Jamaica's total health expenditure, while the combined direct and indirect impacts were equivalent to 4% of GDP. In Thailand for 2005, the direct medical cost of violence-related injuries accounted for approximately 4% of that country's total health budget, while the loss of productivity due to violence-related injuries accounted for approximately 0.4% of GDP.

Source: Butchart, A., Brown., D., Khanh-Huynh, A., Corso, P., Florquin, N., & Muggah, R. (2008). *Manual for estimating the economic costs of injuries due to interpersonal and self-directed violence*. Geneva, Switzerland: World Health Organization.

Studies documenting the economic effects of interpersonal violence have used a broad range of categories to distinguish the various types of costs associated with this condition. Those estimating indirect costs—including the opportunity cost of time, lost productivity, and reduced quality of life—provide higher cost estimates than studies that limit the costs of violence to direct costs alone. Other key methodological issues include the economic values assigned to human life, lost productive time, and psychological distress. The rates at which future costs and benefits are discounted, in accounting terms, also vary across studies.

Risk Factors for Unintentional Injuries and Violence

As with most diseases, the causes of unintentional injuries and violence are considered to be multifactorial. The traditional epidemiologic paradigm of host (including biological and behavioral), vector, and environmental factors, which in combination contribute to the incidence of disease, has been readily adapted and applied in determining the causes of unintentional injury. This paradigm has been extended, however, to consider each factor in relation to the timing of the injury occurrence—that is, factors operating prior to, during, and following the injury that might be associated with both the incidence and the severity of the injury (Haddon, 1968). In determining the causes of violence, especially interpersonal violence, a somewhat different model (described as an ecological model), has more commonly been utilized, which focuses on the interplay between individual, relationship, community, and societal factors (Krug et al., 2002).

In the past few decades, the evidence base identifying risk factors for unintentional injuries and violence has expanded dramatically, as the numbers of both injury researchers and research institutions have increased. The application of public health research methods, commonly used in identifying risk factors for other causes of death and disability, to the problems of unintentional injuries and violence has undoubtedly contributed to the growth in this knowledge. For example, case-control and cohort studies now likely contribute as much to the evidence base in the injury field as they do for other leading causes of death and disability, such as cancer and heart disease.

Most of this research has been undertaken in high-income countries, in large part because of the preponderance of researchers and research institutions in these areas. Nevertheless, the evidence base identifying risk factors for unintentional injuries and violence in LMICs is growing, along with the recognition that certain types of injuries and forms of violence are unique to these countries. Thus, while some risk factors may be common across a wide range of settings (e.g., alcohol misuse), other risk factors are unique to the environments in which they occur (e.g., the significance of water wells in increasing the risks of drowning in LMICs, or the specificity of suicide by self-immolation among women in some Asian societies).

This section summarizes known and potential risk factors for the leading cause-specific injuries. The discussion here highlights the extent to which knowledge has been obtained exclusively in high-income countries, the extent to which this knowledge might be transferred to LMICs, and the areas where the evidence base is still minimal.

Risk Factors for Road Traffic Injuries

Not surprisingly, given the significant burden of road traffic injuries, much is known about risk factors for such injuries, as outlined in detail in *World Report on Road Traffic Injury Prevention* (Peden et al., 2004) and updated most recently in the 2015 *Global Status Report on Road Safety* (WHO, 2015a). The 2004 world report describes road traffic injury risk in terms of four functions: factors affecting exposure to risk, factors influencing crash involvement, factors influencing crash injury severity, and factors influencing the severity of post-crash injuries

Factors Influencing Exposure to Risk

Increasing motorization is, without doubt, one of the main factors contributing to the increase in road traffic injuries worldwide and especially in LMICs. Motorization rates rise with income (Kopits & Cropper, 2003). Thus, in a growing number of LMICs whose economies are experiencing growth, there has been a corresponding increase in the number of motor vehicles used in those countries. Growth rates for vehicle ownership are highest in the world's emerging economies: In 2016, there were a record 72 million new passenger cars on the world's roads and around half of these were produced in middle-income countries (Organization of Motor Vehicle Manufacturers, 2016).

Unfortunately, in some LMICs, traffic growth has included proliferation of less safe forms of travel (i.e., powered two-wheeled vehicles and rickshaws and other three-wheeled auto-rickshaws), resulting in concurrent increases in related injuries (OECD, 2015; WHO, 2015a, 2017a). This growth in powered two-wheeled vehicles is not unique to LMICs, however:

High-income countries are adopting these vehicles in larger numbers as they try to find solutions to the problems of growing traffic congestion. In London, for example, due to the increased use of such vehicles, deaths and injuries among motorized two-wheeler users are increasing (Transport for London, 2016).

Projected demographic changes in high-income countries over the next 20 to 30 years are likely to result in greater numbers of people older than 65 years being exposed to traffic risks and, given their greater physical vulnerability, greater numbers sustaining injury. By comparison, in LMICs, increasing economic growth is fueling both the aspirations of younger people to drive motor vehicles and the need to travel greater distances to work. As a consequence, in many LMICs, this vulnerable road user group will continue to be the predominant population involved in road crashes. In fact, road traffic injuries have been identified as the leading cause of death among adolescents (Sheehan et al., 2017; WHO, 2017b).

Transport, land use, and road network planning have all been shown to be important in determining exposure to injury risk. While many of the technical aspects of planning, highway design, traffic engineering, and traffic management have been the hallmarks of transport systems, such planning systems are frequently absent in LMICs, as evidenced by the fact that only 31 countries surveyed for the global status report had a fully funded national road safety strategy (WHO, 2015a). The necessity for such planning is probably even greater in LMICs than in high-income countries, given the extremely diverse and multiple modes of traffic (both motorized and nonmotorized) seen in the former countries.

Factors Influencing Crash Involvement

The overwhelming influences of speed and alcohol consumption on the risk of crash involvement have been confirmed primarily in studies undertaken in high-income countries, but also in an increasing number of studies undertaken in LMICs. A number of other host-related factors, as outlined in this section, have also been postulated as increasing the risk of crash involvement, although evidence to support their involvement remains limited and is mostly restricted to studies undertaken in high-income countries.

Very good evidence from high-income countries shows a strong relationship between increasing vehicle speeds and increasing risk of crash, both for motor vehicle occupants and for vulnerable road users, particularly pedestrians (Global Road Safety Partnership, 2008; WHO, 2017c, 2017d). This relationship is likely to hold true in LMICs as well. Indeed, data obtained from routinely collected police reports (Sobngwi-Tambekou, Bhatti, Kounga, Salmi, & Lagarde, 2010; Zhao et al., 2009), observational studies (Bachani et al., 2017), and case-control studies (Donroe, Tincopa, Gilman, Brugge, & Moore, 2008) in a number of LMICs show that speed is a leading causal factor in road traffic crashes.

The observation that alcohol is associated with an increased risk of road crashes has been confirmed in many studies of victims and perpetrators conducted both in high-income countries and in LMICs (Global Road Safety Partnership, 2007; Peden et al., 2004). In particular, a survey of studies conducted in LMICs found that alcohol was present in the blood of between 4% and 69% of injured drivers, 18% to 90% of crash-injured pedestrians, and 10% to 28% of injured motorcyclists (Global Road Safety Partnership, 2007). These findings are reinforced by case-control and case cross-over studies that provide clear evidence of alcohol's association with increased rates of road traffic injuries (Odero & Zwi, 1997; Woratanarat et al., 2009).

Other factors that have been shown to increase the risks of road crashes in a number of high-income countries include fatigue, use of hand-held mobile telephones (WHO, 2011), use of illicit drugs (WHO, 2016a), and inadequate visibility of vulnerable road users (Peden et al., 2004); these factors are equally likely to increase these risks in a number of LMICs. Indeed, studies in China show twofold increased risks of car crash associated with driver chronic sleepiness (Liu et al., 2003). In addition, surveys of commercial and public road transport in a number of African countries have shown that drivers often work unduly long hours and go to work when exhausted (Nafukho & Khayesi, 2002), consistent with the overall evidence on the relationship between fatigue and work-related traffic crashes (Robb, Sultana, Ameratunga, & Jackson, 2008).

Clearly, road-related and vehicle-related risk factors may increase the risk of crash involvement. Specific factors related to road planning that have been suggested as risk factors for crashes include through-traffic passing through residential areas, conflicts between pedestrians and vehicles near schools located on busy roads, lack of segregation of pedestrians and high-speed traffic, lack of median barriers to prevent dangerous overtaking on single-carriage roads, and lack of barriers to prevent pedestrian access onto high-speed roads. Studies examining the risks associated with each of these factors are sorely lacking, especially in LMICs, but recent surveys conducted by the International Road Assessment Programme (iRAP, 2015) have revealed that affordable road improvements, such as footpaths, safety barriers, bicycles lanes, and paved shoulders, if applied at

a large scale, could prevent tens of millions of deaths and serious injuries. Although vehicle-related factors clearly have the potential to increase risks of injury, over the last 50 years substantial safety improvements have been made, particularly by vehicles produced in Europe, Japan, and the United States. Even so, 40 countries around the world implement only minimum regulatory standards (WHO, 2015a)—most in emerging markets. The lack of effective vehicle standards contributes to the higher rates of collisions in these countries (Jacobs et al., 2000).

Factors Influencing Injury Severity

In-vehicle crash protection is undoubtedly a factor relating to crash injury severity. While significant improvements have been made to private vehicles in the past decades, many of these advances have not yet made their way into vehicles in LMICs (Odero, Garner, & Zwi, 1997) or are de-specified to keep vehicle costs low. However, the issue of crash protection that reduces injury severity to vulnerable road users is probably of greater relevance, especially in LMICs, where vulnerable road users are predominant. Few countries, whether high- or low-income countries, have established requirements to protect vulnerable road users by means of crash-worthy designs for the front of cars or buses (Mohan, 2002).

A significant risk factor for increased injury severity among motorized two-wheeler users is non-use or inappropriate use of motorcycle helmets (Liu et al., 2008; WHO, 2017a). Likewise, a risk factor for increased injury severity in bicyclists is non-use of helmets (Thompson, Rivara, & Thompson, 2003). Failure to use seat belts is also a significant risk factor associated with injury severity in vehicle occupants, especially in many LMICs that lack any requirement for seat belts to be present in vehicles or used by drivers and passengers (FIA Foundation for the Automobile and Society, 2009; WHO, 2015a).

Studies in high-income countries suggest that roadside hazards, such as trees, poles, and road signs, may contribute to between 18% and 42% of road crash fatalities (Kloeden, McLean, Baldock, & Cockington, 1998). The extent to which this risk applies to LMICs has not been determined.

Factors Influencing Severity of Post-Crash Injuries

Both the availability and the quality of prehospital and in-hospital care are major influences on the outcomes for patients with injuries sustained in a traffic crash. Comparisons between high-income countries and LMICs show clear differences in the proportions of injured individuals who die before reaching a hospital, in large part reflecting the limited access to prehospital medical services in LMICs (Mock, Jurkovich, nii-Amon-Kotei, Arreola-Risa, & Maier, 1998). Factors that determine survival and outcome include early availability of care, the time interval between the injury and the patient's arrival at a definitive-care hospital, referral based on triage, and availability of physical and human resources.

Risk Factors for Poisonings

The global literature on unintentional poisonings includes significant information on occupational-related poisonings, especially pesticide poisonings, and a growing body of information on environmental poisoning, especially lead poisoning. The particular focus of this section, however, is on risk factors for other unintentional poisonings; occupational and environmental poisoning are covered elsewhere in this text under the topic of environmental health.

The literature in this area almost exclusively considers risk factors for poisonings in young children (Peden et al., 2008), even though the majority of poisonings occur in adults, for whom therapeutic errors and adverse reactions to medications may well be significant issues. In high-income countries, product accessibility—in terms of both safe packaging and storage—has long been recognized as the key risk factor in unintentional poisoning (Peden et al., 2008; Shannon, 2000). Storage issues also appear to be risk factors for poisoning in LMICs, including the numbers of used storage containers in the residence, the use of nonstandard containers for storage (e.g., the use of cola bottles for the storage of kerosene), and the storage of poisons at ground level (Peden et al., 2008).

As highlighted in the *World Report on Child Injury Prevention* (Peden et al., 2008), several case-control studies conducted in LMICs show evidence of a number of sociodemographic risk factors for unintentional poisoning, including young age of parents, residential mobility, and limited adult supervision of children (Azizi, Zulkifli, & Kasim, 1993; Soori, 2001). Previous poisoning may also be a risk factor (Soori, 2001).

Risk Factors for Fall-Related Injuries

Fall-Related Injuries in Older People (Including Hip Fractures)

Risk factors for fall-related injuries in older people are generally considered in terms of risk factors for falling (both intrinsic and extrinsic risk factors), risk factors associated with the severity of the impact following the fall, and risk factors associated with low levels of

bone mineral density, insofar as almost all fall-related injuries in older people involve broken bones. The last group of risk factors include low bone density; poor nutritional status and low body mass index (BMI); low calcium intake; comorbid conditions, such as hypertension and diabetes; poor performance in activities of daily living (ADLs and instrumental ADLs [IADLs]); low levels of engagement in physical activity; poor cognitive function; poor perceived health status; poor vision; environmental factors affecting balance or gait; family history of hip fracture; and alcohol consumption (Hippisley-Cox & Coupland, 2009; Robbins et al., 2007). Falls from beds as well as other environmental risk factors related to flooring, lighting, furniture, and fittings such as hand rails are also associated risks (Ambrose, Paul, & Hausdorff, 2013; Lord, Sherrington, Menz, & Close, 2007).

While much of the research in this area has been undertaken in high-income countries, reports from LMICs show that these studies' findings are consistent across most countries (Chew, Yong, Mas Ayu, & Tajunisah, 2010; Coutinho, Bloch, & Rodrigues, 2009). A few studies, however, have identified other factors that have not previously been identified and may be more relevant in the context of LMICs. For example, studies in Thailand have suggested that factors associated with poor socioeconomic status may be risk factors, such as lack of electricity in the house and living in Thai-style houses or huts (Jitapunkul, Yuktananandana, & Parkpian, 2001).

Falls related to the construction industry and on farms are generally more prevalent among working-age adults in low- and middle-income settings (Dandona et al., 2010; Haslam et al., 2005).

Fall-Related Injuries in Younger People

The *World Report on Child Injury Prevention* (Peden et al., 2008) has systematically reviewed the available evidence on risk factors for fall-related injuries in younger people. Much of the research has sought to identify factors associated with falls from heights. In high-income countries, such falls occur from balconies and apartment windows, beds/bunks and nursery equipment (including baby walkers), and playground equipment. In contrast, in LMICs, such falls are more likely to occur from rooftops, trees, and animals, such as in those countries where camel racing is a popular activity. Poverty appears to be a consistent underlying risk factor for falls, while the absence of protective rails/guards or similar equipment is associated with increased risk. Severity of injury appears to be associated with the height of the fall and the nature of the surface on which the child falls.

Risk Factors for Burn-Related Injuries

Burn-related injuries sustained as a result of fires account for the majority of burn-related deaths, although hot water burns are a significant cause of morbidity, especially in LMICs.

In high-income countries, much of our knowledge about risk factors for fire-related injuries has come from cross-sectional studies and only a few case-control studies. In these studies, a number of risk factors have been consistently identified. Risk factors that cannot be modified include age (both younger and older groups), gender, race, or those difficult to modify such as poverty and disability; in contrast, risk factors that are amenable to prevention include place of residence, type of residence (such as mobile homes and homes without a smoke detector or telephone), smoking, and alcohol use as well as unsafe equipment, fireworks, and cooking areas (Peden et al., 2008; Warda, Tenenbein, & Moffatt, 1999). By comparison, few controlled studies have examined risk factors for hot water burns, and most discussion in the literature focuses on the lack of temperature controls for hot water systems or taps (Jaye, Simpson, & Langley, 2001).

Studies undertaken in LMICs have similarly mostly focused on risk factors for burn-related injuries, with few examining risk factors for hot water–related injuries. In the majority of cases, these studies have addressed risk factors for burns in children (Peden et al., 2008). Many of the identified risk factors are related to poverty, such as low family income, lack of water supply, and overcrowding. Lack of parental supervision and history of burns in siblings are risk factors as well. By comparison, maternal education appears to be consistently protective. Not surprisingly, other protective factors relate to the knowledge about burn risks, presence of smoke detectors, and ready access to first aid services.

Risk Factors for Drowning

In high-income countries, the majority of drowning incidents are associated with recreation or leisure activities including swimming pools (Brenner, 2003). In contrast, in most LMICs, these events are associated with everyday activities near bodies of water, including rivers, water wells, or buckets (Hyder, et al., 2003; Kobusingye, Guwatudde, & Lett, 2001; WHO, 2014a).

Only a few studies, in either high- or low-income countries, have examined risk factors for drowning in adults. Nevertheless, evidence consistently shows that a significant proportion of adult drowning incidents are associated with positive blood alcohol levels

(Carlini-Cotrim & da Matta Chasin, 2000; Driscoll, Harrison, & Steenkamp, 2004) as well as flood disasters and traveling on water (WHO, 2014a, 2017e).

Most studies in this area—although there have been few properly controlled studies—have focused on risk factors for drowning in children, as reported in *World Report on Child Injury Prevention* (Peden et al., 2008) and the *Global Report on Drowning* (WHO, 2014a). Children living in rural areas and close to uncovered or unprotected bodies of water appear to be at greatest risk, with lack of parental supervision being noted as a factor across most studies.

Risk Factors for Self-Directed Violence

The report *Preventing Suicide: A Global Imperative* (WHO, 2014b) provides a comprehensive overview of known risk factors for suicidal behavior based on the findings of an extensive body of research, primarily in high-income countries, that has examined the role of psychiatric, biological, social, and environmental factors as well as factors related to an individual's life history.

Case-control studies, using psychological autopsies (i.e., information gathered after death from relatives, healthcare professionals, and medical records), have played an important role in identifying psychiatric risk factors for suicide, as have longitudinal studies. Depression is perhaps the leading psychiatric condition associated with increased risk of suicidal behaviors. Given that this type of mental illness is relatively common, it is not surprising that a large proportion of all suicides are believed to be related to depression. Other conditions associated with increased risk for self-directed violence include schizophrenia, anxiety disorders of conduct and personality, impulsivity, and a sense of hopelessness. Alcohol and drug abuse also play significant roles, although the close relationship between the latter and depression makes it difficult to tease out the independent contributions of these conditions. Most certainly, another important risk factor is previous suicidal attempt, with some studies suggesting that the risk for persons who have attempted suicide in the past could be as high as 20 to 30 times the risk seen in the general population.

Among the biological and medical markers that have been identified as risk factors, family history of suicide is one of the strongest markers, suggesting the possibility of a genetic predisposition; this contention has been supported by twin studies. Other evidence in support of a biological basis for suicide comes from studies of neurobiological processes, particularly those that have examined serotonin levels in psychiatric patients. Such investigations suggest that altered serotonin levels may, in part, be linked to greater risks of suicide. Suicide may also be the consequence of severe and painful illness, although the extent to which any such relationship is independent of psychiatric illness has not been determined as yet.

Certain negative life events may act as precipitating factors for suicide for some individuals, including personal loss (whether through divorce, separation, or death), interpersonal conflict (including bullying), a broken or disturbed relationship, and legal or work-related problems. In particular, studies have shown a higher risk of suicide attempts among victims of violence between intimate partners due to unresolved conflicts, as well as among individuals with a history of physical or sexual abuse in childhood. While in many countries, marriage and having children do appear to be protective factors against suicide, those who marry early may not be equally protected. Studies undertaken in Pakistan and China also suggest that married women, especially older married women, may not necessarily be protected from this risk (Khan & Reza, 1998; Yip, 1998). In contrast, individuals who are socially isolated appear to be at increased risk for suicide, including homosexual adolescents and the elderly.

Social and environmental factors that are believed to increase the risk of suicidal behavior include availability of the means of suicide; a person's place of residence, employment, or immigration status; affiliation with a religion; and economic conditions. Numerous studies, undertaken in a wide range of countries, provide clear evidence that both the ready availability of means of suicide and the lethality of those methods influence the incidence of suicide attempts and completions. Likewise, studies conducted in high-, middle-, and low-income countries show that rural residence is an important risk factor for suicide, possibly related to issues of social isolation and increased accessibility of means of suicide. While some exceptions exist, there does appear to be a consistent relationship between greater religious involvement and lower risk of suicide. Both the economic prosperity of a community and personal economic circumstances appear to be related to risk of suicide, as observed in various studies.

Risk Factors for Interpersonal Violence

The quantity and nature of research on the risk factors for interpersonal violence vary across the categories of child maltreatment, intimate-partner violence, youth violence, sexual violence, and elder abuse, as does the extent to which the research has focused on risk factors associated with perpetrators versus risk factors associated with victims.

While certain risk factors are specific to these different types of interpersonal-directed violence and to perpetrators or victims, a number of common risk factors have been observed across at least three of these different categories and, to some extent, in both high-income and LMICs. In terms of individual risk factors, these characteristics include being male and young, abusing alcohol and other drugs, and being a victim of child abuse or neglect. Family risk factors include low socioeconomic status of the household, marital discord, and parental conflict involving use of violence. Community risk factors include low social capital in the community, high crime levels in the community of residence, and poor access to or inadequate medical care and situational factors. Lastly, societal risk factors include rapid social change (leading to the breakdown of traditional value and social support networks), economic inequality, poverty, weak economic safety nets, poor rule of law and high levels of corruption, a culture of violence, gender inequalities, high firearms availability, and punitive responses to perpetrators and conflict/post-conflict scenarios (Butchart, Phinney, Check, & Villaveces, 2004; Mercy, Butchart, Rosenberg, Dahlberg, & Harvey, 2008; Rosenberg, Butchart, Mercy, Narasimhan, & Waters, 2006).

A number of risk factors for *child maltreatment* have been identified through research in various countries, but not all areas of the world; thus, one cannot assume that they apply to all social and cultural contexts. Nevertheless, the list presented here does provide an overview of risk factors that should be considered when attempting to understand the causes of child maltreatment in any context (WHO & International Society for Prevention of Child Abuse and Neglect, 2006). Child maltreatment risk factors include characteristics and attributes of the child, and of the parent and caregiver. Of course, while they may have risk factors, children themselves are the victims and are never to blame for the maltreatment. Age is a major risk factor among children who suffer maltreatment. Children younger than 4 years of age are at greatest risk of severe injury and death from maltreatment, but across all forms of child maltreatment combined, adolescents are at greatest risk. Other risk factors in children include being an unwanted infant or failing to fulfill parental expectations; having special needs, crying persistently, or having abnormal physical features; and demonstrating symptoms of mental ill health, or personality or temperament traits that are perceived as problematic.

Parental or caregiver factors that can increase the risk of child maltreatment include difficulty bonding with a newborn or not nurturing the child; having been maltreated as a child; lacking awareness of child development or having unrealistic expectations; inflicting inappropriate, excessive, or violent punishment; lacking self-control when upset or angry; misusing alcohol or drugs, including during pregnancy; involvement in criminal activity; being depressed or exhibiting feelings of low self-esteem or inadequacy; and experiencing financial difficulties. Factors within family, friend, intimate-partner, and peer relationships that may increase the risk of child maltreatment include lack of parent–child attachment; physical, developmental, or mental health problems of a family member; family breakdown or violence; being isolated in the community or lacking a support network; breakdown of support for childrearing from the extended family; and discrimination against the family.

Characteristics of communities and societies that can increase the risk of child maltreatment include gender and social inequality; social, economic, health, and education policies that lead to poor living standards or to socioeconomic inequality or instability; lack of adequate housing or services to support families and institutions; high levels of unemployment or poverty; rapid rates of in- and out-migration to neighborhoods; the easy availability of alcohol or a local drug trade; inadequate policies and programs to prevent child maltreatment, child pornography, child prostitution, and child labor; and social and cultural norms that demand rigid gender roles, support the use of corporal punishment or severe physical punishment of children, and diminish the status of the child in parent–child relationships.

Risk factors associated with *youth violence* exist at the level of the individual, relationship, community, and society (Mercy et al., 2002). Individual-level factors include personality and behavioral traits such as hyperactivity; impulsiveness; poor behavioral control; attention problems; history of early aggressive behavior; early involvement with drugs, alcohol, and tobacco; antisocial beliefs and attitudes; low intelligence; low commitment to school and school failure; residence in a single-parent household; experiencing parental separation or divorce at a young age; and exposure to violence and conflict in the family. Additionally, studies show that drunkenness is an important immediate situational factor that can precipitate youth violence.

Factors within family, friend, intimate-partner, and peer relationships that may increase the risk of youth violence include poor monitoring and supervision of children by parents; harsh, lax, or inconsistent disciplinary practices; a low level of attachment between parents and children; low parental involvement in activities; parental substance abuse or criminality; poor family functioning and a low level of family cohesion; low family income; and witnessing

violence or experiencing abuse as a child. Associating with delinquent peers has also been linked to violence in young people.

At community and societal levels, poor social cohesion within a community has been linked to higher rates of youth violence, as have rapid urbanization and unemployment leading to the social dislocation of young people and the erosion of informal social controls. Gangs and a local supply of guns and drugs represent a potent mixture that increases the likelihood of youth violence. Factors such as extreme and highly visible socioeconomic inequalities, rapid social and demographic changes in the youth population, and urbanization can also increase the risk of youth violence. In addition, the quality of a country's governance—its laws and the extent to which they are enforced, as well as policies for social protection—has important implications for such violence.

Intimate-partner violence and *sexual violence* share a number of common risk factors, as described in the WHO and London School of Hygiene & Tropical Medicine (2010) document titled *Preventing Intimate Partner and Sexual Violence: Taking Action and Generating Evidence*. Women and men with lower levels of education are at increased risk of victimization and perpetration of intimate-partner violence, respectively. Childhood sexual abuse is strongly associated with the perpetration of intimate-partner violence and sexual violence by men as well as the victimization of women in the form of intimate-partner and sexual violence. A diagnosis of antisocial personality disorder is a strong risk factor for the perpetration of both intimate-partner and sexual violence. Alcohol abuse is consistently found to be associated with the perpetration of both types of violence as well. Males who have multiple sexual partners or who are suspected by their partners of infidelity are more likely to initiate both intimate-partner and sexual violence. In addition, attitudes that are accepting of violence are strongly associated with perpetration and victimization in the form of such violence (WHO & London School of Hygiene & Tropical Medicine, 2010).

Risk factors that are specific to intimate-partner violence include a past history of violence, which for both perpetrators and victims is a strong risk factor for future intimate-partner violence. Marital discord and dissatisfaction are strongly associated with both perpetration of and victimization by this kind of violence. Likewise, ineffective court/police responses are associated with intimate-partner violence (WHO & London School of Hygiene & Tropical Medicine, 2010).

Risk factor research on *elder abuse* is scant. Although a variety of risk factors have been hypothesized to exist, the evidence cited to support many of these hypotheses—such as the significance of caregiver stress—is not convincing. One of the most consistent findings, however, is the important role of social isolation. Additionally, while little empirical evidence has been documented to support this contention, cultural norms relating to ageism and sexism are thought to play an important role in elder abuse (Krug et al., 2002).

Risk Factors for Collective Violence

As outlined in greater detail in *World Report on Violence and Health* (Krug et al., 2002), the Carnegie Commission on Preventing Deadly Conflict (Carnegie Commission, 1997) has identified a range of factors that—either alone or in combination—may precipitate the risk of political violence. In brief, these factors include political and economic factors (e.g., lack of democratic processes, unequal access to power, distribution of resources and access to resources, and control over both key natural resources and drug production or trading), societal and community factors (e.g., inequalities between groups, fueling of group fanaticism, and ready availability of weapons), and demographic factors (particularly rapid demographic change).

Interventions to Prevent Unintentional Injuries and Violence

Interventions to prevent unintentional injuries have traditionally been considered in terms of the *three E's*: education, enforcement, and engineering. Such measures are also described within the framework of the Haddon matrix—that is, in terms of their focus on preventing the occurrence of the injury event, versus minimizing the severity of injury at the time of the injury event, versus minimizing the severity of injury following the injury event. By comparison, interventions aimed at reducing violence have addressed individual, relationship, community, and societal approaches, mirroring the ecological model outlined in the previous section.

While randomized controlled trials, whether they involve individuals or communities, represent the gold standard by which the effectiveness of preventive interventions might best be assessed, such trials remain relatively uncommon in the injury and violence field. Studies comparing the incidence of injury before and after the implementation of an intervention, sometimes with reference to a control population (i.e., a group in which the intervention has not been introduced), more commonly provide evidence of

effectiveness. Of course, randomized controlled trials are clearly not needed for interventions whose benefits are obvious. In contrast, for other interventions, particularly those that may have modest but important benefits, rigorous evaluation methods are required.

Studies addressing the effectiveness of interventions in LMICs, as distinct from their effectiveness in high-income countries, are also relatively uncommon. While the proven efficacy of some interventions in high-income countries does not require replication in LMICs (e.g., the use of motorcycle helmets), strategies that may be effective in increasing the rates of helmet-wearing in high-income countries may not necessarily be appropriate in LMICs; thus, specific evidence of their effectiveness is required. For this reason, tailoring of the interventions found effective in high-income countries to ensure that they are appropriate in LMICs, with rigorous evaluation to confirm their applicability, is increasingly being endorsed. Moreover, determining how best to implement programs based on such interventions is increasingly needed and implementation research is often needed in these instances.

Interventions to Prevent Road Traffic Injuries

"Safer systems, safer roads, safer vehicles, and safer people" is the motto employed by those working to reduce road traffic injuries (Peden et al., 2004). In the public health sector, much of the emphasis in terms of interventions has—not surprisingly—focused on the last of these elements (WHO, 2015a). In addition, there is significant political support for road safety. The United Nations General Assembly, the World Health Assembly, and more recently the inclusion of a target related to road safety in the 2030 Agenda for Sustainable Development have all encouraged countries to implement good practices in regard to preventing road traffic injuries. Guidance is provided to countries through the global plan for the Decade of Action, which includes five pillars—road safety management, safer infrastructure, safer vehicles, safer road users, and post-crash response (United Nations Road Safety Collaboration, 2011)—and more recently through the Save LIVES technical package on road safety, which encourages countries to put in place 22 evidence-based interventions (WHO, 2017d) (**TABLE 9-6**).

Safer Systems

A focus on safer systems involves managing exposure to the risk of a road traffic injury, by accounting for human error through managing interactions between the environment, infrastructure, and the road user (OECD, 2008). In particular, it involves implementing strategies aimed at reducing motor vehicle traffic, encouraging use of safer modes of traffic, and minimizing exposure to high-risk scenarios. Reductions in motor vehicle traffic are possible through application of efficient fuel taxes, land-use restrictions, and safety impact assessments of transport and land-use plans; by

TABLE 9-6 Save LIVES: 6 Components and 22 Interventions

Acronym	Component	Interventions
S	**Speed management**	Establish and enforce speed limit laws nationwide, locally, and in cities
		Build or modify roads to calm traffic (e.g., roundabouts, road narrowing, speed bumps, chicanes, and rumble strips)
		Require car makers to install new technologies, such as intelligent speed adaptation, to help drivers keep to speed limits
L	**Leadership**	Create an agency to spearhead road safety
		Develop and fund a road safety strategy
		Evaluate the impact of road safety strategies
		Monitor road safety by strengthening data systems
		Raise awareness and public support through education and campaigns

I	**Infrastructure design and improvement**	Provide safe infrastructure for all road users, including sidewalks, safe crossings, refuges, overpasses, and underpasses
		Put in place bicycle and motorcycle lanes
		Make the sides of roads safer by using clear zones, collapsible structures, or barriers
		Design safer intersections
		Separate access roads from through-roads
		Prioritize people by putting in place vehicle-free zones
		Restrict traffic and speed in residential, commercial, and school zones
		Provide better, safer routes for public transport
V	**Vehicle safety**	Establish and enforce motor vehicle safety standard regulations related to: ■ Seat belts ■ Seat belt anchorages ■ Frontal impact ■ Side impact ■ Electronic stability control ■ Pedestrian protection ■ ISOFIX child restraint points
		Establish and enforce regulations on motorcycle antilock braking
E	**Enforcement of traffic laws**	Establish and enforce laws at national, local, and city levels on: ■ Drinking and driving ■ Motorcycle helmets ■ Seat belts ■ Child restraints
S	**Survival**	Develop organized and integrated prehospital and facility-based emergency care systems
		Train those who respond to crashes in basic emergency care
		Promote community first responder training

the provision of shorter, safer routes; and through trip reduction measures, including greater emphasis on the development and use of public transport systems. Minimizing exposure to high-risk scenarios includes strategies such as restricting access to different parts of the road network, giving priority in the road network to higher-occupancy vehicles or to pedestrians and slow-moving transports, placing restrictions on speed and engine performance of motorized two-wheelers, separating different traffic modes, increasing the legal age for operating motorized two-wheelers, and introducing graduated driver licensing systems. While it seems obvious that the implementation of these strategies should lead to reductions in road traffic injuries, only limited documentation of their effectiveness in low-income contexts is readily available.

Safer Roads

Intervention strategies focusing on safer roads need to incorporate safety awareness in planning road networks, safety features in road design, and remedial action

at high-risk crash sites. Although they may not have been examined in rigorously controlled studies, many of these strategies have been adapted and adopted over many years in both high-income countries and LMICs.

Traffic-calming measures are among the strategies recommended with respect to incorporating safety features into road design (Table 9-6). Systematic reviews of the evidence confirm that traffic-calming measures reduce road traffic injuries, although evidence from randomized controlled trials is not yet available (Bunn et al., 2003; Retting, Ferguson, & McCartt, 2003; WHO, 2017d). Although most of the evidence cited in support of these measures comes from high-income countries, a "before and after" study conducted in Ghana showed clearly that speed bumps were effective in reducing traffic injuries, and especially in decreasing pedestrian injuries (Afukaar, Antwi, & Ofosu-Amah, 2003).

The introduction of speed cameras (designed to capture images of drivers violating speed limits) and other speed-enforcement devices has also been shown to be highly cost-effective in reducing road traffic injuries (WHO, 2017c, 2017d). Nevertheless, the quality of these studies remains low and relatively few have been conducted in LMICs (ICF Consulting & Imperial College Centre for Transport Studies, 2003; Wilson, Willis, Hendrikz, & Bellamy, 2006).

Other safety features that might be incorporated into road design include provisions for slow-moving traffic and for vulnerable road users, lanes for overtaking other road users, median barriers, street lighting, advisory speed limits, and systematic removal of roadside hazards, such as trees or utility poles (Beyer & Ker, 2009; Peden et al., 2004).

Safer Vehicles

Strategies focusing on safer vehicles that have been suggested include a core set of seven United Nations vehicle regulations for motor vehicles and one for motorcycles that are expected to decrease the incidence of road traffic injuries and save lives (WHO, 2015a, 2017d). The seven vehicle regulations are standards on frontal and side impact; electronic stability control; pedestrian protection; seat belts and anchorages; and child restraints. A recent study conducted in Latin America revealed that more than 440,000 deaths and serious injuries could be averted and up to $143 billion saved if basic UN vehicle regulations were applied to key countries in the region by 2030 (Wallbank, McRae-McKee, Durrell, & Hynd, n.d.).

Establishing and enforcing regulations on motorcycle antilock braking and daytime running lights are important evidence-based interventions for powered two-wheelers (WHO, 2017a, 2017d). The positive effects of daytime running lights on motorcycles have been shown in LMICs (Radin Umar, Mackay, & Hills, 1996; Yuan, 2000), while meta-analyses of the effects of (automatic) daytime running lights on cars, particularly in countries in the northern hemisphere, have shown that they decrease the frequency of road crashes, including pedestrian and cycle crashes (Elvik & Vaa, 2004).

The installation and maintenance of seat belts in cars is probably the most well-known and most effective crash vehicle design strategy. Nevertheless, data from surveys conducted in 2009 showed that more than one-fourth of all countries that manufacture or assemble cars do not require that seat belts be fitted (WHO, 2009). By 2013, although 161 countries had national seat belt laws, only 105 of them had laws that met best practice standards by requiring all occupants to be belted (WHO, 2015a). Among other intelligent vehicle devices that might prove useful in LMICs are speed limiters and ignition interlock devices that prevent alcohol users from starting a vehicle (McGinty et al., 2017).

Safer People

In recent decades, effective intervention strategies aimed at improving road user behavior have increasingly focused on the introduction and enforcement of relevant legislation, combined with enforcement and education, rather than advocating educational efforts alone (Poli de Figueiredo, Rasslan, Bruscagin, Cruz, & Rocha e Silva, 2001; Staton et al., 2016; WHO, 2013). Many of these legislative intervention strategies have addressed speeding, alcohol use and driving, motorcycle helmet use, seat belts, and child restraints (WHO, 2015a). Despite this focus, few countries have national and subnational laws relating to all five of these risk factors. The situation is most advanced in regard to seat belt laws, as 105 countries now have laws that match the best practice (**FIGURE 9-5**). Even when legislation has been passed, enforcement of the laws is often weak, especially in LMICs.

A large body of research—albeit little of it conducted in LMICs—shows that the setting and enforcement of speed limits can lead to reductions of as much as 34% in road traffic injuries (Peden et al., 2004; WHO, 2017c). Similarly, numerous studies demonstrate that establishment and enforcement of legal blood alcohol limits, minimum drinking-age laws, and use of alcohol checkpoints lead to important reductions in road traffic injuries, albeit of varying magnitude (Peden et al., 2004).

Both bicycle helmets and, in particular, motorcycle helmets have been shown to have a significant impact in reducing head injuries among riders (Liu et al., 2008;

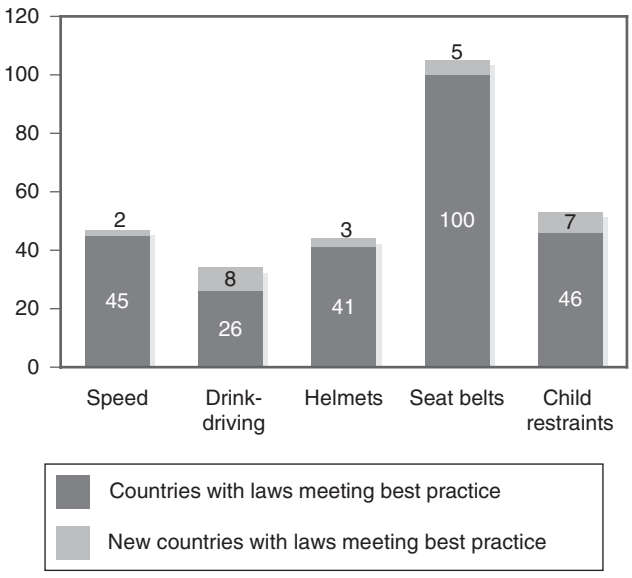

FIGURE 9-5 Countries with road safety laws meeting best practice.

Reprinted from World Health Organization (WHO). (2015). *Global status report on road safety, 2015*. Geneva, Switzerland: World Health Organization.

Thompson et al., 2003; WHO, 2017a). The introduction of mandatory seat belt laws and mandatory child restraint laws has been shown to have a major impact in reducing occupant deaths and injuries—decreases of as much as 25% have been noted in some areas (FIA Foundation for the Automobile and Society, 2009; WHO, 2007). Additionally, systematic reviews have shown the greater effectiveness of enforcement strategies that allow enforcement officers to specifically stop and check seat belt use (primary enforcement) compared with strategies that allow seat belt use to be checked only when other enforcement strategies are the focus of the traffic stop (secondary prevention) (Dinh-Zarr et al., 2001; Rivara, Thompson, Beahler, & MacKenzie, 1999). Moreover, many studies have shown that enforcement needs to be selective, highly visible, and well publicized; conducted over a sufficiently long period; and repeated several times a year (European Transport Safety Council, 2016; Solomon, Ulmer, & Preusser, 2002).

Interventions to Prevent Poisonings

The prevention of unintentional poisonings includes consideration of both occupational and non-occupational poisonings, including household poisonings. Efforts to prevent occupational exposures include the promotion, legislation, and enforcement of nonchemical methods of pest control and the promotion of the safe use of pesticides when nonchemical methods are not feasible. Interventions such as these largely fall within the domain of specialists working in occupational and environmental health and are not considered further in this chapter.

Suggested interventions to reduce exposure to non-occupational poisonings include better storage of poisonous materials, in terms of both the storage position and the nature of the storage vessels (Nixon, Spinks, Turner, & McClure, 2004; Peden et al., 2008). With respect to the former, the suggested interventions include storing poisonous materials outside the home, and at levels beyond the reach of children (above head height). With respect to the nature of the storage containers, it has been suggested that efforts need to be directed toward reducing the use of *secondhand* household containers (e.g., cola bottles), including the introduction and enforcement of legislation to prohibit sales of poisons in such containers (Nhachi & Kasilo, 1994). While these interventions clearly have merit, evidence demonstrating their effectiveness is lacking.

The efficacy of child-resistant containers (CRCs) in preventing access to poisons has been demonstrated, however. According to data from a controlled "before and after" study undertaken in South Africa, the free distribution of CRCs appears to be a highly effective means of preventing poisoning in children (Krug, Ellis, Hay, Mokgabudi, & Robertson, 1994).

Other interventions that have been suggested, but not rigorously examined, include the use of warning labels on poison packaging, appropriate first aid education, and the introduction of poison control centers that are charged with monitoring the incidence of poisonings and providing appropriate preventive advice (Nixon et al., 2004; Peden et al., 2008). Likewise, home safety education and the provision of safety education have been proposed as potentially effective interventions; while the available evidence appears promising, the impact of such interventions on poisoning rates is unclear (Kendrick et al., 2008).

Interventions to Prevent Fall-Related Injuries

Fall-Related Injuries in Older People

In community-dwelling individuals, exercise interventions show the greatest promise in reducing the risk and rate of falls. These include multiple-component group exercises such as Tai Chi, which involve balance and strengthening exercises, as well as individually prescribed multiple-component home-based exercise (Gillespie et al., 2012).

Assessment and multifactorial interventions have been shown to reduce the rate of falls but not the risk of falling, as has gradual withdrawal of psychotropic medication. Overall, vitamin D supplementation does

not reduce the risk of falls, although this measure may well do so in persons with lower vitamin D levels. Similarly, home safety interventions do not reduce falls overall, but are effective in preventing falls among persons with visual impairment and among others at higher risk of falling. Other effective interventions are directed toward individuals who reside in certain living environments and those with specific medical conditions (Gillespie et al., 2012).

Some evidence indicates that multifactorial interventions can reduce both the number of falls and the risk of falling in hospitals, and may do so in nursing care facilities as well. Vitamin D supplementation is also effective in reducing the rate of falls in nursing care facilities. By comparison, exercise in subacute hospital settings appears effective in decreasing falls, but its effectiveness in nursing care facilities remains uncertain (Cameron et al., 2012).

Hip protectors initially appeared to be a promising intervention to reduce the impact of a fall in older people. More recently, a growing number of studies have questioned the effectiveness of these devices, especially given the relatively poor compliance rates that are achieved in real-life settings (Cameron et al., 2010; Parker, Gillespie, & Gillespie, 2006).

Fall-Related Injuries in Younger People

The *World Report on Child Injury Prevention* document (Peden et al., 2008) highlights a number of areas where interventions to prevent falls among children have been shown to be effective or appear promising. These strategies include engineering measures focused on the redesign of equipment, such as nursery equipment, and environmental measures that focus on the redesign of playgrounds or buildings. Previous successes with the Children Can't Fly program in low-income areas in the United States have been replicated in low-income countries, where the use of window guards have been shown to be a promising approach to the prevention of falls from buildings. By comparison, while educational strategies for the prevention of falls in children might seem to be appealing at first glance, little evidence supports the effectiveness of such approaches in reducing the rates of falls (Kendrick et al., 2008; Kendrick et al., 2013).

Interventions to Prevent Burn-Related Injuries

Installed, working smoke detectors have been found to reduce the risk of death from fires by up to 50%; the challenge, however, is making sure that all homes have working smoke alarms on all levels of the residence (DiGuiseppi et al., 2010). Most studies in high-income countries have focused on the effectiveness of smoke detector giveaway programs, community- and school-based educational campaigns, and community-based burns prevention measures. Unfortunately, these education-based approaches have little evidence supporting their effectiveness in terms of reduced incidence of fires and fire-related injuries. Notably, combining building codes and legislation on smoke alarms with education seems to have a greater effect in achieving this goal (DiGuiseppi et al., 2010).

Interventions that have been proposed but not yet shown to be effective largely rely on reducing exposure to fires and flames (Peden et al., 2008). These measures include separating cooking areas from living areas (including efforts to reduce the use of indoor fires for cooking), ensuring cooking surfaces are at appropriate heights, reducing the storage of flammable substances in households, and providing for greater supervision of younger children. Other proven or promising interventions include the introduction of safer lamps and stoves, child-resistant lighters, banning the sale of fireworks to children, and treatment of patients at dedicated burn centers (Peden et al., 2008).

Evidence for the effectiveness of interventions to prevent water-related burn injuries is minimal, but promising. In an increasing number of high-income countries, much effort has been directed toward measures that not only educate communities about the dangers of high tap water temperatures, but also legislate and enforce efforts to regulate the temperature of water flowing from household taps (DiGuiseppi et al., 2010; Macarthur, 2003). In contrast, in low-income countries, scalds due to hot water are more likely to be associated with cooking and boiling of water, rather than water from taps. Consequently, interventions related to the separation of the cooking areas from living and play areas have been emphasized, as well as suggestions that cooking vessels holding water might be better designed to minimize the chances of spillage.

Finally, interventions directed at increasing awareness of burns prevention (whether fire or water related) have been proposed, especially given the success of *safe community* interventions involving a multitude of strategies (Ytterstad & Sogaard, 1995). To date, limited evidence shows that such interventions can be successful (Peden et al., 2008; Turner, Spinks, McClure, & Nixon, 2004).

Interventions to Prevent Drowning

Evidence for the effectiveness of interventions to prevent drowning has been recently summarized in a new global report on drowning (WHO, 2014a). In this

report, ten actions to prevent drowning were identified. These included community-based actions, such as installing barriers (e.g., pool fencing, doorway barriers and playpens, well covers); providing safe places for children away from water; teaching school-age children basic swimming skills; and training bystanders. In addition, the report recommended more effective policies or laws, such as setting and enforcing safe boating standards; building resilience and managing floor risk; coordinating drowning efforts; and developing a national water safer plan. Finally, the report authors called for well-designed studies to address priority research questions in this area (WHO, 2014a).

The effectiveness of learn-to-swim programs, while a common component of prevention programs in high-income countries, have only recently been studied in LMICs. Programs in Australia, Bangladesh, China, Thailand, the United States, and Vietnam have shown that teaching children (older than 5 years) basic swimming, water safety, and safe rescue skills reduces the risk of drowning; in one study in Bangladesh, such a program was shown to be cost-effective (Rahman et al., 2012).

Education regarding the burden and risk factors for drowning, especially the risks posed by prior consumption of alcohol, has also been postulated as a potential intervention strategy (Quan, Bennett, & Branche, 2007). Increased supervision of children around bodies of water and the provision of lifeguards at popular swimming areas have been proposed as other measures that might reduce drowning (Hyder et al., 2003; WHO, 2017e).

Recent work largely done in Bangladesh has been exploring the use of barriers such as playpens and door barriers, as well as keeping at-risk children away from the hazard in community day care centers or crèches (Hyder et al., 2014a, 2014b). The crèches appeared very promising on earlier studies (Rahman et al., 2012); in a large study conducted more recently, they were found to protect children age 1–4 years from drowning deaths. The crèches also involve community mobilization, the development of village injury prevention committees, and educational programs for both children and parents (Hyder et al., 2014a, 2014b).

Interventions to prevent water-related transport drowning include equipping boats with flotation devices, ensuring that boats and flotation devices are well maintained, introducing legislation and enforcing regulations relating to the maximum number of individuals who may be carried on specific types of boats, and providing fully trained and responsive coast guard services (WHO, 2014a). However, as with the preventive measures proposed to prevent non-transport-related drowning, evidence of these interventions' effectiveness is lacking (Peden et al., 2008).

Interventions to Prevent Self-Directed Violence

Knowledge about risk factors for suicide and effective prevention strategies has increased dramatically over the past decade, although only 28 countries today have national suicide prevention strategies (WHO, 2014b). Effective strategies for preventing suicides and suicide attempts include restricting access to the most common means, including pesticides, firearms, and certain medications (WHO, 2014b). Attempts to limit the availability of suicide means have included reducing access to sedatives, pesticides, carbon monoxide in domestic gas and in car exhausts, and handguns in the home. Safer storage, bans, and replacement of pesticides with less toxic alternatives could prevent many of the estimated 370,000 suicides caused by ingestion of these chemicals every year. Although international conventions have long attempted to manage hazardous substances, many highly toxic pesticides continue to be widely used. Research suggests, however, that bans must be accompanied by evaluations of agricultural needs and replacement with low-risk alternatives for pest control.

Early identification and effective management of mental disorders and harmful alcohol use can contribute to reducing suicides and should be systematically integrated in the health sector response. Community-based prevention efforts include encouraging attendance at suicide prevention centers and self-help groups and school-based interventions that involve training of school staff, community members, and healthcare providers to identify those persons at risk and refer them to treatment. By comparison, societal approaches include both restricting access to the means of suicide and managing media reports of suicides.

Interventions to Prevent Interpersonal Violence

This section is adapted from *INSPIRE—Seven Strategies for Ending Violence Against Children*, which is a technical package of prevention strategies that have shown success in reducing interpersonal violence, in particular violence against children (WHO, 2016b). The strategies were selected based on convergence in the research-based guidance already published by the 10 international agencies that endorsed INSPIRE. While the INSPIRE technical package is specifically aiming to reduce violence against children age 0–18 years, most of these strategies have been shown to have preventive effects on violence in adulthood as well, and benefits in areas

such as mental health, education, and crime reduction (WHO, 2016b). This section summarizes the seven strategies and spotlights the effectiveness of those interventions within each strategy that have the strongest evidence for preventing violence. **TABLE 9-7** presents an overview of the seven strategies, specific approaches within each strategy, and the sectors that are usually responsible for its implementation.

Implementation and Enforcement of Laws

The aim of this strategy is to ensure that laws to prevent violent behaviors, reduce excessive alcohol use,

TABLE 9-7 INSPIRE Strategies, Approaches, and Sectors for Preventing and Responding to Violence Against Children

Strategy	Approaches	Sectors	Cross-cutting Activities
Implementation and enforcement of laws	■ Laws banning violent punishment of children by parents, teachers, or other caregivers ■ Laws criminalizing sexual abuse and exploitation of children ■ Laws that prevent alcohol misuse ■ Laws limiting youth access to firearms and other weapons	Justice	Multisectoral actions and coordination
Norms and values	■ Changing adherence to restrictive and harmful gender and social norms ■ Community mobilization programs ■ Bystander interventions	Health, education, social welfare	Multisectoral actions and coordination
Safe environments	■ Reducing violence by addressing "hotspots" ■ Interrupting the spread of violence ■ Improving the built environment	Interior, planning	Multisectoral actions and coordination
Parent and caregiver support	■ Delivered through home visits ■ Delivered in groups in community settings ■ Delivered through comprehensive programs	Social welfare, health	Multisectoral actions and coordination
Income and economic strengthening	■ Cash transfers ■ Group saving and loans combined with gender equity training ■ Microfinance combined with gender norm training	Finance, labor	Monitoring and evaluation
Response and support services	■ Counseling and therapeutic approaches ■ Screening combined with interventions ■ Treatment programs for juvenile offenders in the criminal justice system ■ Foster care interventions involving social welfare services	Health, justice, social welfare	Monitoring and evaluation
Education and life skills	■ Increase enrollment in preschool, primary schools, and secondary schools ■ Establish a safe and enabling school environment ■ Improve children's knowledge about sexual abuse and how to protect themselves against it ■ Life and social skills training ■ Adolescent intimate-partner violence prevention programs	Education	Monitoring and evaluation

and limit youths' access to firearms and other weapons are both implemented and enforced (WHO, 2016b, p. 31). Implementation and enforcement of such laws has the potential to reduce physical violence, sexual abuse and exploitation, and firearms-related deaths, and nonfatal injuries among children (DeSimone, Markowitz, & Xu, 2013; Matzopoulos, Thompson, & Myers, 2014; Modig, 2009; Santaella-Tenorio, Cerdá, Villaveces, & Galea, 2016). Laws prohibiting violent behaviors including sexual abuse or violent punishment of children signal that society does not consider these behaviors acceptable (Modig, 2009; United Nations, 2014). Such laws provide a way to hold perpetrators accountable for their actions. Laws and policies can also reduce key risk factors for violence against children, such as excessive alcohol consumption and binge drinking (Fitterer, Nelson, & Stockwell, 2015; Wagenaar, Toomey, & Erickson, 2005; Wechsler & Nelson, 2010).

Norms and Values

This strategy aims to strengthen norms and values that support nonviolent, respectful, nurturing, positive, and gender-equitable relationships for all children and adolescents (WHO, 2016b, p. 37). Achieving this often requires modifying deeply ingrained social and cultural norms and behaviors—in particular, the idea that some forms of violence are not only normal, but sometimes justifiable. It involves approaches such as community mobilization programs, bystander interventions, and small-group programs that challenge harmful gender and social norms (WHO, 2016b, p. 37).

Successful implementation of this strategy should result in greater recognition of what constitutes abusive behavior toward intimate partners and children, a reduced acceptance of this violence, and, ultimately, a decrease in the occurrence of such violence (Abramsky et al., 2014; Jewkes et al., 2008; Kyegombe et al., 2015; Paine et al., 2002; Raising Voices, 2016; Usdin, Scheepers, Goldstein, & Japhet, 2005; Verma et al., 2008). In addition, it is intended to produce more favorable attitudes and beliefs toward nonviolent approaches to parental discipline, gender equity, and gender-equitable division of labor (Dworkin, Hatcher, Colvin, & Peacock, 2013; Lundgren, Beckman, Chaurasiya, Subhedi, & Kerner, 2013).

Safe Environments

This strategy aims to create and sustain safe streets and other environments where children and youth gather and spend time, and in so doing reduce assault-related injuries (WHO, 2016b, p. 43). It focuses on modifying communities' social and physical environment (rather than the individuals within it) to foster positive—and deter harmful—behaviors. It involves approaches like problem-oriented policing directed toward "hotspots" for violence, interrupting violent conflicts by stopping retaliatory violence, and changing the built environment through, for example, lighting, creation of green places in vacant lots, and renovating abandoned buildings (Braga, Papachristos, & Hureau, 2012; Cassidy, Inglis, Wiysonge, & Matzopoulos, 2014; Cerdá et al., 2012; Florence, Shepherd, Brennan, & Simon, 2011, 2014; Henry, Knoblauch, & Sigurvinsdottir, 2014; Picard-Fritsche & Cerniglia, 2013; Skogan, Harnett, Bump, & DuBois, 2009; Webster, Whitehill, Vernick, & Parker, 2012).

Parent and Caregiver Support

This strategy aims to reduce harsh parenting practices and create positive parent–child relationships by helping parents and caregivers understand the importance of positive, nonviolent discipline and of close, effective communication. Parent and caregiver support can be provided through parent training programs delivered via home visits or in groups. In these approaches, parents are educated about their children's development and trained to adopt positive parenting practices, such as nonviolent discipline, and to engage in effective parent–child communication on sensitive topics (WHO, 2016b, p. 49).

The parent and caregiver support strategy has been shown to reduce child maltreatment; bullying and being bullied; physical, emotional, and sexual violence victimization by partners or peers; and aggression and delinquency during adolescence; and to increase parental monitoring of child and youth safety (Beets et al., 2009; Bilukha et al., 2005; "Building Happy Families," 2014; Kärnä et al., 2011; Knerr, Gardner, & Cluver, 2013; Knox & Burkhart, 2014; Nurse Family Partnership, 2011; Olds et al., 1998; "Parents Make the Difference," 2014; Salmivalli & Poskiparta, 2012; Washburn et al., 2011).

Income and Economic Strengthening

This strategy aims to improve families' economic security and stability, thereby reducing intimate-partner violence and child maltreatment. It involves interventions such as making cash transfers to families in combination with parent training and/or on condition that they ensure their children attend school, or providing microfinance in combination with education for men and women on gender norms, domestic violence, and sexuality (WHO, 2016b, p. 55).

The income and economic strengthening strategy can be expected to reduce physical violence

toward children by parents or other caregivers; early and forced marriage of young girls; intimate-partner violence; children witnessing intimate-partner violence in the home; and social norms and attitudes that approve of intimate-partner violence (Cancian, Yang, & Slack, 2013; Gupta et al., 2013; Huston et al., 2003; Jan et al., 2011; Kim et al., 2007; Ozer, Fernald, Manley, & Gertler, 2009; Pronyk et al., 2006; Pronyk, Hargreaves, & Morduch, 2007; Vyas & Watts, 2009).

Response and Support Services

This strategy aims to improve access to good-quality health, social welfare, and criminal justice support services for all children who need them—including for reporting violence—to reduce the long-term impact of violence (WHO, 2016b, p. 61). Children who have experienced violence need access to a variety of health and support services to help them heal. These services can also help break the cycle of violence in children's lives and help them better cope and recover. Basic health services, such as emergency medical care for violence-related injuries, and clinical care for victims of sexual violence (including post-exposure prophylaxis against human immunodeficiency virus [HIV] in cases of rape when indicated), are the main priority (WHO, 2016b, p. 61). Where these basic health services are in place and are child focused, mechanisms for children to seek help, protection, support, and care—and to report violent incidents—can be put in place. These mechanisms can include counseling and therapeutic approaches, screening combined with interventions, treatment programs for juvenile offenders in the criminal justice system, and foster care interventions involving social welfare services (WHO, 2016b, p. 61).

Successful implementation of the strategy should reduce the recurrence of the same type of violence in the short term; victimization or perpetration of violence in the short and long terms; sexually transmitted infections and negative reproductive health outcomes; and trauma symptoms (e.g., post-traumatic stress disorder, depression, anxiety) (Dubowitz, Feigelman, Lane, & Kim, 2009; Koehler, Lösel, Akoensi, & Humphreys, 2013; MacMillan & Wathen, 2014; Murray et al., 2015; Wethington et al., 2008).

Education and Life Skills

This strategy aims to increase children's access to education, social–emotional learning, and life-skills training, and to ensure that school environments are safe and enabling (WHO, 2016b, p. 67). Gains in education protect against both victimization and perpetration of violence. This strategy involves approaches such as increasing enrollment of children in preschool, primary schools, and secondary schools; establishing a safe and enabling school environment; improving children's knowledge about sexual abuse and how to protect themselves against it; adolescent intimate-partner violence prevention programs; and life and social skills training programs. Programs that strengthen children's social and emotional learning enhance their communication and relationship skills and help them learn to solve problems, deal with emotions, empathize, and safely manage conflict—all life skills that can prevent violence (WHO, 2016b).

The education and life skills strategy can be expected to result in higher levels of school attendance and academic success and increased awareness of, and improved attitudes toward, intimate-partner violence. It should also lead to reductions in bullying, aggressive, and violent behaviors; physical and sexual intimate-partner violence victimization and perpetration; and drug use and excessive alcohol use (Chaux, 2007; Devries et al., 2015; Foshee et al., 2005; Hahn et al., 2007; Institute of Medicine, 2011; Reynolds, Temple, Ou, Arteaga, & White, 2011; Shek & Ma, 2012; Wallace, 2006; Wilson & Lipsey, 2007; WHO, 2015a).

Effects of Multiple Strategies

Research specifically on the combined effects of multiple INSPIRE strategies has yet to become available, but some examples of such studies can be gleaned from the literature on HIV prevention. For instance, a study in rural South Africa examined the effects on mental health, substance abuse, violence, and risk behavior for HIV/AIDS of a program geared toward social protection (cash) and psychosocial support (care). In boys, violence perpetration incidence was 20% without cash and care provision, 14% with cash provision, 13% with care alone, and 9% with cash plus care. In girls, sexual exploitation incidence was 14%, without cash or care, 11% with cash provision, 11% with care, and 8% with cash plus care; and HIV risk behavior incidence was 15% without cash and care, 10% with cash provision, 10% with care, and 7% with cash plus care (Cluver, Orkin, Boyes, & Sherr, 2014). The findings from these studies suggest that the additive effects of multiple INSPIRE strategies could be large, and that a priority for future research should be to evaluate the appropriate effects of multiple interventions.

Interventions to Prevent Collective Violence

The prevention of collective violence involves reducing the potential for violent conflicts and providing appropriate responses to violent conflicts when they

occur. Not surprisingly, scientific evidence about the effectiveness of such interventions is lacking (Zwi, Garfield, & Loretti, 2002). A systematic review focusing on the evidence for approaches to reduced sexual violence in the context of armed conflict and humanitarian crises found only one study that specifically addressed the disaster setting. Most studies focused on opportunistic forms of sexual violence committed in post-conflict settings (Spangaro, Adogu, Ranmuthugala, Davies, Steinacker, & Zwi, 2013). The evidence is inconclusive, but it appears that multicomponent interventions that engaged the affected communities were among the more promising approaches. Nevertheless, policies that facilitate reductions in poverty, that make decision making a more accountable process, that reduce inequalities between groups, and that reduce access to biological, chemical, nuclear, and other weapons have been recommended. When planning responses to violent conflicts, recommended approaches include assessing at an early stage which populations are most vulnerable and what their needs are, coordinating the activities of the various players, and working toward global, national, and local capabilities so as to deliver effective health services during the various stages of an emergency (Zwi et al., 2002).

The Role of Health Services in Preventing Death and Disability from Unintentional Injuries and Violence

While the focus of this section has been on identifying strategies to prevent the occurrence of injuries, it is important to recognize that access to health services plays a major role in preventing death and disability from injuries and violence. Differential access to health and medical services has been identified in other fields of health as having an important bearing on long-term outcomes, and the importance of such services is now being increasingly recognized in the injury field (Razzak & Kellermann, 2002).

For example, although prehospital transport systems exist in major cities in LMICs, the prehospital care that is delivered to trauma victims in the field is typically minimal or nonexistent in rural areas. Not surprisingly, this lack of quality emergency medical services care and timely transport to the hospital translates into higher mortality rates. Significant reductions in mortality have been reported as a result of improvements in trauma care (Mock, Lormand, Joshipura, Goosen, & Peden, 2004). WHO has recently suggested that even in environments where fewer resources are available, injury mortality and disability can be reduced by reorganizing systems, upgrading the skills of the health staff, and ensuring minimum physical and human resources are available (Mock, Quansah, Krishnan, Arreola-Risa, & Rivara, 2004).

In most LMICs, access to violence-related health services is limited. In the Violence Against Children Surveys, fewer than 10% of children who experienced sexual violence reported receiving services in Cambodia, Haiti, Kenya, Malawi, Swaziland, Tanzania, and Zimbabwe (Sumner et al., 2015).

Basic health services to mitigate the negative consequences of violence include emergency medical care for violence-related injuries and clinical care for victims of sexual violence, including post-exposure prophylaxis against HIV in cases of rape, when indicated. These services should be available at the primary healthcare level everywhere. More comprehensive services include counseling and social services for victims and perpetrators of violence; notably, such services can help victims better cope with violence (WHO, 2016b).

Economic Analyses of Interventions to Prevent Unintentional Injuries and Violence

Currently, there is a dearth of literature on economic evaluations of interventions for injuries. This scarcity of research in large part reflects the infancy of this field and the limited, but growing evidence base identifying effective preventive strategies. Unfortunately, even for interventions that are routinely used in high-income countries, proof of their cost-effectiveness is not always easy to find. The situation is even more critical in LMICs, where evaluations of these interventions are rarely available.

Exemplifying this paucity as well as the potential importance of such data are two reviews that documented economic analyses of interventions directed at reducing road traffic injuries (Hyder, Waters, Philipps, & Rehwinkel, 2004; Waters, Hyder, & Phillips, 2004). These reviews, which relied on mostly data from high-income countries, suggest that interventions such as mandatory helmet laws, laws mandating motor vehicle inspections, installation of automatic daytime running lights, and seat belt laws are likely to provide widespread benefits with high benefit–cost ratios, even in LMICs. A recently published article by Sheehan et al. (2017) indicated that investing $5.20 per capita across 75 LMICs in five areas, including road safety, would result in economic and social benefits 10 times their costs and save up to 12.5 million lives. This study identified seven road safety interventions—namely, behavioral measures (helmet use, speed compliance, alcohol testing, seat belt use, and graduated licensing), motor vehicle safety

measures, and infrastructure expenditures (safer roads)—as most effective at reducing deaths, injuries, and disabilities among adolescents.

Costs of interventions for injuries were analyzed as part of the Disease Control Priorities project (www.dcp-3.org/dcp2/; Norton, Hyder, Bishai, & Peden, 2006). Specifically, Bishai and Hyder (2006) estimated the cost-effectiveness of five interventions that could reduce injuries in LMICs: enforcing traffic laws more strictly, erecting speed bumps, promoting helmets for bicycle riders, promoting helmets for motorcycle riders, and storing kerosene in childproof containers. They estimated what each intervention would cost in six world regions over a 10-year period from both governmental and societal perspectives, with costs being measured in U.S. dollars for 2001. Some data were available on the effectiveness of each intervention and were used to form models of DALYs averted by each strategy for various regions. The interventions had cost-effectiveness ratios ranging from $5 to $556 per DALY averted, depending on the region. Enhanced speeding control, for example, was found to be highly cost-effective at $93 per DALY. Similarly, at $13.98 per DALY, placing speed bumps at 25% of the most dangerous junctions turned out to be highly cost-effective, although this measure requires the identification of such intersections. Bicycle helmet legislation is not universally implemented in the high-income world, yet its cost-effectiveness ($170 per DALY) makes it an attractive option. Interestingly, motorcycle helmet legislation in East Asia was found to have a higher cost and lower benefit at $556 per DALY. At $96 per DALY, child-resistant containers are a highly cost-effective intervention that warrants serious consideration by a large part of the low- and middle-income world where paraffin (kerosene) is used for cooking and heating purposes, including sub-Saharan Africa, South Asia, East Asia, and parts of the Middle East.

Empirical work conducted in LMICs remains rare. One notable example of such work is a study that examined the costs and potential effectiveness of increasing traffic enforcement in Uganda, as assessed on the four major roads to the capital Kampala (Bishai, Asiimwe, Abbas, Hyder, & Bazeyo, 2008). By using monthly data on traffic citations and casualties for the years 2001 to 2005 and employing time series regression, the researchers computed costs from the perspective of the police department. The average cost-effectiveness of better road safety enforcement in Uganda was determined to be $603 per death averted or $27 per life-year saved discounted at 3% (amounting to 1.5% of Uganda's $1,800 GDP per capita).

Economic impact studies on other types of unintentional injuries are scarce, especially from LMICs. A recent study reported that the average out-of-pocket payments varied significantly (range: $8–$830) by injury type and outcome (fatal versus nonfatal), while the total injury out-of-pocket expenditures were $355,795 and $5,000 for nonfatal and fatal injuries, respectively, per 100,000 people in Bangladesh (Alfonso et al., 2017). In the same study, the majority of household heads with injuries reported financial distress following that injury.

Although relatively few economic evaluations of interventions targeting interpersonal violence have been published, the available studies suggest that behavioral, legal, and regulatory interventions cost less money than they save, in some cases by several orders of magnitude (Waters et al., 2004). An evaluation of the Cardiff model, which strengthened data collection regarding the place, the time, the mechanism, and the perpetrators of violence-related injuries in hospital emergency departments, and anonymized and shared this information with the police, showed that this model reduced hospital admissions by 42% and police-recorded injuries by 32%. These reductions represented savings of £6.9 million (~$9.6 million) per year and a cost–benefit ratio of £82 million (~$115 million) in benefits for each £1 million ($1.4 million) spent on the program (Florence, Shepherd, Brennan, & Simon, 2014). A review of the costs and benefits of early intervention programs to prevent child maltreatment concluded that some home-visiting programs targeting high-risk/low-income mothers returned between $2 and $3 for each $1 spent (Aos, Lieb, Mayfield, Miller, & Pennucci, 2004). In a further review of nine early childhood programs, seven were found to be cost-effective, yielding between $2 and $17 in benefits for every dollar invested (Kilburn & Karoly, 2008). Despite this benefit, both reviews concluded that not all childhood interventions are cost-effective, with some being ineffective and expensive.

Along with outcome evaluation studies, investigations into the cost-effectiveness of preventive strategies for interpersonal violence should be a research priority.

Advancing the Injury and Violence Prevention Agenda: Opportunities and Challenges

Over the past decades, our knowledge about the burden of injuries and violence, as well as risk factors and effective interventions addressing these issues, has increased exponentially. In many high-income countries, the benefits of this increased knowledge

have resulted in significant declines in injury- and violence-related mortality and morbidity rates. In contrast, for many LMICs, increases in rates of injury and violence are predicted over the next 20 years, as a result of both changing socio-demographic patterns and these countries' success in addressing the burden of communicable disease and maternal and child ill health. Consequently, there is an imperative to rapidly advance an injury and violence prevention agenda, while recognizing that many of the challenges faced by LMICs will be different from those that have been faced in the previous decades.

Advocacy for Injury and Violence Prevention

It remains critical that the global health community fully understand the health, economic, and social impacts of unintentional injuries and violence. Likewise, the health sector must recognize that clearly defined risk factors for injuries and violence exist and that effective interventions can prevent these problems and reduce the burden of death and disability to which they give rise. One of the challenges is that while the health sector often has to deal with the consequences of injuries and violence, many of the approaches to prevent injuries and violence come under the auspices of other sectors. However, despite the recent efforts by WHO and many injury and violence prevention professionals throughout the world, many governments and the wider community often fail to recognize that injuries are no "accident" and that violence does not "just happen"—and that we can work to prevent increases in the incidence of these conditions. For this reason, targeted and evidence-based advocacy is essential at local, national, and international levels.

The key messages to be transmitted in advocacy efforts are as follows: Injuries and violence cause considerable death and disability; they are predictable events with clearly identified causes; and they can be effectively prevented. Moreover, there is a great need, especially in LMICs, to initiate national conversations around key injury issues and stimulate an intersectoral approach to address them. The WHO reports on violence and health, on road traffic injury prevention, and on child injury prevention, for example, propose such an approach to national stakeholders and stress the need for national ownership and local action (Krug et al., 2002; Peden et al., 2004; Peden et al., 2008; WHO, 2014b). Some early successes can be seen at the global level. For example, two ministerial summits on global road safety were held in Moscow in 2009 and in Brasilia in 2015, led by the United Nations Road Safety Collaboration; national leaders have pledged their support for the "Decade of Action for Global Road Safety 2010–2020"; many countries have sponsored United Nations General Assembly resolutions on "improving global road safety" as well as two World Health Assembly resolutions (2004 and 2016); and most recently two road safety targets were included in the 2030 Agenda for Sustainable Development. These high-level advocacy events call on all members of the global community to pay attention to the increasing burden of road traffic injuries and encourage them to invest in evidence-based efforts to improve road safety.

The emergence of violence prevention as a key component of the global health agenda can in part be ascribed to the role played by the World Health Assembly and its partner organizations in highlighting violence prevention and injury prevention in general. Since the publication of *World Report on Violence and Health* in 2002, two World Health Assembly resolutions have called on countries to invest in violence prevention; by 2010, three out of six WHO regional committees (Africa, the Americas, and Europe) had adopted similar resolutions. The inclusion of violence prevention on the agenda of other multilateral agencies is another indication of this topic's emergence as a global priority. The World Health Assembly particularly recognized the need to strengthen national health systems in addressing interpersonal violence, and adopted a resolution in during the 67th assembly in 2014. WHO's member states adopted the "global plan of action to strengthen the role of the health system within a national multisectoral response to address interpersonal violence, in particular against women and girls and against children" at the 69th World Health Assembly in May 2016.

For the first time in history, violence and injury prevention have taken a prominent place on the global development agenda. The Sustainable Development Agenda 2030 has several targets that directly focus on the reduction of homicide, violence against children, violence against women, and road traffic accidents. It further addresses a number of important risk factors for violence and injury prevention, such as harmful alcohol use.

The United Nations General Assembly has also reviewed special reports on violence against children, violence against women, and armed violence, which have resulted in resolutions calling for greater investment in multisectoral efforts to address these forms of violence.

Research and Development Needs

To date, global investments in injury and violence research and interventions, compared with

investments made in other health areas, have not matched the burden of disease. Historically, road traffic injuries have been identified as a highly neglected area for investments compared with the burden of disease they represent, measured in dollars per DALY (approximately $0.40 per DALY), especially when considered in relation to other major health problems (Ad Hoc Committee on Health Research Relating to Future Intervention Options, 1996). And in the past century, it was not surprising that national analyses of safety investments demonstrated low investment rates in low-income countries such as Pakistan and Uganda—approximately $0.07 per person in Pakistan (Bishai, Hyder, Ghaffar, Morrow, & Kobusingye, 2003).

Some notable exceptions to this pattern do exist, such as the multi-million-dollar investments made by Bloomberg Philanthropies to establish model intervention areas in 10 countries and 10 cities since 2009 to demonstrate the impact of road traffic injury prevention and control measures (Hyder & Bishai, 2012; Hyder, Allen, Peters, Chandran, & Bishai, 2013). Even so, while we already know a great deal about the burden, causes, and effective interventions for injuries and violence, significant gains in our understanding of these factors could still be made if equitable resources were directed to the field.

Given that 90% of the world's population lives in LMICs, and the burden of injuries and violence is predicted to increase in these countries, it is imperative that future research and development activities focus especially on the needs of these countries. While it would be inappropriate to outline a detailed agenda for future research and developments that is relevant to all countries, a generic framework that encompasses the types of research required can be recommended.

Epidemiologic research describing the existing burden, causes, and distribution of unintentional injuries and violence is still needed in LMICs. Assessing the loss of health and life from unintentional injuries and violence, identifying the populations affected by these conditions, and determining the specific circumstances in which they occur all deserve a place on the continuing research agenda for LMICs. Problems of underreporting and other biases in the available data need to be addressed, along with the specific impacts of these conditions on the very poor. Organizations such as the global Road Traffic Injuries Research Network[9] are attempting to promote key research on such issues and produce important findings that benefit prevention and control (Road Traffic Injuries Research Network Multicenter Study Collaborators, 2013).

Of course, it is critical not only to identify the determinants of unintentional injuries and violence, but also to address them. The lack of *intervention research* in LMICs has left a huge gap in health research globally. Scientific trials of injury and violence prevention interventions have generally not been conducted in these countries, and there is a great need to modify, adapt, and test both existing and proposed interventions in these settings. While some might argue that such research should be a priority in most LMICs, unless the basic research on the burden and determinants of unintentional injuries and violence has been conducted, the political and financial support for such follow-on research will not be forthcoming.

The lack of empirical information on the cost-effectiveness of injury and violence prevention interventions remains a major policy issue, especially given that interventions used in high-income countries might potentially be transferred to LMICs without regard to their appropriateness or relevance in the latter regions. Perhaps equally important is the concern that without such research, highly cost-effective interventions will not be implemented at all. *Policy-oriented research* that identifies the barriers to implementation and translation of research findings is, therefore, an essential component in advancing the injury and violence prevention agenda.

The Significance of a Trained Workforce

Research and programs in the field of unintentional injuries and violence require trained individuals with specific skills and tools. Injury and violence prevention is a science replete with conceptual frameworks, epidemiologic approaches, intervention testing methods, and analytical techniques. Well-developed training programs in high-income countries have emerged that can produce a workforce who can carry the injury and violence prevention agenda forward. At present, the general lack of such trained human resources in the low- and middle-income world means that advocates must necessarily focus on developing the appropriate human resources capacity in these countries.

[9] https://rtirn.net/

Issues of both quantity and quality arise with regard to the development of a trained workforce. Clearly, there needs to be a critical mass of trained injury and violence prevention professionals in a country if authorities there are to understand, develop, and implement interventions. At the same time, the field covers a broad range of topics, so a diverse group of skills are needed for prevention. Epidemiology, statistics, health information systems, health policy, economics, sociology, and criminology—these are merely some of the fields that have a role in reducing the burden of disease from injuries and violence. In this context, the role of the public health sector is both to assume leadership in developing and organizing a response to injuries and violence and to facilitate the inputs provided by other fields and disciplines. For this reason, management and leadership skills are important assets for a well-trained workforce in injury and violence prevention.

Efforts to address these capacity development needs are being implemented both in high-income countries and in LMICs. For example, WHO has created a teaching curriculum (TEACH-VIP) that may be freely used in training programs and courses and that covers all basic aspects of injury prevention and control.[10] It focuses on enhancing the knowledge base of participants and their technical foundations for work in the injury field. A number of electronic learning courses are also available. The most recent course on legislation and road safety, developed by WHO in collaboration with Johns Hopkins Bloomberg School of Public Health's International Injury Research Unit, was launched in 2017.

WHO also has a free mentoring program (MENTOR-VIP) that allows people from LMICs to enroll in a one-year mentoring relationship with more experienced colleagues from around the world.[11] The mentoring program focuses on hands-on learning and the development of specific skills for practicing injury prevention and control.

Other examples of capacity building include the work by partner organizations such as the Road Traffic Injuries Research Network, which facilitates the development of both junior and senior researchers from LMICs who are seeking to develop their research skills in road traffic injuries research. In addition, WHO Collaborating Centers such as the Johns Hopkins International Injury Research Unit have a free, online road safety training program that leads to the award of a certificate.[12]

The Roles of National and International Organizations

The roles of national agencies (e.g., ministries of health and medical research councils), international organizations (e.g., the United Nations Development Program [UNDP], WHO, UNICEF, and the World Bank), and international societies (e.g., International Federation of the Red Cross and Red Crescent, Handicap International) need to be emphasized in advancing the injury and violence prevention agenda. The roles of national organizations include the following:

- *Advocacy*: Accepting ownership of the problem and promoting engagement with other national institutions.
- *Implementation*: Developing policy and ensuring programs are available on the ground in countries for addressing injuries and violence.
- *Evaluation*: A continuous process of assessing interventions and programs, in addition to supporting nationally relevant research.

The role of international organizations and societies can be summarized as follows:

- *Strategic*: First internally recognizing the toll on societies of injuries and violence, and then convincing governments externally to appreciate the same. This has already been done in the case of road traffic injuries by the joint WHO-World Bank report in 2004 and for child injuries by the joint WHO–UNICEF report in 2008.
- *Facilitation*: Providing technical assistance, appropriate advice, and relevant tools for national policies and action.
- *Resource mobilization*: Demonstrating true commitment to supporting the implementation of effective interventions in countries and promoting research in the field.

The international movements currently under way for violence prevention and road traffic injuries prevention are examples of how joint global–national partnerships are needed for making change.

Conclusion

Unintentional injuries and violence represent a major global health problem, and one that will increase in magnitude unless systematic, scientifically based approaches to prevention are implemented. While the public health community has recognized the significance of the global injury epidemic only relatively recently, much new knowledge has been generated in a short time. Much of this new knowledge has focused on the burden of injury in high-income countries, however. The challenge for the future, therefore, is to extend our knowledge to the growing injury and violence burden faced by LMICs.

The international public health community has an important role to play in addressing this challenge, by facilitating the description of the problem, the development of solutions, the implementation of programs, and the analysis of effects. Moreover, the public health community can play a leadership role in galvanizing a multisectoral response to injuries and violence, advocating for investments at national and international levels, and catalyzing the sharing of experiences around the world. The large and often devastating health impacts of injuries and violence make it imperative that the international public health community not only take an interest in these issues, but also engage in proactive efforts to address the burden of disease from injuries and violence at local, national, and international levels.

In summary, injuries are no "accident," and violence does not "just happen"; rather, these are highly predictable and preventable events. The international public health community has already played an important role in taking this message forward. The challenge is to continue to do so, thereby ensuring that the predicted epidemics of unintentional injuries and violence in LMICs can be prevented.

Discussion Questions

1. Why should public health programs in LMICs address injuries and violence?
2. List three indicators you would expect to change as a result of a road traffic injury program in a country. Which data would you need to measure these changes? How would you obtain those data?
3. Choose a specific type of injury. Which steps can be taken to reduce the burden of this injury in LMICs?
4. Suppose you were funding research on violence. Describe five topics or studies that would be your priority for research in LMICs.
5. Compare and contrast how the prevention of violence and unintentional injuries differ in respect to their use of passive versus active prevention strategies.
